(1157.) Another disease to which sheep are subject on passing from a state of poverty to improved condition is *scab*, and hoggs are most susceptible of it. This disease indicates its existence by causing sheep to appear uneasy and wander about without any apparent object; to draw out locks of wool with its mouth from the affected parts, as the disease increases; and, lastly, to rub its sides and buttocks against every prominent object it can find, such as a stone, a tree, a gate post, the nets, and such like. Mr. Youatt says that it arises from an insect, a species of *acarus*;* but whether this be the case or not, one remedy is efficacious, namely, mercurial ointment; a weak one of 1 part of the ointment with 5 of lard for the first stage, and the other a stronger, of 1 part of ointment and 3 of lard, for an aggravated case. The ichorous matter from the pustules adheres to and dries upon the wool, and gets the name of *scurf*, which should first be washed off with soap and water before applying the ointment. The scab is a very infectious disease, the whole flock soon becoming contaminated; but the infection seems to spread not so much by direct contact as by touching the objects the animals infected have rubbed against. Its direct effects are deterioration of condition, arising from a restlessness preventing the animal feeding, and loss of wool, large portions not only falling off, but the remainder of the broken fleece becoming almost valueless; and its indirect effects are propagation of the disease constitutionally, and hence the loss to the owner in having a scabbed flock, for no one will purchase from one to breed from that is known to be, or to have been, affected by scab. With regard to the very existence of this disease, it is held disgraceful to a shepherd not to be able to detect its existence at a very early stage, and more so to allow it to make head in his flock, however unobservant he may have been of its outbreak. When it breaks out in a standing flock, it must have been latent in its constitution or in the ground, when the shepherd took charge of it, for some shepherds have only the skill to suppress, not eradicate it; but it is his duty to examine every sheep of his new charge, and of every one newly purchased; before they are allowed to take to their hirsel, and also to make inquiry regarding the previous state of the ground.

(1158.) On soft ground sheep are liable to be affected with *foot-rot*, when on turnips. The first symptom is a slight lameness in one of the fore-feet, then in both, and at length the sheep is obliged to go down, and even creep on its knees, to get to its food. The hoof, in every case, first becomes softened, when it grows misshaped, occasioning an undue pressure on a particular part; this sets up inflammation, and causes a slight separation of the hoof from the coronet; then ulcers are formed below where the hoof is worn away, and then at length comes a discharge of fetid matter. If neglected, the hoof will slough off, and the whole foot rot off; which would be a distressing termination with even only one sheep, but the alarming thing is, that the whole flock may be similarly affected, and this circumstance has led to the belief that the disease is very contagious. There is, however, much difference of opinion among store-farmers and shepherds on this point, though the opinion of contagion preponderates. For my part, I never believed it to be so, and there never would have been such a belief, had the disease been confined to a few sheep at a time; but though numbers are affected at one time, the fact can be explained from the circumstance of all the sheep being similarly situate; and as it is the nature of the situation which is the cause of the disease, the wonder is that any escape affection, rather than that so many are affected. The first treatment for cure is to wash the foot clean with soap and water, then pare away all superfluous hoof, dressing the diseased surface with some caustic, the spirit of tar and blue vitriol being most in vogue, but Professor Dick recommends butter of antimony as the best; the affected part being bound round with a rag, to prevent dirt getting into it again; and removing the sheep to harder ground, upon bare pasture, and there supplying them with cut turnips. The cure indicates the prevention of the disease, which is careful examination of every hoof before putting sheep upon red land, and paring away all extraneous horn; and should their turnips for the season be upon soft, moist ground, let them be entirely sliced, and let the sheep be confined upon a small break at a time, and thus supersede the necessity of their walking almost at all upon it for food. I may mention that sheep accustomed to hard ground, when brought upon that which is comparatively much softer, are most liable to foot-rot, and hence the necessity of frequent inspection of the hoof when on soft ground; and as some farms contain a large proportion of this state of land, frequent inspection should constitute a prominent duty of the shepherd.

(1159.) Erysipelatous complaints occur in winter among sheep. "*Wildfire*, it is said," remarks Professor Dick, "generally shows itself at the beginning of winter, and first attacks the breast and belly. The skin inflames and rises into blisters, containing a reddish fluid, which escapes and forms a dark scab. The animal sometimes fevers. Venesection (blood-letting) should be used, the skin should be washed with a solution of sugar of lead, or with lime-water, and physic given, such as salts and sulphur; afterward a few doses of nitre."†

(1160.) There is, perhaps, no circumstance upon which an argument could be better founded in favor of arable land being attached to a hill-farm, for the purpose of raising food to be consumed in stormy weather, than on the fatality of the disease commonly called *braxy*. It affects young sheep, and chiefly those of the Black-faced breed, which subsist upon the most elevated pasture. Indigestion is its primary cause, exciting constipation, which sets up acute inflammation of the bowels, and death ensues. The indigestion is occasioned by a sudden change from succulent to dry food, and the suddenness of the change is imposed by the sudden occurrence of frost and snow, the latter concealing the green herbage which the sheep have been eating; and obliging

* Youatt on Sheep. † Dick's Manual of Veterinary Science.

them to subsist upon the tops of old heather, and twigs and leaves of bushes that overtop the snow. By this account of the origin of the disease, it is obvious that, were stells provided for shelter, and turnips for food, the braxy would never affect young hill-sheep, at least under the circumstances which usually give rise to it. The Ettrick Shepherd thus describes its symptoms: "The loss of cud is the first token. As the distemper advances, the agony which the animal is suffering becomes more and more visible. When it stands, it brings all its four feet into the compass of a foot; and sometimes it continues to rise and lie down alternately every two or three minutes. The eyes are heavy and dull, and deeply expressive of its distress. The ears hang down, and, when more narrowly inspected, the mouth and tongue are dry and parched, and the white of the eye inflamed. . . . The belly is prodigiously swelled, even so much that it sometimes bursts. All the different apartments of the stomach are inflamed in some degree."* Violent inflammation succeeds, with a tendency to mortification and sinking, so that, after speedy death, the touch of the viscera, and even of the carcass, is intolerable. Its effects are so sudden, that a horg apparently well in the evening will be found dead in the morning. Cure thus seems almost unavailable, and yet it may be effected, provided the symptoms of the disease are observed in time; when, if blood is drawn freely from any part of the body, such as by notches made across the under side of the tail, from the vein under the eye, and that behind the fore-arm, and a dose of salts administered in warm water, the animal will most probably recover.† But the grand object is *prevention* of the disease by a timely supply of succulent food; and if turnips cannot be obtained, it may be worth the store-master's consideration whether oil cake should not be given to the sheep along with hay, during a storm. The laxative property of oil-cake is well established, and its carriage to the remotest hill-farm comparatively easy. Mr. Fairbairn recommends salt to be given to young sheep, when shifted suddenly from fresh to dry food; and no doubt, as a condiment in support of the healthy action of the stomach, it would prove useful; and more especially in the case of cattle and sheep, the structure of whose digestive organs renders them peculiarly liable to the effects of indigestion; and on this account it would be a valuable assistant to the more nutritious oil-cake. And instead of entirely acquiescing in the Ettrick Shepherd's recommendation "to pasture the young and old of the flocks all together," as has been done in Peebles-shire, to the eradication, it is said, of the braxy—as being in many cases impracticable and attended with no profit, Mr. Fairbairn rather observes, "Let the pasture for a hirsel, as was observed before, be as nearly as possible of one soil. To overlook this is a mighty error, and the surest means of making the flock unequal. The heath should also be regularly burned, and the sheep never allowed to pasture *long upon soft grass*." And as a last resource in an attempt to eradicate the disease everywhere, he would have the sheep put on turnips, as "an infallible antidote against the progress of the malady;" and which he has "invariably found gives a settling stroke to the disease."‡ This last remedy doubtless being effective, I would recommend its adoption rather as a preventive than a cure of the disease.

(1161.) The Ettrick Shepherd mentions the existence of 4 kinds of braxy—namely, the *bowel sickness*, the *sickness in the flesh and blood*, the *dry braxy*, and the *water braxy*—all originating in the same cause, producing modified effects—namely, a sudden change of food from succulent to dry, inducing constipation of the bowels and consequent inflammation; and they are all a class of diseases allied in their nature to hoven in cattle, and flatulent colic or botts in horses.

31. DRIVING AND SLAUGHTERING SHEEP.

"Pierced by Roderick's ready blade,
Patient the sickening victim eyed
The life-blood ebb in crimson tide
Down his clogged beard and shaggy limb,
Till darkness glazed his eye-balls dim."
SCOTT.

(1162.) ALTHOUGH it is unusual for farmers who possess a *standing* flock—and most farmers who practice the mixed husbandry have one—to dispose of their fat sheep in winter—that is, before the turnips are all consumed—yet as farmers, who, having no standing flock, purchase a flying one every year, of sheep in forward condition, and in such numbers as to consume the turnips allotted to them in a short time, do dispose of their fat sheep in winter, it is proper that you should be made acquainted here with the *driving of sheep upon roads*, and the general practice of the *mutton-trade*. The sheep most forward in condition in autumn are yeld ewes and wethers, the tup-eill ewes being already fat and sold.

(1163.) Sheep are purchased from farmers both by *dealers* and *butchers*.

* Hogg's Shepherd's Guide. † The Mountain Shepherd's Manual.
‡ A Lammermuir Farmer's Treatise on Sheep in High Districts.

Dealers buy from farmers in wholesale, and sell to butchers in retail; so they constitute a sort of middle-men; but, unlike most middle-men, their avocation is fully as useful to both parties as to themselves, inasmuch as they purchase at once the whole disposable stock of the farmer, and they assort that stock, and present it at the markets which the different classes of their customers, the butchers, are in the habit of frequenting, in the most suitable form. They thus act the part which the wool-staplers do, in assorting the different qualities of wool between the grower and the manufacturer. They buy either at fairs, or on the farmer's own premises. In the former case they pay ready money, and lift the stock immediately; in the latter they pay at the time the stock is lifted by agreement. In lifting their bargains, they appoint one time among all the places they have purchased, to make up their entire drove; for it is less costly for their people to drive a large one than a small. Dealers chiefly buy at the country fairs, where they have ample choice, and only purchase on the farmer's premises when stock happens to be scarce, and prices likely to advance. Butchers purchase chiefly in the market-towns in which they reside, though they also attend fairs, and pick up a few fat lots which will not bear the long journeys of the dealers; and in this case they pay ready money and lift immediately, as dealers do. But when they purchase on the farmer's premises, they usually lift so many at a time, according to agreement, and pay only for what they lift. Every farmer should avoid this practice, as every time the butcher comes for his lot the sheep have to be gathered, and the whole handled, that he may take away only those which suit his present purpose; and this commotion is made most probably every week, the whole stock being disturbed by the shouting of men and the barking of dogs, among whom those of the butcher are not the least noisy or the least active. Farmers take their stock either to fairs or market-towns, and there meet the respective sorts of purchasers, the dealers never appearing as purchasers in towns, the butchers there ruling paramount.

(1164.) When a dealer purchases on the farmer's premises, he lifts his lot *at any time of day* that best suits his own arrangements. He begins to lift the first lot in the more distant part of the country, and, proceeding on the road in the direction of their destination, he lifts lot after lot until the whole are gathered, to the amount of many hundreds. In this way he may lift a lot in the forenoon on one farm, and another in the afternoon on another; and this is a much more satisfactory way for the farmer to dispose of his stock than the one he allows the butcher to adopt. But when a farmer is to drive his own sheep to market, he starts them at a time when the journey will do them the least injury. Sheep should not begin their journey either when too full or too hungry; in the former state they are apt to purge on the road, in the latter they will lose strength at once.—The sheep selected for market are the best conditioned at the time; and, to ascertain this, it is necessary to handle the whole lot, and shed the fattest from the rest; and this is best done about midday, before the sheep feed again in the afternoon. The selected ones are put into a field by themselves, where they remain until the time appointed them to start. If there be rough pasture to give them, they should be allowed to use it, and get quit of some of the turnips in them. If there is no such pasture, a few cut turnips on a lea-field will answer. Here all their hoofs should be carefully examined, and every unnecessary appendage removed, though the *firm* portion of the horn should not be touched. Every clotted piece of wool should also be removed with the shears. The sheep should also be marked with *keil*, or *ruddle*, as it is called in England—the ochrey-red ironstone of mineralogists, which occurs in abundance near Platte, in Bohe-

mia.* The keil-mark is put on the wool, and on any part of the body you choose—the purpose being to identify your own sheep in case of any being lost in the fair. The parts usually chosen for marking Leicester sheep are top of shoulder, back, rump, far and near ribs. The mark is made in this way: Take hold of a small tuft of wool at any of the above parts with the right-hand fingers, and seize it between the fore and middle fingers of the left hand, with the palm upward; then color it with the keil, which requires to be wetted, if the wool itself is not damp. Short-wooled sheep are usually marked on the head, neck, face and rump, or with a bar across the shoulders, and generally too much keil is put upon them. The sheep being thus prepared should have food early in the morning, and be started on their journey about midday—the season, you will remember, being winter. Let them walk gently away; and, as the road is new to them, they will go too fast at first—to prevent which, the drover should go before them, and let his dog bring up the rear. In a short distance they will assume the proper speed, about 1 mile the hour. Should the road they travel be a green one, the sheep will proceed nibbling their way onward at the grass, along both sides; but if a turnpike, especially a narrow one, the drover will require all his attention in meeting and being passed by every class of vehicle, to avoid injury to his charge. In this part of their business, drovers generally make too much ado, both themselves and their dogs; and the consequence is that the sheep are driven more from side to side of the road than is requisite. On meeting a carriage, it would be much better for the sheep were the drover to go forward, instead of sending his dog, and point off, with his stick, the leading sheep to the nearest side of the road; and the rest will follow, as a matter of course, while the dog walks behind the flock, and brings up the stragglers. Open gates to fields are sources of great annoyance to drovers, the stock invariably making an endeavor to go through them. On observing an open gate before, the drover should send his dog behind him over the fence, to be ready to meet the sheep at the gate. When the sheep incline to rest, let them lie down. Before night-fall the drover should inquire of lodging for them for the night, as in winter it is requisite to put them in a grass-field, and supply them with a few turnips or a little hay, the road-sides being bare at that season. If turnips or hay are laid down near the gate of the field they occupy, the sheep will be ready to take the road in the morning; but, before doing this, the drover should ascertain whether the road is infested with stray dogs; if which be the case, the sheep should be taken to the safest spot and watched. Many dogs that live in the neighborhood of drove-roads, and more especially village dogs, are in the habit of looking out for sheep to worry, at some distance from their homes. The chief precaution that can be used under such an apprehension is, for the drover to go frequently through the flock with a light, and be late in retiring to rest, and up again early in the morning. This apprehension regarding dogs is not solely in regard to the loss sustained by worrying, but, when sheep have been disturbed by them, they will not settle again upon the road. The first day's journey should be a short one, not exceeding 4 or 5 miles.—Upon drove-roads, farms will be found at stated distances with food and lodging for the drover and his flock, at a moderate charge. Allowing 8 miles a day for a winter-day's travel, and knowing the distance of your market by the destined route, the sheep should start in good time, allowance being made for unforeseen delays, and one day's rest near the market.

* Jameson's Mineralogy, vol. iii.

(1165.) The *farmers' drover* may either be his shepherd, or a professional drover hired for the occasion. The shepherd knowing the flock makes their best drover, if he can be spared so long from home. A hired drover gets 2s. 6d. a day of wages, besides traveling expenses, and he is intrusted with cash to pay all the necessary dues incidental to the road and markets, such as tolls, forage, ferries, and market custom. A drover of sheep should always be provided with a dog, as the numbers and nimbleness of sheep render it impossible for one man to guide a capricious flock along a road subject to many casualties; not a young dog, who is apt to work and bark a great deal more than necessary, much to the annoyance of the sheep, but a knowing, cautious tyke. The drover should have a walking-stick, a useful instrument at times in turning a sheep disposed to break off from the rest. A shepherd's plaid he will find to afford comfortable protection to his body from cold and wet, while the mode in which it is worn leaves his limbs free for motion. He should carry provision with him, such as bread, meat, cheese or butter, that he may take luncheon or dinner quietly beside his flock while resting in a sequestered part of the road, and he may slake his thirst in the first brook or spring he finds, or purchase a bottle of ale at a roadside ale-house. Though exposed all day to the air, and even though he feel cold, he should avoid drinking spirits, which only produce temporary warmth, and for a long time after induce chilliness and languor. Much rather let him drink ale or porter during the day, and reserve the allowance of spirits he gives himself until the evening, when he can enjoy it in warm toddy beside a comfortable fire, before retiring to rest for the night. The injunction to refrain from spirits during the day I know will sound odd to the ear of a Highland drover; but though a dram may do him good in his own mountain-air, and while taking *active* exercise, it does not follow that it will produce equally good effects on a drove-road in the low country in winter, in raw and foggy weather. I believe the use of raw spirits does more harm than good to all drovers who indulge in the practice. He should also have a good knife, by which to remove any portion of horn that may seem to annoy a sheep in its walk; and also a small bottle of a mixture of tobacco-liquor and spirit of tar, with a little rag and twine, to enable him to smear and bandage a sheep's foot, so as it may endure the journey. He should be able to draw a little blood from a sheep in case of sickness. Should a sheep fail on the road, he should be able to dispose of it to the best advantage; or, becoming ill, he should be able to judge whether a drink of gruel, or a handful of common salt in warm water, may not recover it so as to proceed; but, rather than a lame or jaded sheep should spoil the appearance of the flock, it should be disposed of before the flock is presented in the market.

(1166.) The many casualties incidental to sheep on travel, more especially in winter, require consideration from the farmer before undertaking to send his stock to a distant market-town, in preference to taking them to a fair, or accepting an offer for them at home. A long journey in winter will cost at least 1s. a head, and their jaded appearance may have the effect of lowering their market price 2s. or 3s. a head more. Under any circumstances, when you have determined on sending your sheep to a market-town, it is, I believe, the best plan, after the journey, to intrust them to a salesman, rather than stand at market with them yourself, as you cannot know the character of the buyers so well as he does, nor can you know what class of purchasers your lot may best suit. The convenience attending the employment of a salesman is now generally felt, because it not only saves the personal annoyance of attending a market, but your money is remitted to you through a bank in the course of the day. The only pre-

caution requisite in the matter is to become acquainted with a salesman of judgment; for as to honesty, if he have not *that*, he is of course quite worthless. In attending country fairs, the case is otherwise; there being no salesman, you yourself must stand by your lot. Before attending the fair, you should make up your mind what to ask for your stock, in accordance with the current market prices; but, notwithstanding this, you may come away with more or less cash than you anticipated, because the actual state of *that* market will be regulated by the quality and quantity of the stock brought forward, and by the paucity or numbers of buyers who may appear. After your sheep are fairly placed, you should inquire of friends of the state of prices before you sell, and on doing this you will frequently find the market in a most perplexing state from various causes. Thus, there may be too many sheep for the buyers, when the market will be dull, and remain so all day. On the other hand, the stock may be scanty for the buyers, when a briskness may start in the morning and continue even till the whole stock are sold off. There may be briskness in the morning, the buyers purchasing; dullness at midday, buyers declining; and briskness again in the afternoon, buyers again purchasing. There may be excessive dullness in the morning, occasioned by the buyers lying off and beating down prices, and, finding they cannot succeed, buy briskly all the afternoon. There may be dullness in the morning, arising from the dealers finding the condition of the stock below their expectation. The markets are never better for the farmer than when they begin brisk early in the morning, and the stock are all sold off early. These are the vicissitudes of a market; they are interesting, demand attention, and are worth examination. You will frequently observe a trifling circumstance give a decided tone to a market. A dealer, for instance, who generally buys largely, and having bought for many years respectably in that particular fair, will mark the prices of the day by his purchases; so that other people, particularly sellers, observing the prices given by him, will sell briskly and with confidence. There is no use, at any time, of asking a much higher price than the intrinsic value of your stock, or than you will willingly take; for, although your stock may be in particularly fine condition, and of good quality, and therefore worth more than the *average* price of the market, still their value must conform to the *rate* of the market, be it high or low, and it is not in your power to control it; though, if prices dissatisfy you, you have it in your power to take your stock home again. There is a common saying applicable to all public markets, and is now received as a maxim, because indicating the truth, that "the first offer is the best," that is, the first offer from a *bona fide* buyer; for there are people to be found in all markets who, having no serious intention of buying at market price, make a point of offering considerably below it, with the view of catching a bargain from a greenhorn, or from one tried of standing longer in the fair, and they sometimes succeed in their wishes; but such people are easily discovered, and therefore cannot *deceive* any but inexperienced sellers.

(1167.) There are certain *rules* which, by tacit consent, govern the principles upon which all public markets of stock are conducted, and they are few and simple. There is a *custom* payable for all stock presented at fairs, exigible by the lord of the manor, or other recognized authority. After entering the field, your stock can take up any unoccupied position you choose, appointed for the particular kind of stock you have to show. No one, on pretence of purchasing, has a right to interfere with a lot which is under inspection by another party. Neither have you any right to show your lot to more than one party at a time, unless each party consent to it. When a bargain is made, there is no necessity for striking hands, or ex-

changing money, as an earnest of it. When a bargain is made, a time may be stipulated by the purchaser for lifting the stock; and, until they are delivered to him or his accredited agents, they continue at the risk of the seller. When counted over before the purchaser, the price becomes immediately due. When the money is paid, there is no obligation on the seller to give a discount off the price, or a *luck-penny*, as it is termed; but purchasers sometimes make offers in a way to humor the prejudices of the seller—that is, they offer the price demanded, on condition of getting back a certain sum, or amount of luck-penny, to bring the price down to their own ideas; in such a case, when such an offer is accepted, the seller must return the luck-penny conditioned for, when he receives the money. Sometimes, when parties cannot agree as to price, the offerer proposes to abide by the decision of a third party; but, in doing this, you virtually relinquish your power over your own stock. Sometimes bills and bank-postbills are tendered by dealers in part or entire payment of what they purchase; but it is in your power to refuse any form of cash but the legal tender of the country, such as Bank of England notes, or gold, or silver. If a bill of exchange or promissory note is proffered instead of ready money, you are quite entitled to refuse the bargain; for the usage of trade in a fair implies the condition of ready money;* or you may demand a higher price to cover the risk of the bill being dishonored. The notes of any bank you know to be good, you will, of course, not refuse. After the stock are delivered, they are at the risk of the purchaser. Some dealers' *top's-men*—that is, the men who take charge of their master's lots after delivery—demand a gratuity for their trouble, which you are at liberty to refuse. All these rules, in as far as relates to money and the delivery of stock, apply to the stock purchased by dealers on your own farm. When you *purchase* stock at a fair, people will be found on the ground willing to render your drover assistance in taking them out of it, and of setting them fairly on the road. Such people are useful on such occasions, as it may happen, especially in the case of sheep, that one or more may break away from their own flock and mix with another, when there may not only be difficulty in shedding them out, but those into whose lot yours have strayed may show unwillingness to have their stock disturbed for your sake, though it is in your power to follow your strayed stock, and claim it anywhere by the wool-mark.

(1168.) The way that fat is laid on sheep while on turnips, and the mode of judging of a fat sheep, are these: Hoggs, when put on turnips in winter, are generally lean; for although they had been in good condition as lambs when weaned from their mothers in summer, their growth in stature afterward is so rapid that their flesh is but little intermixed with fat. For the first few weeks on turnips, even in the most favorable circumstances as to quality of food, warmth of shelter, dryness of land, and pleasantness of weather, they make no apparent advancement in condition; nay, they rather seem to fall off, and look clapped in the wool, and indicate a tendency to delicacy, in consequence, I suppose, of the turnips operating medicinally on their constitution as an alterative, if not as a laxative; but immediately after that trying period of young sheep, especially trying in bad weather, is past, when the grass has completely passed through them, and the stomach and intestines have become accustomed to the more solid food of the turnip, their improvement is marked, the wool seeming longer and fuller, the carcass filled out, the eyes clear and full, and the gait firm and steady. They then thrive rapidly, and the more rapidly the drier the weather.

* The Farmer's Lawyer.

(1169.) The formation of fat in a sheep destined to be fattened, commences in the inside, the *net* of fat which envelops the intestines being first formed, and a little deposited around the kidneys. After that, fat is seen on the outside, and first upon the end of the rump at the tail-head, which continues to move on along the back, on both sides of the spine or back-bone to the bend of the ribs, to the neck. Then it is deposited between the muscles, parallel with the cellular tissue. Meanwhile, it is covering the lower round of the ribs descending to the flanks, until the two sides meet under the belly, whence it proceeds to the brisket or breast in front, and the shaw or cod behind, filling up the inside of the arm-pits and thighs. While all these depositions are proceeding on the outside, the progress in the inside is not checked, but rather increased, by the fattening disposition encouraged by the acquired condition; and hence, simultaneously, the kidneys become entirely covered, and the space between the intestines and lumbar region or loin gradually filled up by the net and kidney fat. By this time, the cellular spaces around each fibre of muscle is receiving its share, and when fat is deposited there in quantity, it gives to meat the term *marbled.* These inter-fibrous spaces are the last to receive a deposition of fat; but after this has begun, every other part simultaneously receives its due share, the back and kidneys receiving the most, so much so that the former literally becomes *nicked*, as it is termed; that is, the fat is felt through the skin to be divided into two portions, from the tail-head along the back to the top of the shoulder, the tail becoming thick and stiff, the top of the neck broad, the lower part of each side of the neck toward the breast full, and the hollows between the breast-bone and the inside of the fore-legs, and between the cod and the inside of the hind thighs, filled up. When all this has been accomplished, the sheep is said to be *fat* or *ripe.*

(1170.) When the body of a fat sheep is entirely overlaid with fat, it is then in the most valuable state as mutton; but few sheep lay on fat entirely over their body, one laying the largest proportion on the rump, another on the back; one on the ribs, another on the flanks; one on the parts adjoining the fore-quarter, another on those of the hind-quarter; one more on the inside, and another more on the outside. Taking so many parts, and combining any two or more of them together, you may expect to find, in a lot of fat sheep, a considerable variety of condition, and yet any one is as ripe in its way as any other.

(1171.) Taking these data for your guide, you will be able to detect, by handling, the state of a sheep in its progress toward ripeness. A *ripe* sheep, however, is easily known by the *eye*, by the fullness exhibited in all the external parts of the particular animal. It may exhibit wants in some parts when compared with others, but you easily see that these parts would never become so ripe as the others; and this arises from some *constitutional* defect in the animal itself, because, if this were not so, there is no reason why all the parts should not be alike ripe. Whence this defect arises remains to be considered afterward. The state of a sheep that is obviously not ripe cannot altogether be ascertained by the eye; it must be *handled*, that is, it must be subjected to the scrutiny of the hand. Now, even in so palpable an act as handling discretion is requisite. A full-looking sheep need hardly be handled on the rump, for he would not seem so full unless fat had been first deposited there. A thin-looking sheep, on the other hand, should be handled on the rump, and if there be no fat there, it is useless handling the rest of the body, for assuredly there will not be so much as to deserve the name of fat. But between these two extremes of condition there is every variety to be met with; and on that

account examination by the hand is the rule, by the eye alone the exception; but the hand is much assisted by the eye, whose acuteness detects deficiencies and redundancies at once. In handling a sheep the points of the fingers are chiefly employed, and the accurate knowledge conveyed by them through practice of the true state of condition is truly surprising, and settles a conviction in the mind that some intimate relation exists between the external and internal state of an animal. And hence this practical maxim in the judging of stock of all kinds, that no animal will appear *ripe to the eye*, unless as much fat had previously been laid on in the inside as his constitutional habit will allow. The application of this rule is easy. Thus, when you find the rump nicked on handling, you may expect to find fat on the back; when you find the back nicked, you would expect the fat to have proceeded to the top of the shoulder and over the ribs; and when you find the top of the shoulder nicked, you would expect to find fat on the under side of the belly. To ascertain its existence below, you will have to *turn him up*, as it is termed; that is, the sheep is set upon his rump with his back down and his hind-feet pointing upward and outward. In this position you see whether the breast and thighs are filled up. Still, all these alone would not let you know the state of the inside of the sheep, which should, moreover, be looked for in the thickness of the flank; in the fullness of the breast, that is, the space in front from shoulder to shoulder toward the neck; in the stiffness and thickness of the root of the tail, and in the breadth of the back of the neck. All these latter parts, especially with the fullness of the inside of the thighs, indicate a fullness of fat in the inside; that is, largeness of the mass of fat on the kidneys, thickness of net, and thickness of layers between the abdominal muscles. Hence the whole object of feeding sheep on turnips seems to be to lay *fat* upon all the bundles of fleshy fibres, called muscles, that are capable of acquiring that substance; for as to bone and muscle, these increase in weight and extent independently of fat, and fat only increases their magnitude.

(1172.) I have spoken of the *turning up* of a fat sheep; it is done in this way: Standing on the *near* side of the sheep, that is, at *its* left side, put your left hand under its chin, and seize the wool there, if rough, or the skin, if otherwise; place your knees, still standing, against its ribs, then bowing forward a little, extend your right arm over the far loin of the sheep, and get a hold of its flank as far down as you can reach, and there seize a large and firm hold of wool and skin. By this, lift the sheep fairly off the ground, and turning its body toward you upon your left knee under its near ribs, place it upon its rump on the ground with its back to you, and its hind feet sticking up and away from you. This is an act which really requires strength, and if you cannot lift the sheep off the ground, you cannot turn it; but some people acquire a sleight in doing it, beyond their physical powers. I believe the art consists in jerking the sheep off its feet at once, before it suspects what you are going to do; for if you let it feel that you are about to lift it as a dead weight, the probability is, that you will not be able to make it lose hold of the ground, as it is surprising how dexterously sheep contrive, in the circumstances, to retain hold of the ground with the point of the hoof of the *near hind-foot*, which, if you cannot force away, you cannot turn the sheep. I remember seeing 4 shepherds defeated in the attempt to turn 5 dinmonts belonging to the late Mr. Edward Smith, Marledown, Northumberland. None of the shepherds, even the longest and strongest, could turn all the 5 sheep, and one of them, a short though stout man, could not turn one of them, they were so broad in the back, so round and heavy. The ability to turn a sheep is

not to be regarded as a feat in a shepherd, but a necessary act in connection with many important operations, as you shall see afterward.

(1173.) Sheep are easily *slaughtered*, and the operation is unattended with cruelty. They require some preparation before being deprived of life, which consists of food being withheld from them for not less than 24 hours, according to the season. The reason for fasting sheep before slaughtering, is to give time for the paunch and intestines to empty themselves entirely of food, as it is found when an animal is killed with a full stomach, the meat is more liable to putrefy, and not so well flavored; and as ruminants always retain a large quantity of food in their intestines, it is reasonable they should fast somewhat longer to get quit of it than animals with single stomachs. Sheep are placed on their side on a stool, called a *killing stool*, to be slaughtered, and requiring no fastening with cords, are deprived of life by a thrust of a straight knife through the neck, between its bone and the windpipe, severing the carotid artery and jugular vein of both sides, from which the blood flows freely out, and the animal soon dies. The skin, as far as it is covered with wool, is taken off, leaving that on the legs and head, which are covered with hair, the legs being disjointed by the knee. The entrails are removed by an incision along the belly, after the carcass has been hung up by the tendons of the houghs. The net is carefully separated from the viscera, and rolled up by itself; but the kidney fat is not then extracted. The intestines are placed on the inner side of the skin until divided into the *pluck*, containing the heart, lungs, and liver; the *bag*, containing the stomach; and the *puddings*, consisting of the viscera or guts. The bag and guts are usually thrown away, that is, buried in the dunghill, unless when the bag is retained and cleaned for haggis. The pluck is either fried or made into haggis. The skin is hung over a rope or pole under cover, with the skin-side uppermost, to dry in an airy place.*

[* By the Abbé Cornea, a man of great learning and observation, it was remarked that the people of the United States possessed "*bacon*-stomachs." Their want of relish, not to say their distaste—more especially females—for *mutton*, is one of the obstacles to the extension of sheep husbandry in the United States. An opinion generally prevails—borrowed, as many of our opinions are, from England—that mutton does not attain perfection in juiciness and flavor under four or five years; but we are disposed to believe, with an experienced victualer of our acquaintance, and a good judge of mutton, alike in the field and the shambles, that this is a mistake, and that well-fed and fatted mutton is never better than when it gets its full growth, in its second year; nor can the farmer afford to keep it longer, unless the wool would pay for the keep. We have not the epicures and men of wealth who would pay the butcher the extra price, which he must have, that would enable him to pay a remunerating price to the grazier for keeping his sheep two or three years over.

The common mistake in the management of mutton in our country is that we *eat it exactly at the wrong time after it is killed*. It should be eaten, as a fried chicken should, immediately after being killed, and, if possible, before the meat has time to get cold; *or*, if not, then it should be kept a week or more—in the ice-house, if the weather require—until the time is just at hand when the fibre passes the state of toughness which it takes on at first, and reaches that incipient or preliminary point in its progress toward putrefaction when the fibres begin to give way and the meat becomes tender.

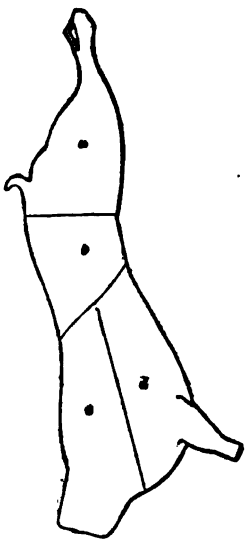
We were gratified lately to see, in a large *smokery* of Mr. Clements, in Philadelphia, quite a large number of *corned legs of mutton*, which had been sent in from Ohio. If mutton can be brought into vogue in that shape, it will be an additional inducement for rearing sheep in many situations removed from available markets.

Who need complain, at a watering-place, if he can secure for his breakfast or his dinner a good mutton-chop, such as is to be had at Caldwell's White Sulphur Springs, peppered, and broiled, and served up hot, *with no gravy but its own*? Can anything be more *toothful*—more *wholesome*? *Ed. Farm. Lib.*]

(1174.) The carcass should hang 24 hours in a clean, cool, airy, dry apartment, before it is cut down. I say *cool* and *dry*, for if warm the meat will not become firm, and if damp a clamminess will cover it, and will never feel dry, and have a fresh, clean appearance. The carcass is divided in two by being sawed right down the back-bone. The kidney-fat is then taken out, being only attached to the peritoneum by the cellular membrane, and the kidney is extracted from the *suet*—the name given to sheep tallow in an independent state.

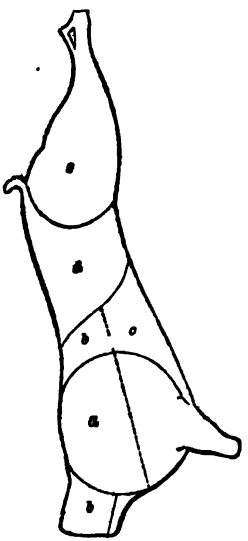
(1175.) In almost every town there is a different way of cutting up a carcass of mutton; and, it being here impossible to advert to them all, I shall select those of Edinburgh and London, and distinguish them as the Scotch and English modes. Although the English mode is upon the whole preferable, having been adopted to suit the tastes of a people long acquainted with domestic economy, it must nevertheless be admitted that meat is cut up in Scotland in a cleanly and workmanlike manner; but on the other hand, it will not be denied by those who have observed for themselves, that the beauty and cleanliness of meat, as exhibited in London, call forth the admiration of every connaisseur. The Scotch mode is represented in fig. 255, where, in the hind-quarter, *a* is the *jigot* and *b* the *loin*, and, in the fore-quarter, *c* the *back-ribs* and *d* the *breast*. It will be observed that the jigot is cut with a part of the haunch or rump, and the fore-quarter right through the shoulder into 2 pieces. The English mode is represented in fig. 256, where, in the fore-quarter, *a* is the shoulder, *b* and *b* the

Fig. 255.



THE SCOTCH MODE OF CUTTING UP A CARCASS OF MUTTON.

Fig. 256.



THE ENGLISH MODE OF CUTTING UP A CARCASS OF MUTTON.

neck, and *c* the breast after the shoulder is removed; and, in the hind-quarter, *d* is the loin and *e* the leg. The leg here is cut short, without any of the haunch, like a ham; and the shoulder is preserved whole.

(1176.) The jigot *a*, fig. 255, is the handsomest and most valuable part of the carcass, and on that account fetches the highest price. It is either

a roasting or a boiling piece. Of Black-faced mutton it makes a fine roast, and the piece of fat in it called the *Pope's eye* is considered a delicate *morceau* by epicures. A jigot of Leicester, Cheviot or South-Down mutton makes a beautiful "boiled leg of mutton," which is prized the more the fatter it is, as this part of the carcass is never overloaded with fat. The loin *b* is almost always roasted, the flap of the flank being skewered up, and it is a juicy piece. For a small family, the Black-faced mutton is preferable; for a large, the South-Down and Cheviot. Many consider this piece of Leicester mutton roasted as too rich, and, when warm, this is probably the case; but a cold roast loin is an excellent summer dish.—The back-rib *c* is divided into two, and used for very different purposes. The fore-part, the neck, is boiled, and makes sweet barley-broth; and the meat, when well boiled, or rather the whole pottage simmered for a considerable time *beside* the fire, eats tenderly. The back-ribs make an excellent roast; indeed, there is not a sweeter or more varied one in the carcass, having both ribs and shoulder. The shoulder-blade eats best cold, and the ribs warm. The ribs make excellent chops. The Leicester and South-Downs afford the best mutton-chops. The breast *d* is mostly a roasting piece, consisting of rib and shoulder, and is particularly good when cold. When the piece is large, as of South-Down or Cheviot, the gristly part of the ribs may be divided from the true ribs, and helped separately. The breast is an excellent piece in Black-faced mutton, and suitable to small families; the shoulder being eaten cold, while the ribs and brisket are sweet and juicy when warm. This piece also boils well; or, when corned for 8 days, and served with onion sauce, with mashed turnip in it, there are few more savory dishes at a farmer's table. The shoulder *a*, fig. 256, is separated before being dressed, and makes an excellent roast for family use, and may be eaten warm or cold, or corned and dressed as the breast mentioned above. The shoulder is best from a large carcass of South-Down, Cheviot or Leicester, the Black-faced being too thin for the purpose; and it was, probably, because English mutton is usually large, that the practice of removing it originated. The neck-piece *b b* is partly laid bare by the removal of the shoulder, the fore-part being fitted for boiling and making into broth, and the best end for roasting or broiling into chops. On this account this is a good family piece, and in such request among the tradesmen of London that they prefer it to any part of the hind-quarter. Heavy mutton, such as the Leicester, South-Down and Cheviot, supply the most thrifty neck-piece. The breast *c* is much the same sort of piece as in the Scotch method, but the ribs are here left exposed at the part from which the shoulder has been removed, and constitute what are called the *spare ribs*, which may be roasted, or broiled, or corned. The back end of the breast makes a good roast for ordinary use. The flap of the loin left attached to this piece may be used in making broth. The loin *d* is a favorite roast in a family; and when cut double, forming the chine or saddle, it may grace the head of the table of any public dinner. Any of the kinds of mutton is large enough for a saddle; but the thicker the meat, of course the larger the slice. The leg *e* is cut short and roasted. When cut long, taking in the hook-bone, it is similar to a haunch of venison, and roasted accordingly. A fat Black-faced wether yields a good haunch.

(1177.) The different sorts of mutton in common use differ as well in quality as in quantity. The flesh of the Leicester is large, though not coarse-grained, of a lively red color, and the cellular tissue between the fibres contains a considerable quantity of fat. When cooked it is tender and juicy, yielding a red gravy, and having a sweet, rich taste; but the fat

is rather too much and too rich for some people's tastes, and can be put aside; and it must be allowed that the lean of fat meat is far better than lean meat that has never been fat. Leicester sheep generally attain to heavy weights—hoggs reaching 18 lbs. or 20 lbs., and dinmonts 30 lbs. per quarter; but the 5 dinmonts which I mentioned before as having defeated the shepherds in turning up, were 55 lbs. a quarter overhead, when killed at Newcastle in November, a few weeks after they were shown.

(1178.) Cheviot mutton is smaller in the grain, not so bright of color, with less fat, less juice, not so tender and sweet, but the flavor is higher and the fat not so luscious. The weight attained by a hogg may be taken at 14 lbs. or 15 lbs., and by a wether at 22 lbs.; but Mr. Fairbairn mentions having fattened 5 wethers in 1818 which averaged 30 lbs. a quarter.*

(1179.) Black-faced mutton is still smaller in the grain, of a darker color, with still less fat, but more tender than the Cheviot, and having the highest flavor of all. The ordinary weight of a fat wether is about 18 lbs. or 20 lbs. a quarter; but I remember seeing a lot of 5-year-old Black-faced wethers, exhibited at the first Show of the Highland and Agricultural Society at Perth, belonging to Lord Panmure, that averaged 40 lbs. a quarter.

(1180.) The mutton of South-Downs is of medium fineness in grain, color pleasant red, fat well intermixed with the meat, juicy, tenderer than the Cheviot, and of pleasant though not of so high a flavor as the Black-faced. The ordinary weight may be from 16 lbs. to 22 lbs. a quarter, but 3 wethers exhibited by Mr. Grantham, at the Show of the Smithfield Club in 1835, weighed, on the average, 41½ lbs. a quarter.†

(1181.) Tup-mutton of any breed is always hard, of disagreeable flavor, and in autumn not eatable. The mutton of old ewes is dry, hard and tasteless, but of young well enough flavored, but still rather dry. Hogg-mutton is sweet, juicy and tender, but flavorless. And wether-mutton is the meat in perfection, according to its kind.

(1182.) The average quantity of fat afforded by each sheep of every class, sold in any given market in Scotland, is perhaps not great. In Glasgow, for example, where heavy animals of all sorts are generally sold, the fat afforded by all the sheep—consisting chiefly, I presume, of Cheviot and Black-faced—exclusive of lambs, amounting to 57,520 head, sold in 1822, was only, on the average, 4 lbs. 13 oz. per head.‡ From 8 lbs. to 12 lbs. is the ordinary quantity obtained from *Leicester* sheep slaughtered on farms of good land; and in Edinburgh I find that 7 lbs. is considered an average from Black-faced and Cheviot sheep, which shows that the quality of mutton sold there is better than that in Glasgow.

(1183.) As you may frequently hear it remarked in the course of your experience as a farmer, that 5-year-old mutton is the best, it is worth while considering whether the case can be so. Two subjects of inquiry immediately present themselves on hearing this remark: one, whether sheep require 5 years to put them in condition for use? and the other is, whether it is treating them properly to postpone putting them in condition for use until they shall attain the age of 5 years? If truth is implied in the first inquiry, then that breed of sheep must be very unprofitable which takes five years to attain its best state; but there is no breed of sheep in Great Britain which requires 5 years to bring it to perfection. Therefore, if truth is implied in the second inquiry, then it must be folly to restrain sheep coming to perfection until they have attained the age of

* A Lammermuir Farmer's Treatise on Sheep in High Districts. † Youatt on Sheep.
‡ Cleland's Account of the Highland and Agricultural Society's Show at Glasgow, in 1828.

5 years. It is not alleged by the lovers of 5-year-old mutton that it bestows profit on the farmer, for the allegation only insists on its being best at that age. But such an allegation involves one of two absurd conditions in Agriculture; namely, the keeping a breed of sheep that cannot, or the keeping of one that you should not allow to attain to perfection before it is 5 years. Either of these conditions makes it obvious that mutton cannot be in its *best* state at 5 years. The fact is, the idea of 5-year-old mutton being super-excellent, is founded on a prejudice, which probably arose from this circumstance: Before winter food which could maintain the condition on stock that had been acquired in summer, was discovered, sheep lost much of their summer-condition in winter, and of course an oscillation of condition occurred year after year until they attained the age of 5 years; when their teeth beginning to fail, would cause them to lose their condition the more rapidly. Hence, it was expedient to slaughter them not exceeding 5 years of age; and, no doubt, at that age mutton would be high flavored that had been exclusively fed on natural pasture and natural hay. But such treatment of sheep cannot now be justified on the principles of modern practice; because both reason and taste concur in mutton being at its *best* whenever sheep attain their *perfect state of growth and condition*, not their largest and heaviest; and as one breed attains its perfect state at an earlier age than another, its mutton attains its best before another breed attains *its* best state, although its sheep may be older; but taste alone prefers one mutton to another, even when both are in their best state, from some peculiar property. The Black-faced sheep, for instance, it is preferred by many, because of the flavor of its mutton; and this property it has most probably acquired from the heathy pasture upon which it is brought up. But if flavor alone is to decide the point, the Welch mutton is much the superior. So far as juiciness is concerned, a Leicester hogg has more of it than any Black-faced sheep; and the darkness of the flesh of the latter arises solely from the breed, as it seems to form the connecting link, in this country, between the sheep and the goat, the latter of which always has dark-colored flesh. Judged by the scale of perfection of growth, Leicester mutton is best in the dinmont; and as it may require five years to bring a Black-faced wether to that state when constantly confined upon the hills, Black-faced mutton may then be considered in its best state, *because* it is 5-year-old, but so far from being in the condition it would have attained had it been brought down to the low country when a lamb and fed upon the best food, it would still be lean, and, of course, not in a state of perfect growth; whereas, in the low country, it would attain perfection of growth at 3 years, and then its mutton must be at its *best*; for beyond that age—that is, if kept to 5 years on such food—it would become too fat, and lose much of its delicacy. The cry for 5-year-old mutton is thus based on very untenable grounds.

(1184). *Markets* for sheep are held in all large towns, and the butchers in the small ones supply themselves from the farmers. The Edinburgh weekly market, on Wednesday, supplies the Black-faced mutton in perfection, and the Cheviot is also very good. In Morpeth, on Wednesdays, are to be seen Leicesters in the highest state of condition, which are brought up with avidity for the colliers around Newcastle. In London, on Mondays, the South-Downs are seen in great perfection, this being the favorite mutton of the Capital.

(1185). A great trade in the transmission of live-stock and meat from the east coast of Scotland to London, has arisen since the establishment of steam navigation. From inquiry, I found that, in the year ending May 1837, there were shipped 4,221 old sheep, and 11,672 barrel-bulk of meat,

chiefly mutton, which, at 2½ cwt. per barrel-bulk, give 29,175½ cwt.* The meat is sent by butchers at the different shipping ports, and the live-stock by dealers, butchers and farmers. When you determine to send your stock to London, you should, in the first place, establish a correspondence with a live-stock salesman, who will pay all charges on board ship and at market, and remit the balance in course of post. The charges consist of freight, which for sheep is 3s. 6d. a herd, commission, hay or grass on board, dues and wharfage, hay or grass on shore, and driving to market. You will, of course, never ship meat, but you should, nevertheless, be well acquainted with all the pieces into which a carcass of beef or mutton is cut up, that you may know whether your stock is of the description to supply the most valuable pieces of meat; for, without this knowledge, unless, in short, you know the wants of a market, you cannot know whether you are supplying its requirements, or whether your stock ought to realize the top prices.

(1186.) On the supposition that you send sheep to London by steam on your own account, they should be of the following description, to command the best prices, and unless they are so you had much rather dispose of them at home. They should be ripe, compact, and of light weight; carrying a large proportion of lean on the back, loins, and shoulders, with a full, round leg and handsome carcass. Such, from 14 lbs. to 20 lbs. a quarter, will take readily, but they will draw the most money at from 16 lbs. to 18 lbs. The nearer in their form and quality they approach the South-Downs, the more likely to command top prices. True-bred Cheviots and the Black-faced Linton breed approach very near to the South-Down, and command as high a price. Half-breds, between Leicester tups and the above sorts of Cheviot and Black-faced ewes, form valuable sheep. The old Black-faced breed are too *thin*, and therefore styled *goaty* in Smithfield, and when only half-fat, or *half-meated*, as the condition is there termed, fetch middling prices, however good their flavor may be. Pure-bred Leicesters are too *fat*, unless sent young, and not exceeding 20 lbs. a quarter, but above that weight, fetch inferior prices, so much so that a difference of only 1d. per lb. may perhaps constitute all the difference between a profit and loss on their export. This last remark applies to every other breed, and shows the expediency of only exporting the best form of sheep.

(1187.) Never attempt to drive stock on foot on your own account to a distant market, when you have steam-conveyance to the place of destination. A simple comparison of the results of the two methods of traveling will show you at once the advantage of steam-conveyance. It has been ascertained that a journey of 400 miles on land causes a loss of 6 stones out of 40 stones, or 12 per cent.; whereas the loss by steam is only 2 stones out of 50. But besides this great difference in the loss itself, the state in which the remainder of the flesh is left, it is worth 6d. a stone less after land travel; and when stock are sent to graze in that state, they require a month to take with the pasture, whereas the steam-carried will thrive again at the end of a fortnight. Besides all these disadvantages of land travel, the juices of the meat of fat stock never recover their natural state, while, by being carried by steam, they do. Were heavy and high-conditioned stock to be traveled by land, they would inevitably sink under the attempt, while by steam any degree of condition may be conveyed

* See an article on the preparation of live-stock and meat for exportation by steam, in vol. viii. of the Quarterly Journal of Agriculture, drawn up by me on information derived from Mr. James Dickson, in Orkney, who has had great experience in every matter relating to meat and live-stock; and also from other sources.

with comparative ease. The *time*, too, spent on a land journey is of consideration, when a more expeditious mode of traveling is in your option.

(1188.) With regard to the relative weights of offal and meat afforded by sheep, there are recorded instances of their proportions, and of a fat South-Down wether they were these, namely:

Live weight, 13 *st.*, 10 *lbs.*

Offal.	Lbs.	Oz.	Meat.	Lbs.	Oz.
Blood and entrails	13	0	Fore-quarter	29	0
Caul and loose fat	21	4	do.	28	12
Head and pluck	8	12	Hind-quarter	33	8
Pelt	15	12	do.	32	0
Total	58	12	Total	113	4*

I may mention that the *carcass* consists of the entire useable meat of the body, which, when sawed down the middle of the back-bone, is divided into two *sides*, which, when again divided by the 5th rib, makes the carcass to consist of 4 *quarters*. The remainder of the animal consists of offal—namely, of fat, entrails, head and skin. In purchasing fat live-stock, the butcher is supposed to pay the market value of the carcass, bone and meat to the farmer, reserving the offal to himself for his profit and risk. The relative proportions of mutton and offal have probably never been absolutely ascertained, as they must differ in different breeds of sheep; but there is little doubt that, in the Leicester breed, the meat bears a higher proportion to the offal than in any other breed. In the above case, the meat is about ⅞ and offal ⅛ of the whole weight; or, more nearly, the meat is as 123½ : 182, and the offal as 58½ : 182. And in the same breed it has been said that the proportion of bone is as low as 1 oz. to 1 lb. flesh; but I much doubt this, because Mr Donovan found in a leg of mutton, which is the most fleshy part of the carcass in proportion to the bone in it, weighing 9½ lbs., 16 oz. of bone; another of 9 lbs. 6 oz., 15 oz.; and a leg of small Scotch mutton, of only 6 lbs. weight, afforded 10½ oz. of bone.

(1189.) There is a rule mentioned by Mr. Ellman, of Glynde, in Sussex, by which the age of mutton may be ascertained by certain marks on the carcass, and it is an infallible one. He says: "Observe the *color* of the *breast-bone* when a sheep is dressed—that is, where the breast-bone is separated—which, in a lamb, or before it is 1 year old, will be quite red; from 1 to 2 years old, the upper and lower bone will be changing to white, and a small circle of white will appear round the edges of the other bones, and the middle part of the breast bone will yet continue red; at 3 years old, a very small streak of red will be seen in the middle of the 4 middle bones, and the others will be white; and at 4 years, all the breast-bone will be of a white or gristly color."†

(1190.) The experiments of Mr. Donovan prove that meat of all kinds loses a considerable proportion of weight on being cooked. His results on mutton were: The average loss on *boiling* legs of mutton is 10 per cent.; so that, if the butchers' price were 6d. per lb., the boiled mutton would cost 7½d. The average loss of *roasting* legs of mutton is 27 7-10 per cent.; so that, at the butcher's price of 6d. per lb., the roasted mutton would cost 8¼d. per lb. The average loss of roasting shoulders of mutton is 28 per cent.; and, were the butcher's price 5d. per lb., the roasted shoulder would cost 6 9-10d. per lb. The average loss, therefore, in boiling mutton is 10 per cent., and in roasting it 27 85-100 per cent. These results differ considerably from those obtained by Professor Wallace, who, in the case of *boiling* 100 lbs. of mutton, detected a loss of 21½ per cent., instead of 10 per cent.; and in that of *roasting* 100 lbs., the loss was 31½ instead of 28 per cent.—These discrepancies might, perhaps, be easily explained were we acquainted with every particular connected with both sets of experiments, such as the state of the meat before and after being cooked. In these respects, in his own experiments, Mr. Donovan says: "I used meat of sufficient but not unprofitable fatness, such as is preferred by families; the meat was, in all cases, a little rare at its center, and the results were determined with the utmost care."‡

(1191.) Good *ham* may be made of any part of a carcass of mutton, though the *leg* is preferred, and for this purpose it is cut in the English fashion. It should be rubbed all over with good Liverpool salt, and a little saltpetre, for 10 minutes, and then laid in a dish and covered with a cloth for 8 or 10 days. After that it should be rubbed again slightly for about 5 minutes, and then hung up in a *dry* place, say the roof of the kitchen, until used. Wether mutton is used for hams, because it is fat, and it may be cured any time from November to May; but tup mutton makes the largest and highest flavored ham, provided it be cured in spring, because it is out of season in autumn.

(1192.) There is an economical way of using fat mutton well adapted for the laboring people of a farm. The only time Scotch farm-servants indulge in butcher-meat is when a sheep *fills*, as it is termed—that is, when it is killed before being affected with an unwholesome disease, and the mutton is sold at a reduced price. Shred down the suet small, removing any flesh or cellular membrane adhering to it; then mix among it intimately ¼ oz. of salt and a tea-spoonful of pepper to every pound of suet; put the mixture into an earthen jar, and tie up tightly with bladder. One table-spoonful of seasoned suet will, at any time, make good barley-broth or potato soup for two persons. The lean of the mutton may be shred down small, and seasoned in a similar manner, and used when required; or it may be corned with salt, and used as a joint.

(1193.) Where Leicester sheep are bred, and the farmer kills his own mutton, suet will accumulate beyond what can be used for domestic purposes. As long as it is fresh it should be *rynded* or *rendered*, as it is termed—that is, prepared for preservation—because the fibrous and fleshy matter mixed with it soon promotes putrefaction. It should be cut in small pieces, removing only fleshy matter. It is then put in an earthern jar, which is placed within a pot containing warm

* Sussex Agricultural Report. † British Husbandry, vol. ii. ‡ Donovan's Domestic Economy, vol. ii.

water, at the side of the fire, merely to simmer, and not to boil. As every portion put in is melted, another succeeds, until the whole is melted; and the melted mass should be very frequently stirred. Suet melts at from 98° to 104° Fahr. After being fused a considerable time, the membraneous matter comes to the top, and is taken off; and when obtained in quantity, and squeezed, this scum constitutes the *cracklings* which are sometimes used for feeding dogs. The purified suet may then be poured through a cullender, into a dish containing a little water, upon which it consolidates into a cake; and the cakes are either sold to the candle-makers or candles taken in exchange. "Many plans for purifying fats," says Ure, "have been proposed. One of the best is to mix 2 per cent. of strong sulphuric acid with a quantity of water, in which the tallow is heated for some time with much stirring, to allow the materials to cool, to take off the supernatant fat, and re-melt it with abundance of hot water. More tallow will thus be obtained, and that considerably whiter and harder than is usually procured by the melters."* Some people melt suet in a pot over the fire, where it is apt to be burnt; and some even fry it in a frying-pan, which may answer for culinary purposes, but cannot, of course, be disposed of to the candle-makers.

(1194.) Mutton-suet consists of about 77 parts of stearine and 23 of oleine in every 100 parts.—The former is solid, the latter fluid. The specific gravity of suet is 0·936. When a piece of solid suet is broken, innumerable minute granules separate from the mass; and these, when examined by the microscope, exhibit definite forms, being polyhedral, bounded within the limits of a sphere, or oblong, of very firm consistence, and, when measured, give dimensions varying in length from 1·400 to 1·900, and in breadth from 1·200 to 1·500 part of an inch.† The constituent parts of suet, according to Chevreul, are carbon 78·996, hydrogen 11·700, and oxygen 9·304.‡

(1195.) Fat is very generally distributed in the animal frame. It is "abundant under the skin, in what is called the cellular membrane, round the kidneys, in the folds of the omentum, at the base of the heart, in the mediastinum, the mesenteric web, as well as upon the surface of the intestines, and among many of the muscles. It varies in consistence, color and smell, according to the animal from which it is obtained. Thus, it is generally fluid in the cetaceous tribes, soft and rank-flavored in the carnivorous, solid and nearly scentless in the ruminants; usually white and copious in well-fed young animals, yellowish and more scanty in the old. Its consistence varies also according to the organ of its production, being firmer under the skin and in the neighborhood of the kidneys than among the movable viscera. Fat forms 1-20 of the weight of a healthy animal; but as taken out by the butcher it is not pure, for, being of a vesicular structure, it is always inclosed in membranes, mixed with blood, blood-vessels, lymphatics, &c."‖

(1196.) Sheep is one of the most useful, and therefore one of the most valuable, of our domestic animals; it not only supports our life by its nutritious flesh, but clothes our bodies with its comfortable wool. All writers on diet have agreed in describing mutton as the most valuable of the articles of human food. "Pork may be more stimulating, beef perhaps more nutritious, when the digestive powers are strong; but, while there is in mutton sufficient nutriment, there is also that degree of consistency and readiness of assimilation which renders it most congenial to the human stomach, most easy of digestion, and most contributable to health. . . . . Of it, almost alone, can it be said that it is our food in sickness as well as in health; its broth is the first thing that an invalid is permitted to taste, the first thing that he relishes, and is his natural preparation for a return to his common aliment.§ In the same circumstances, it appears that fresh mutton, broiled or boiled, takes 3 hours to digest; fresh mutton, roasted, 3¼ hours; and mutton-suet, boiled, 4¼ hours.¶

(1197.) But the products of sheep are not merely useful to man, they also promote his luxuries. The skin of sheep is made into leather, and, when so manufactured with the fleece on, makes comfortable mats for the doors of our rooms, and rugs for our carriages. For this purpose the best skins are selected, and such as are covered with the longest and most beautiful fleece. Tanned sheep-skin is used in coarse book-binding. White sheep-skin, which is not tanned, but so manufactured by a peculiar process, is used as aprons by many classes of artisans, and, in Agriculture, as gloves in harvest; and, when cut into strips, as twine for sewing together the leathern coverings and stuffings of horse-collars. Morocco leather is made of sheep skins as well as of goats, and the bright-red color is given to it by cochineal. Russia leather is also made of sheep-skins, the peculiar odor of which repels insects from its vicinity, and resists the mould arising from damp—the odor being imparted to it in currying, by the empyreumatic oil of the bark of the birch tree. Besides soft leather, sheep-skins are made into a fine, flexible, thin substance, known by the name of parchment; and, though the skins of all animals might be converted into writing materials, only those of the sheep and she-goat are used for parchment. The finer quality of the substance called vellum is made of the skins of kids and dead-born lambs, and for the manufacture of which the town of Strasburgh has long been celebrated.

(1198.) Mutton-suet is used in the manufacture of common *candles*, with a proportion of ox-tallow. Minced suet, subjected to the action of high-pressure steam in a digester at 250° or 260° Fahr., becomes so hard as to be sonorous when struck, whiter, and capable, when made into candles, of giving very superior light. Stearic candles, the late invention of the celebrated Guy-Lussac, are manufactured solely from mutton suet.

(1199.) Besides the fat, the intestines of sheep are manufactured into various articles of luxury and utility, which pass under the absurd name of catgut. "All the intestines of sheep," says Mr. Youatt, "are composed of 4 coats or layers, as in the horse and cattle. The outer or *peritoneal* one is formed of that membrane by which every portion of the belly and its contents is invested, and confined in its natural and proper situation. It is highly smooth and polished, and it secretes a watery fluid which contributes to preserve that smoothness, and to prevent all friction and concussion during the different motions of the animals. The second is the *muscular* coat, by means

§ Edinburgh Encyclopædia, art. *Aliments*, as quoted by Youatt on Sheep.
¶ Combe on Digestion and Dietetics.

of which the contents of the intestines are gradually propelled from the stomach to the rectum, thence to be expelled when all the useful nutriment is extracted. The muscles, as in all the other intestines, are disposed in two layers, the fibres of the outer coat taking a longitudinal direction, and the inner layer being circular; an arrangement different from that of the muscles of the œsophagus, and in both beautifully adapted to the respective functions of the tube. The submucous coat comes next. It is composed of numerous glands, surrounded by cellular tissue, and by which the inner coat is lubricated, so that there may be no obstruction to the passage of the food. The *mucous* coat is the soft villous one lining the intestinal cavity. In its healthy state, it is always covered with mucus; and when the glands beneath are stimulated—as under the action of physic—the quantity of mucus is increased; it becomes of a more watery character; the contents of the intestines are softened and dissolved by it; and by means of the increased action of the muscular coat, which, as well as the mucous one, feels the stimulus of the physic, the fæces are hurried on more rapidly and discharged."* In the manufacture of some sorts of cords from the intestines of sheep, the outer peritoneal coat is taken off and manufactured into a thread to sew intestines, and make the cords of rackets and battledores. Future washings cleanse the guts, which are then twisted into different-sized cords for various purposes. Some of the best known of those purposes are whip-cords, hatters' cords for bow-strings, clock-makers' cord, bands for spinning-wheels (which have now almost become obsolete), and fiddle and harp strings. Of this last class of cords—the source of one of our highest pleasures—it has long been subject of regret that those manufactured in England should be so inferior in goodness and strength to those of Italy; and the reason assigned is that the sheep of Italy are both smaller and leaner than those of this country.—The difficulty lies, it seems, in making the treble strings from the fine peritoneal coat, their chief fault being weakness, whence the smaller ones are hardly able to bear the stretch required for the higher notes in concert-pitch—maintaining, at the same time, in their form and construction, that tenuity or smallness of diameter which is required to produce a brilliant and clear tone.†—However contemptible this subject may appear in the estimation of some, it is worth attending to by those interested in enhancing the profits of our native products, and more especially when it is considered that harp-strings sell as high as from 6d. to 2s. apiece.

(1200.) While adverting to the uses of the skin of the sheep, it may be useful to give an idea of its physical structure, a knowledge of which being requisite for an acquaintance of the rationale of its diseases. "It is composed of 3 textures. Externally is the *cuticle* or *scarf-skin*, which is thin, tough, devoid of feeling, and pierced by innumerable minute holes, through which pass the fibres of the wool and the insensible perspiration. It seems to be of a scaly texture; but this is not so evident in the sheep as in many other animals, on account of a peculiar substance, the *yolk*, which is placed on it to nourish and protect the roots of the wool. It is, however, plainly enough to be seen in the scab and other cutaneous eruptions to which the sheep is liable. Below this is the *rete mucosum*, a soft structure, its fibres having scarcely more consistence than mucilage, and being with great difficulty separated from the skin beneath. This seems to be placed as a defence to the termination of the blood-vessels and nerves of the skin, and these are in a manner enveloped and covered by it. The color of the skin, and probably that of the hair or wool also, is determined by the *rete mucosum*, or at least the hair and wool are of the same color as this substance. Beneath is the *cutis* or *true skin*, composed of innumerable minute fibres crossing each other in every direction—highly elastic, in order to fit closely to the parts beneath, and to yield to the various motions of the body; and dense and firm in its structure, that it may resist external injury. Blood-vessels and nerves, countless in number, pierce it, and appear on its surface under the form of *papillæ*, or minute eminences; while, through thousands of orifices, the exhalant absorbents pour out the superfluous or redundant fluid. The true skin is composed principally or almost entirely of gelatine; so that, although it may be dissolved by long continued boiling, it is insoluble in water at the common temperature. This organization seems to have been given to it not only for the sake of its preservation, while on the living animal, but that it may become afterward useful to man." It would appear that there are circumstances which materially limit the action of the power of excretion and absorption in the skin of the sheep. It is surrounded by a peculiar secretion, adhesive and impenetrable to moisture, the yolk, destined chiefly to preserve the wool in a soft, pliable and healthy state. On this account there can be little perspiration going forward from the skin, and hence few diseases are referable to change in that excretion. Also, there is little radiation of animal heat both on account of the interposition of the yolk, and of the non-conducting power of the wool. The caloric disengaged from a sheep is only 1-7 part of that from man, though the weight of the animal is ⅓ of that of man—that is, only half the animal heat radiates from a sheep, from a given surface, that does from a man. This it is which enables the ewe and its lamb to endure the colds of spring without detriment; and also, when sheep are crowded together in an open fold, no unnatural or dangerous state of heat is thereby produced.‡

32. REARING AND FEEDING CATTLE ON TURNIPS IN WINTER.

"The cattle from th' untasted fields return,
And ask, with meaning low, their wonted stalls,
Or ruminate in the contiguous shade."

THOMSON.

(1201.) THE first thing to be done with the courts in the steading, before being taken possession of by the cattle, is to have them *littered plentifully with straw*. The first littering should be abundant, as a thin layer of straw upon the bare ground makes an uncomfortable bed; whereas a thick one is not only comfortable in itself, but the lower part of it acts as a drainer to the heap of manure above it. There is more of comfort for cattle involved in this little affair than most farmers seem to be aware of; for it is obvious that the first layer of litter, when thin, will soon get trampled down, and in rainy weather soon become poached—that is, saturated with wet and pierced with holes by the cattle's feet—so that any *small* quantity of litter that is afterward laid upon it will but absorb the moisture below it, and never afford a *dry* lair to the cattle. On the other hand, when the first layer is thick, it is not poached even in wet weather, because it is with difficulty pierced through by feet, and it instantly drains the moisture that falls upon it, and of course keeps the bedding comparatively dry.

(1202.) There is, however, sometimes a difficulty of obtaining sufficient straw at this season, from various causes, among which may be mentioned a dislike in farmers to thresh a stack or two of the new crop at so early a period, even when there is no old straw or old stack of corn to thresh; but however recently formed the stacks may be, and inconvenient to thresh their produce at the time, it should be done rather than stint the cattle of bedding; and should bad weather immediately set in—an event not unlikely to happen—the cattle may be so chilled in their ill-littered quarters as not entirely to recover from it during the winter; and hence may arise a serious reduction of profit.

(1203.) It may happen, on the other hand, with plenty of old stacks, there may be want of water to drive the threshing-machine; and this is no uncommon predicament at the commencement of winter on many farms which depend upon surface-water for their supply; and a windmill is in no better plight in want of wind. Where such contingencies *may* happen, a sufficient quantity of litter should be provided for in good time, and there are various ways of doing this. Those who still use the flail may employ it at any season; and those having horse threshing-mills are equally independent. Access to bog-land gives the command of making coarse herbage into hay during summer; but in regard to the use of other products of bog-land for litter, precaution is requisite, for the turfy matter on the top on being used as a bottoming for courts, with the view of absorbing their moisture, will inevitably become as a sponge of water after the first fall of rain, and the cattle will soon render the whole bedding a poached mass. I once tried the experiment under the most favorable circumstances of getting the turf well dried, and yet could not get rid of the inconvenience of poaching until the courts were entirely cleared of their contents. Those who are annoyed with ferns in their pastures should cut them down and won them for litter, and a most excellent foundation they

make for straw. Those who can cut grass, or gather dry leaves in woods, should do so in summer, or immediately after harvest, for a day or two, with the harvest people. By attending to one or all of these provident measures, a comfortable bed may be provided for cattle at the commencement of the season, under the most unfavorable circumstances in regard to a command of straw.

(1204.) Suppose, then, that all the courts and hammels are plentifully littered for the reception of the cattle, the next step is to arrange the different classes of cattle in their respective places. The different classes of cattle are cows, calves of the year, 1-year-olds, 2-year-olds, bulls, heifers in calf, and any extra cattle.

(1205.) *Cows* occupy the byre Q, fig. 3, Plate III. (42.) Each should always occupy the stall she has been accustomed to, and all will then go and come into their stalls without interfering with one another. They thus learn to become very quiet in the stall, both to the cattle-man who feeds them, and the dairy-maid who milks them. Each stall should have a manger *c*, fig. 10 (47), elevated 20 inches above the floor, lined with wood or stone, and having an edging of plank 8 inches in depth, to keep in the food. The usual plan is to place the mangers of byres on a level with the floor, down to which the cow has to stretch her neck to get to the turnip, or other food, and in doing this she is obliged to support herself almost wholly on one leg. This awkwardness of position is itself a certain proof that the animal is ill at ease while eating. There should be as much room behind the manger to the gutter as to allow the cow to lie at ease, whatever be her size, like a horse in a stall with a low hay-rack. Each stall should have a travis-board to separate it from the next (149). Some people are great advocates for double stalls, both in byres and stables, to hold a pair of animals each. In a byre, that plan is objectionable for several reasons; a cow is a capricious creature, and not always friendly to her neighbor, and one of them, in that case, must be bound to the stake on the same side as she is milked from; to avoid which inconvenience to the dairy-maid, the cow must be put aside nearer her neighbor in the same stall, which may prove unpleasant to both parties, or her neighbor in the adjoining stall be put aside nearer *her* neighbor, which may prove equally inconvenient. Neither is it a matter of indifference to the cow from which side she is milked, for many will not let down their milk if the milk-maid sits down to the unaccustomed side. The safest plan, therefore, in every respect, is for each cow to have her own stall. The floor of the stall should be causewayed only as far as shown at *m*, fig. 10, and the remainder at *f* should be of beaten earth, and this plan is intended to save the fore-knees of cows from injury. *Cattle* lie down and rise up by resting on the fore-knees, and when they have to do so on a hard pavement, injury will likely arise to the knees, if the pavement is not always covered with litter. I remember seeing a valuable Short-Horn cow, in Ireland, get injured in the knees from this cause; they swelled so much and continued so long in a tender state that she would not lie down at all; and all the while her owner was not aware of the cause until I suggested it. On the removal of the pavement, and proper treatment of the parts affected, they recovered. Cows are bound to the stake *h*, fig. 10, either by seal *c d*, fig. 11, or baikie, *e k g*, fig. 12, and *either* secures the animal sufficiently. The seal is made entirely of iron chain, and slides up and down the inclined stake *h* by means of the iron ring *d*; the baikie is made partly of wood *e*, and partly of rope *k* and *g*. Of the two modes of ligature I prefer the seal, because its construction permits the animal turning its head so much round as to be able to lick herself as far as the loin, whereas the baikie only admits of

a constrained up and down motion along a perpendicular stake (48); and, besides, it is an impracticable mode of binding in connection with the use of a manger, because it prevents the animal stepping back to avoid it.

(1206.) *Calves of the year* should occupy court K, fig. 3, Plate III. (62.) In such receptacles they are put together male and female, strong and weak, but having plenty of trough room around two of the walls, they can all be amply provided with food at the same time, without the danger of the stronger buffeting about the weaker. The openings into the shed in which they take up their abode at night is at D, and in the center of the court stands the straw-rack *o*, formed like fig. 19 where straw is scarce, as on gravelly soils, or like figs. 20 and 21 where it is plenty. The troughs for the turnips are fitted up as in fig. 18, which is there represented as a short one, to show the finishings of the ends, but which, of course, may be extended to any length, as may be seen by *z* in K, fig. 4, Plate IV. There is a water-trough *w* in the same court, it being essential for young stock to have water at will, and especially when they do not get as many turnips as they can eat. When they do, cattle do not feel the want of water, the juice of the turnip supplying them with sufficient liquid. In the same Plate IV. may be seen the shed D, under the granary, connected with the court K, having a straw-rack *h'* fitted up at one end. The turnip-store for this court is at *g*; and *x* is the mouth of the liquid-manure drain, to carry off any superfluous water. In the calves of the year occupying this court K, where there is a good deal of traffic in going to and from the corn-barn C, the young creatures will become familiarized with the people, and have a chance of getting pickings of corn from the barn.

(1207.) The court I is fitted up precisely with the same conveniences of feeding-troughs *z*, water-trough *w*, straw-racks *h'* and *o*, and turnip-store *i*, as the other court for the 1-year-olds. It will be observed that the shed D, in both courts, has two entrances, which is the usual plan; but, in my opinion, the comfort of the cattle is more secured with only one entrance, inasmuch as all draft is prevented; and although the object of two entrances is a laudable one in affording a means of escape to a beast that may be ill-used by the rest, that advantage to one is dearly bought at the sacrifice of comfort to the others, and after all it is doubtful whether the contingency can be avoided in this way.

(1208.) As I have said before (62), I prefer hammels to large courts, for young beasts; because the heifers could be separated from the steers, and each of the classes subdivided to suit color, strength, age, temper, or any other point in which a few agree, and differ from the rest; and it is surprising how much better the same beasts look when assorted. In a large court, all are put together, and, if there be plenty of room for every one to do as it likes, no harm may accrue; but where too many are crowded together, which is almost always the case on farms where winterings are bought, some will be knocked about and kept back from their meat, and obliged to eat it at untimeous hours; and in either plight will be stinted in their growth and condition. Only one beast so used makes a serious drawback on the value of the lot, for it must be drafted from the rest and sold separately, at a reduced price, to the vexation of the owner, when too late to retrieve the loss. Now, no such occurrence can take place in hammels, where every difference in character, age, and strength of animals, can be nicely assorted; and this is the more requisite in beasts that have been bought in to be fed, than those brought up together at home.

(1209.) The *2-year-olds, intended to be fattened for the butcher*, occupy the hammels M, where are inner sheds at M, feeding-troughs *z*, liquid-manure drains *x*, in the courts, and where fodder is supplied in the inside

of the sheds, in racks, in three of the corners, and the turnip-stores of which are at *e* and *f*. The sheds being 14 feet wide and 18 feet long, and the courts 30 feet long by 18 feet in width, each hammel will accommodate 4 steers, not merely at the beginning of the feeding season, but at its end, when they shall have attained the weight of at least 70 stones each imperial.

(1210.) Occasionally the cow stock requires to be renewed, one or two at time, by *young heifers;* and as these, when in calf, should not of course be fattened, they not be put in the hammels of the feeding-stock of their own age, namely, the 2-year-olds, but have hammels to themselves at N, which are fitted up in precisely the same manner as at M, with feeding-troughs *z*, straw-racks in the corner of the sheds, liquid-manure drains *x*, and turnip-stores *p* and *q*. Their size, inside the shed, is 17 feet long by 14 feet wide, and the court 20 feet long by 17 feet wide, so that each can accommodate 3 heifers in calf. The *old cows* which these heifers are intended to supersede have to be fattened, and they can be accommodated with one of the hammels at N.

(1211.) The *servants' cows* are accommodated in the byre Y, fitted up in the same manner as the other byre Q, having an outer court *v*, water-trough *w*, liquid-manure drain *x*, and turnip-store *h*.

(1212.) When *oxen are fattened in byres* instead of hammels, they are accommodated in the same manner as the cows are in either Q or Y; but instead of each having a stall, they are usually bound up in pairs in double stalls, with a partition in the turnip-trough, placed on the ground, and a travis between every pair. Stalls of this construction are often as narrow as 7 feet, but 8 feet is the more common width. I have already condemned the crowded state in which oxen, fed in byres, are usually placed (49), and shall not again advert to the subject here. When cattle are bound to the stake for the first time, for the season, they are apt to be restless until reconciled to their confinement, which they will be ere long, if provided with plenty of food.

(1213.) Bulls occupy the hammels X, which are fitted up with feeding-troughs *z*, water-troughs *w*, liquid-manure drains *x*, and racks in the corners of the sheds X. More than one bull-calf may be put together; but more than one bull that have served cows are never intrusted together.

(1214.) Having thus accommodated all the cattle, according to their kinds and ages, in their respective places in the steading, for the winter, let us now attend to the treatment which each class should daily receive during their confinement.

(1215.) And to begin with the *cows*. The first piece of work connected with the treatment of cows in winter, is to milk them at day-break, which cannot be at a very early hour this season. On farms on which cows are bred, they are heavy in calf in winter; so most of them will be dry, and those still yielding milk, being the latest to calve, will give but a scanty supply. It is, therefore, not as *milch*-cows they are treated at this season. After milking is finished by the dairy-maid, the usual practice is to give the cows, though heavy in calf, a feed of cold turnips, on an empty stomach, which I have always considered an injudicious practice; and its injudiciousness is evinced by the fact of the fœtus showing unequivocal symptoms of its existence in the womb, in the same manner as after a drink of cold water in the morning. I would, therefore, give them a mouthfull of fresh oat-straw, to prepare the stomach for the turnips. While amusing themselves with this fodder, the cattle-man, whose duty it is to take charge of all the cattle in the steading in winter, cleans out the

byre of its litter and dung with the graip, fig. 257, and shovel (fig. 149), and wheelbarrow, and spreads it equally over the court, sweep the gutter and causeway clean with a birch or broom-besom. Having shut the byre-door and left the half-door into the court open for fresh air, the cattle-man leaves the cows until he has supplied the fattening and young beasts with turnips, which having done, he returns to the cow-byre, bringing litter-straw with him, and gives them their allowance of turnips for the first meal. Cows in calf never get as many turnips as they can eat, the object being not to fatten, but support them in a fair condition for calving; for were they fed fat, they would run the risk of life at calving through inflammation, and the calves would be small. It is not easy to specify the number or weight of turnips that should be given to cows; but I conceive that ½ of what a feeding ox would consume will suffice.

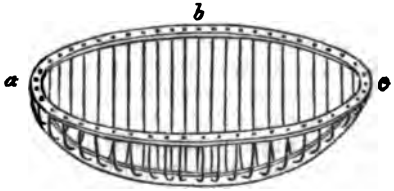
Fig. 257.

THE GRAIP.

(1216.) There are three ways of supplying cows with turnips, either through the openings of the wall at their heads, as at *o*, fig. 10, and through the door, fig. 9, from the store in the shed *s*, into the trough *c*; or with basketfulls, carried by the stall; or with barrow-loads, wheeled along a passage at their head, as described in (45), and emptied into the same trough *c* from the same store *s*, as seen in plan at *m*, fig. 4, Plate IV., by the back-door into the byre.

(1217.) With the willow-basket or *skull*, is the most common way of serving cows or cattle in byres with turnips. It is about 2 feet in diameter, with holes wrought into each side, under the rim, for handles, and costs about 1s. 6d.; but they are apt to become rotten or broken after the natural sap is dried out of the willows, which is generally in a few months' time, and then they become very brittle. In short, a skull seldom lasts more than a year or two; and as a number of them are required about a steading where a variety of beasts are fed on turnips, their cost, though individually trifling, becomes in the aggregate so considerable as to make its avoidance desirable. A basket of wire or small iron rods has been substituted in some places. A wire basket is represented by fig. 258, where the rim *a b c*, which forms its mouth, is a flat slip of iron about ¾ of an inch in breadth, and the keel or bottom *a d c* is of the same dimensions and materials. Holes are punched through them, at about 3 inches apart from each other. The small iron rods are inserted through them, receiving a bend to suit the form of the basket, and the ends of those attached to the rim *a b c* are shouldered below, and made fast with a counter-sink rivet above. The spaces left at the ends of the keel, under the rim, at *a* and *c*, form the handles. The cost is about 2s. 6d. each, and with due care—such as the replacement of a rod now and then, when broken—will last from 5 to 10 years. Were the keel made straight at *d*, the basket would stand steadier to be filled.*

Fig. 258.



THE WIRE TURNIP-BASKET.

(1218.) Before the turnips are put into the troughs, the remains of the

* Quarterly Journal of Agriculture, vol. xi.

fodder given in the morning should be strewed down for litter, and the troughs cleaned out. The turnips should always be put into the troughs in a regular order, beginning at the same end of the byre, and finishing at the other, and after the turnips have been given, the cows should be permitted to eat them in quiet, for nothing irritates animals more than to be handled and worked about when feeding. The turnips consumed, and the stalls comfortably littered with straw, the cows will lie down and chew the cud until mid-day, when they should be turned into the court to enjoy the fresh air, lick themselves and one another, drink water from the trough, and bask in the sun. They should go out a while every day, in all weathers, until they calve, except perhaps in a very cold, wet day. One hour may be long enough at a time. In loosening cows from their stalls, a plan requires to be pursued to prevent confusion. In the first place, every cow, in the beginning of the season, should be put in the stall she has occupied since she first became an inmate of the byre; and she will always go to *it*, and no other, avoiding the least collision with the rest. In loosening them from the stalls, they should be so one by one, always beginning at the same end of the byre, and finishing at the other, and not indiscriminately. This will prevent collision on the floor and jamming in the doorway on going out—accidents injurious to animals with young. After their return, they should also be bound in the same regular order from one end of the byre to the other, and this will prevent any one being forgotten to be bound, and to remove every temptation from even a greedy cow running up into another one's stall for the sake of snatching a little of her food, no food should be lying in the troughs when they return to their stalls; and no food that they like—such as turnips, mangel-wurzel, and the like—should be given them immediately on returning to the byre, because the expectation of receiving it will not only render them impatient to leave the court, but make them restless in the stall until they receive it. This plan, contrary to usual practice, will, it is obvious, suppress all anxiety, and thereby prevent violation of discipline, and, of course, necessity for correction. When subjected to this regular form of discipline, they will soon obey it, and make no confusion, but conduct themselves peaceably. On their return to the byre, let a little fodder be given; and after a lapse of time, say at 3 P. M., give them their evening meal of turnips, after which they should be littered for the night.

(1219.) The treatment of *oxen* in a byre is different from that of cows; they get as many turnips as they can eat, and are not permitted to leave their stalls until sold off fat. As it is not usual for oxen to be fed in byres and hammels on the same farm, what I have to say in regard to feeding in the byre should be considered in lieu of the plan of what I shall have to say on feeding them in hammels. After the cow-byre doors have been opened, and the stalls cleared into the gutter of any dung that might annoy the dairy-maid, the cattle-man goes to the feeding-byre, and, first removing any fodder that may have been left from the previous night, and any refuse of turnips or other dirt, from the troughs, gives the cattle a feed of turnips at once. The quantity to be given at this time should be ⅓ of what they can eat during the day; for they should be fed 3 times a day—in the morning, at noon, and at sunset; and in distributing the food, the same regularity should be observed as in the case of the cows, that is, the same ox should always be the first supplied, and the same ox the last to receive his portion. When cattle find their food given them in regular order, they never become impatient for their turn. It is a good plan to begin serving at the farthest end of the byre, because then the cattle-man has no occasion to pass and disturb those which have been served; and in the case

of what is called a *double-headed* byre, in which cattle stand on both sides, tail to tail, both sides should be served simultaneously by alternate beasts, thus still leaving those which have been served undisturbed. With the half-door left open for the admission of fresh air, and the expulsion of heated air through the ventilators (fig. 8), the cattle-man leaves them to enjoy their meal in quietness.

(1220.) Much has been said on the expediency of wisping and currying cows and fattening-beasts in the byre; and no doubt many satisfactory reasons could be urged in favor of the practice, when they are entirely confined. But, as it occurs to me, animals that are allowed to be at liberty at one part of the day do not require—or at least to a much smaller degree—any artificial dressing, inasmuch as they can dress their own skin, when at liberty, much better than any cattle-man. Nevertheless, where cattle are constantly confined in the byre, as is the case of all beasts fattened in a byre, it seems indispensable for their good health to rub their skin every day by some process; and I believe there are no better instruments for the purpose than a simple curry-comb and a wisp of straw. In performing this operation, however, it should only be done when the cattle are not at food; and you should see to this, for there is a strong propensity in people who have charge of animals to dress and fondle with them when at food; from no desire, I am sure, of tormenting them, but the contrary. Still it is a habit which has a tendency to irritate all animals unnecessarily, and should be prevented; for any one may soon satisfy himself, from observation, that an animal is never more jealous of being approached than when eating his food—as witness the grumble from a dog or the scowl from a horse.

(1221.) Whenever the cattle have eaten their turnips the byre should be completely cleared of the dung and dirty litter with the graip, shovel, besom and barrow belonging to the byre. A fresh foddering and a fresh littering being given, they should be left to themselves to rest and chew the cud, until the next time of feeding, which should be about mid-day, when another $\frac{1}{3}$ of turnips is given to each ox; after finishing which more fodder should be supplied, and what dung may prove annoying, drawn into the gutter. In the afternoon, before daylight goes, the dung should again be cleared out, and the last supply of turnips for the day, another $\frac{1}{3}$, given to each ox; and before leaving them for the night, and after the turnips are eaten up, a fresh foddering should be given, and the litter shaken up and augmented where requisite. After eating a little fodder the cattle lie down and rest until visited at night.

(1222.) Where cattle are fattened in *hammels*, a somewhat different procedure is adopted. While the dairy-maid is milking the cows in the byre, the cattle-man cleans the troughs of the hammels with an old shovel, and gives the first supply of turnips for the day to the cattle; and in doing this he should adopt the same rule as to regularity as with the cows in the byre, always beginning with the same hammel

(1223.) It is now well understood that sliced turnips afford great facilities to cattle in filling their stomachs with food with the least trouble; and the instruments used for this purpose are much simpler than those which have been described for sheep in (1138) and (1145). Not an uncommon instrument for the purpose is an old sharp spade, with which turnips are broken in as many pieces as desired; but it is objectionable, in as far as it breaks them into unequal pieces, the round turnips rolling away from its strokes, and it scatters the hard ones in splinters. Much better instruments will be found in the two hand turnip-choppers described below, figs. 263 and 264. A single perpendicular stroke with either of these instruments

cuts a turnip into a certain number of pieces; but in using fig. 263 a little dexterity is required to save its cutting edges from being injured against the bottom of the trough. The dexterity consists in first getting a hold of the turnip with the instrument by a gentle tap, and then lift up the turnip, striking it against the bottom of the trough with a smart stroke, when it will fall into pieces before the knives touch the trough; but the constant exercise of dexterity is scarcely to be looked for in an ordinary cattle-man, and, therefore, fig. 264 may be pronounced the more useful instrument of the two, for the studs serve to guard the cutting surface from injury. But where a cattle-man has charge of a large number of cattle receiving cut turnips, a more expeditious process of slicing them is required, and this will be obtained by the use of the lever turnip-slicer, described below in fig. 259. This machine is placed beside the turnip-store, where it slices the turnips into the skull placed under it, and, being light, can easily be carried from store to store, unless where the distance is great, when another machine should be provided. It will be observed that all these implements cut turnips into large pieces, which are sufficiently small for cattle, sheep requiring theirs cut into long narrow slips, to suit the form of their mouth.

(1224.) Cattle naturally feeling more appetized in the morning than during the day, their morning meal should be large, and while employed at it the cattle-man should furnish their racks with fresh oat-straw, to which they will repair from the turnips, and lie down in the open court or within the shed, according to the state of the weather, and chew their cud with composure. At mid-day their troughs should again be replenished with turnips, and again before daylight is gone. The quantity given at the evening meal partly depends upon the state of the moon; for cattle, as well as sheep, will always feed during the night in moonlight, a habit which I have frequently observed in both animals; and from this fact I conclude that if light were placed beside cattle in the byre, they would also feed during the long winter nights, and, of course, fatten quicker.* The last foddering of straw is given after the evening meal of turnips; and, during the day, whenever the shed or court requires litter, the refuse straw of the foddering may be spread abroad, and in rainy weather it should be brought direct from the straw-barn.

(1225.) The younger cattle in the courts next receive their turnips, and of these the calves should have the precedence, as they take longer time to finish their meal than their older compeers. They occupying the court K, fig. 4, Plate IV., the turnips are wheeled from the store *g* to the troughs, and there broken with one of the hand turnip-choppers, fig. 263 or 264, or sliced in the store with the lever-slicer, fig. 259. Their fodder is put both in the open straw-rack *o* and that under the shed at *h'*, and their litter strewed after the young beasts in the other large court have been served with turnips.

(1226.) Immediately after the calves, the year-olds in the court I are served with turnips, fodder and litter, in the same order. All young beasts should get as many turnips as they can eat; but should the crop prove insufficient for this, let the calves have their full share, and the year-olds rather put on short allowance; but in a case of this kind occurring, the most prudent plan, perhaps, would be to purchase oil-cake for the fattening beasts, to be given along with some turnips, and let all the young

* That highly-prized bird in France, the ortolan, feeds at dawn, and when confined for the purpose of being fattened, an artificial dawn is produced every three hours during the night by artificial light, when it eats its food, and thereby becomes much sooner fat.

beasts have their full share of turnips. To insure them still farther with this, the cows might also have oil-cake.

(1227.) The young heifers in the hammels N, and the bulls in the hammels X, next receive their turnips, and as neither of them get as many as they can eat, their proportion is divided into two small meals, one served after all the rest in the morning, and the other before the rest in the evening. Both these classes depending much upon fodder for food, it should be of the sweetest and freshest straw, and supplied at least 3 times a day, morning, noon and evening; and having water at command, and liberty to move about, they will maintain a fair condition. The heifers are supplied from their own turnip-stores *p* or *q*, and the bulls from that belonging to the servants' cow-byre *k*.

(1228.) With regard to the supply of turnips to the servants' cows, much depends on the terms of the agreement made with the servants. Where a specified number of cart-loads are given, the servant may choose to give them to his cow during the earlier part of the winter or not, because, when she is dry, it is not usual to give her turnips; but if in milk, the servant's family may give what they choose from their own store. On the other hand, if the farmer has agreed to treat the servants' cows in the same manner as his own, then the cattle-man takes charge of them in the manner I have already described (1215).

(1229.) From the beginning of the season until the end of the year, white turnips alone are used, after which, to the end of the winter season, the yellows are brought into requisition, or Swedes where these are not cultivated. When turnips are brought from the field in a very dirty state, which will inevitably be the case in wet weather from clayey soil, they ought to be washed in tubs of water, and when they are so as long as the earth is fresh, they will be the more easily cleansed; and this is not so troublesome and expensive a business as may at first sight appear. A large tub of water, placed at a store when about to be filled with turnips, a field-worker, taking a small fork, picks up a turnip with it, and dashing it about in the water for an instant, pulls it off against the edge of the store or barrow; and in this way cleanses a great number in a short time, much faster than the cattle-man can wheel them away and serve and break them to the beasts. A friend of mine used a very curious mode to wash turnips. Whenever any of the fields of his farm, along which was the lead that conducted the water from the dam to the threshing-mill, were in turnips, he filled the lead pretty full of water, by keeping down the sluice at the mill. He then topped and tailed the turnips in the field, and emptied them into the lead, from a cart when the distance to the turnips was considerable, and from a hand-barrow, carried by field-workers, when they were near. The sluice at the mill was then opened a little, and the gentle current thereby created in the water floated the turnips to the steading, where they were taken out and carried to the stores in barrows. When the turnips were very dirty, they were washed in the lead by a person pushing them about with a pole. That some provision for cleaning turnips is sometimes necessary, is obvious to me, for I have seen very fine cattle getting turnips to eat in such a state that the dirt actually bedaubed them to the very eyes, the tops being left on to make the matter worse. Surely no one will say that filth, in any shape, is beneficial to cattle; not that they dislike to lick earth, but then they do so only when they feel they require it to rectify acidity in the stomach.

(1230.) When turnips have not been stored, and are brought from the field as required, it is highly probable that they will be in a frozen state at times, when, even if broken by the instruments in use, they will be

masticated by cattle with difficulty, besides the danger they run of being chilled by them; for cattle always have a staring coat after eating frozen turnips. This being the case, means should be taken to thaw them, and the most available is to put them in tubs of cold water for some hours before being given to the cattle. Such expedients, to avoid greater evils, of course always incur expense, and it will be much greater than the comparatively trifling one of storing the same quantity of turnips at the proper season, which, when done, every such petty source of vexation will be removed.

(1231.) It is supposed that a fattening ox, which will attain 70 stones imperial at the end of the season, consumes on an average, during the season, a double horse load of turnips per week, and, as carts are usually loaded in field work in winter, their weight may be estimated at about 12 cwt.; so each ox will consume about $1\frac{3}{4}$ cwt. or 14 stones a day, or $4\frac{2}{3}$ stones of each 3 meals, and about 16 tons during the season of 26 weeks. The calves may consume $\frac{1}{2}$ or 7 stones, and the 2-year-olds $\frac{3}{4}$, or $10\frac{1}{2}$ stones a day. These comparative statements are given from no authenticated data, for I suppose that no comparative trials with different ages of cattle have ever been made, but only from what I imagine to be near the truth; and some such estimate, at the beginning of the season, is useful to be made, that you may know whether your turnips will answer the stock. It has been correctly ascertained, however, by Mr. Stephenson, Whitelaw, East Lothian, in a careful experiment of 17 weeks, that an ox, yielding under 30 stones of beef, consumes 1 cwt., or 8 stones every day;* and if cattle consume food somewhat in proportion to their live weight, in similar circumstances, as is believed, the above ratios may be pretty correct. And yet Mr. Boswell of Kingcausie's four 2-year-olds, fed entirely on turnips, and which increased in live weight, in four months, from 40 to 45 cwt., only consumed a little more than 27 tons of yellow bullock turnips, or $8\frac{1}{2}$ stones each day.† So that Mr. Boswell's cattle, of from 45 to 50 stones each, consumed only a very few more turnips than Mr. Stephenson's, of 28 stones each. Such discrepancies show how little we can yet anticipate when we undertake to fatten cattle. But there is this that may be said in explanation of this difference, which is, however, merely conjectural, that Mr. Stephenson's lightest lot experimented on may have been West Highlanders, Mr. Boswell's Aberdeenshires, and my supposition is made in reference to well-bred Short-Horns. It will be observed that cows receiving $\frac{1}{3}$ of oxen, namely, $4\frac{2}{3}$ stones a day, each skullful will contain rather more than 32 lb.

(1232.) The most personally laborious part of the duty of a cattle-man in winter is *carrying straw in large bundles on his back to every part of the steading*. A convenient means of carrying it is with a soft rope about the thickness of a finger, and 3 yards in length, furnished at one end with an iron ring through which the other end slips easily along until it is tight enough to retain the bundle, when a simple loop-knot keeps good what it has got. Provided with 3 or 4 such ropes, he can bundle the straw at his leisure in the barn, and have them ready to lift when required. The iron ring permits the rope to free itself readily from the straw when the bundle is loosened.

(1233.) The *dress* of a cattle-man is worth attending to, in regard to its appropriateness for his business. Having so much straw to carry on his back, a bonnet or low-crowned hat is most convenient for him; but what is of more importance, when he has charge of a bull, is to have the color

* Prize Essays of the Highland and Agricultural Society, vol. xii. † Ibid., vol. xi.

of his clothes of a sombre hue, free of all gaudy or strongly-contrasted colors, especially *red*, because that color from some cause is peculiarly offensive to bulls. It is with red cloth that the bulls in Spain are irritated at their celebrated bull-baits. Instances are in remembrance of bulls turning upon their keepers, not perhaps because they were habited in red clothes, but probably because there was some red color about them, or that they contrasted strongly with what their keepers usually wore. It was stated at the time, that the keeper of the celebrated bull Sirius, belonging to the late Mr. Robertson of Ladykirk, had on a red night-cap when he was killed by him. One day, when walking with a lady across a field, for a short cut to a road, my own bull, the one represented in the plate of the Short-Horn bull, than which a more gentle and generous creature of his kind never existed, made toward us, and seemed unusually excited. This conduct did not arise from the circumstance of a stranger being in the field, for many strangers, both male and female, visited him in the field. I could ascribe his extraordinary excitement to no other cause than to the red shawl worn by the lady; for when she left the field he resumed his wonted quietness of conduct. I remember observing him more than usually excited, on another occasion, in his hammel, when his keeper, an aged man who had attended him for years, was beside him on a Sunday afternoon, I ascribed his excited state to the new red night-cap, instead of the usual black hat, which his keeper wore on the occasion; and on my desiring him to throw it away, the animal became again quite quiet. Be the *rationale* of the thing what it may, it is prudential in a *cattle*-man to be always habited in a sober suit of clothes.

(1234.) *Regularity in regard to time* is the chief secret in the successful treatment of cattle. Cattle, dumb creatures though they be, soon understand your plans in regard to what affects themselves, and there is none with which they reconcile themselves more quickly than regularity in the time of feeding; and none on the violation of which they will more readily show their discontent. No cattle-man can keep regular time without a watch; and if he has not one of his own, lend him one that will keep time well. His day's work in winter may be divided thus: Let him be astir and have his breakfast over by daybreak, which cannot be very early at that season. The first thing he should do is to go to the cow-byre, and remove with the graip, into the gutter, any dung that would immediately interfere with the dairy-maid in milking the cows. She should be at the byre in time for this purpose. Leaving her there, he goes to the fattening beasts in the hammels, and first cleans out the same trough, always beginning at the same end, of all refuse, with his shovel; and immediately as he cleans one trough he replenishes it with turnips from the store at hand, and breaks them with any of the instruments used. He thus proceeds from one hammel to another until the six are gone over, or as many as are occupied. It is not an easy matter to say exactly how long time this should take in doing, but say half an hour, 30 minutes. He then proceeds immediately to the calves in the large court, cleans out the dirt from the troughs, replenishes them with fresh turnips from the store, and breaks them; and he does this, having long troughs and fewer turnips, say in 15 minutes. He next goes to the 2-year-old court, and does the same in it; and, having a few more turnips to wheel out of the store and break, he will take a little more time, say 20 minutes. The bulls in the hammels may take 10 minutes to clean out their troughs and supply them with their small quantity of turnips. And the same time, 10 minutes, may suffice to give the heifers a little fresh fodder, for they should not get cold turnips on empty stomachs, more than cows; with another 10 minutes to supply-

ing the old cows, or extra beasts, with turnips. Having thus given all the cattle that are at liberty something to do for some time, he returns to the cow-byre with a bundle of fodder of fresh oat-straw, which he distributes among the cows, and which they pick during the time he is clearing the byre of litter and dung; and to do all this may require 30 minutes. Shutting the principal door of the byre, and leaving the half-door to the court open for air, he leaves the cows with the fodder, and cleans out the servants' cow-byre, and fodders the cows, which may take other 30 minutes. Taking then a bundle of litter, he goes again to the byre, and spreading any refuse fodder as litter, and cleaning out the troughs, he supplies the cows with their allowance of turnips, and shaking up the straw which he has just brought as litter, he leaves them again to eat and rest awhile. All this may require other 30 minutes; and 10 minutes may suffice to give the heifers their small quantity of turnips, and the old cows their fodder, and 10 minutes more to litter the servants' cows, the servants themselves having supplied the turnips as they choose. All the cattle having now been once fed, brings the time to 25 minutes past 10 A. M., if the operations began at 7 o'clock. The next step to be taken is to supply those which get as many turnips as they can eat, with fodder and litter, and for this purpose he takes the fodder fresh from the straw-barn, and fills all the straw-racks in the large courts, whether in the open air or under the shed. The old fodder should be pulled out before the fresh is put in; but this is seldom attended to. He then strews the open courts and sheds with litter where it is chiefly required; namely, along the side of the troughs where the beasts stand to eat the turnips, and where they have lain under the sheds. The hammels are then supplied with fodder and litter, the refuse fodder probably being sufficient for the latter purpose, as long as the weather is dry. The bulls and heifers should also have fodder and litter. All this business with the straw, and making it up into bundles for the afternoon, may take up 50 minutes, and bring the time to ¼ past 11 A. M. What with cleaning out the troughs and supplying the hammels and courts again with turnips of the midday meal, and letting out all the cows—including those of the servants—into their respective courts, 12 o'clock will have arrived, which is the hour of dinner for all the work-people. The people have an hour to themselves, to 1 P. M., to refresh and rest. At 1 P. M. the cattle-man resumes his labors by bunching up *windlings* of straw, which are small bundles having a twisted form, of 10 lbs. weight or more each, for each of the cows' supper, and also larger bundles in the ropes for fodder. Having prepared these just now or at any other leisure moment, he takes a bundle of fodder to the byre, supplies the troughs, and brings the cows in from the court, and ties them to their stakes. He does the same with the servants' cows. He then replenishes the straw-racks in the courts and hammels with what little fodder is required. He then litters the sheds comfortably for the night. He lays the windlings of straw in a corner of the servants' cow-byre for the night's suppering, and he does the same in the other byre; and the reason he does this in preference to letting them remain in the straw-barn is, to avoid the danger of taking a light into the straw-barn when the windlings are to be used. By the time all this business with the straw has been done, it is time to give the cows their second meal of turnips, so that they may have them eaten up before the milk-maid comes again at dusk to milk them. The feeding beasts in the hammels are then supplied with turnips broken for them, then the calves, then the young beasts in the other court, and then the bulls and heifers, in the same order as formerly. He then litters the servants' cows for the night, by which time it will be time for the other cows

to be milked; immediately after which they are littered for the night, and the doors closed upon them, and thus the labors of the day are finished.

(1235.) In thus minutely detailing the duties of the cattle-man, my object has been to show you rather how the turnips and fodder should be distributed relatively than absolutely; but at whatever hour and minute the cattle-man finds, from experience, he can devote to each division of his work, you should see that he performs *the same operation at the same hour and minute every day*. By paying strict attention to time, the cattle will be ready for and expect their wonted meals at the appointed times, and will not complain until they arrive. Complaints from his stock should be distressing to a farmer's ears; for, he may depend upon it, they will not complain until they feel hunger; and if allowed to hunger, they are not only losing condition, but rendering themselves, by discontent, less capable of acquiring it, even should their food happen to be regularly given them for the future. Whenever, therefore, you hear petitioning and impatient lowings from cattle at any steading, you may safely conclude that matters there, in so far as regards the cattle, at least, are conducted in a very irregular manner. The rule, then, simply is, *Feed and fodder cattle at fixed times, and dispense their food and fodder in a fixed routine*. I had a striking instance of the bad effects of irregular attention to cattle. An old staid laborer who was appointed to take charge of the cattle, was quite able and very willing to undertake the task. He was allowed to take his own way at first; for I had observed that many laboring men display great ingenuity in arranging their work. Lowings from the stock were heard in all quarters, both in and out of doors; and they intimated that my ancient cattle-man was not endowed with the organ of order, while I observed that the poor creature himself was constantly in a state of perspiration. To put an end to this disorderly state of things, I apportioned his whole day's work by his own watch; and on his implicitly following the plan, he was not only soon able to satisfy the wants of every creature committed to his charge, but had abundant leisure besides to lend a hand at anything else that required temporary assistance. His heart overflowed with gratitude when he found he could easily make all the objects of his charge happy; and his kindness to them all was so sincere, that they would have done whatever he liked. A man better suited for this occupation I never saw.

(1236.) Now, you may consider that all these minute details regarding the treatment of cattle are frivolous and unnecessary. But the matter is really not so; and it is of importance for your own interests to tell you so, for you will admit that where a number of minutiæ have to be attended to, unless taken in some order, they are apt either to be forgotten altogether, or attended to in a hasty manner; and none of these conditions, you will also admit, are conducive to correct management. Observe, then, the number of minute things the cattle-man has to attend to. He has various classes of cattle under his charge—cows, fattening beasts, young steers, calves, heifers, bulls, and perhaps extra beasts besides; and he has to keep all these clean in their various places of abode, and supply them all with food and fodder 3 times in a short winter's day of 7 or 8 hours. Is it possible to attend to all these particulars, as they should be, without a matured plan of operations? The cattle-man requires a plan for his own sake, for were he to do one thing just when the idea struck him, his mind, being guided by no fixed rule, would be as apt to forget as to remember anything he had to do. And besides, the injurious effects which irregularity of attendance tends to produce upon the condition of animals,

seem to render a plan of operations absolutely necessary to be adopted. Before you can see the full force of this observation, you require to be told that food given to cattle in an irregular manner—such as too much at one time and too little at another, frequently one day and seldom in another—and the same with fodder and litter, thus surfeiting them at one time, hungering them at another, and keeping them neither clean nor dirty, never fails to prevent them acquiring that fine condition which better management insures. And still farther to show you its force, you may not be sensible of any deficiency of condition under the most irregular management, from the want of the means of comparing your beasts with others; but an appeal to figures will show you the risk of loss you are unconsciously incurring. Suppose you have 3 sets of beasts, of different ages, which should get as many turnips as they can eat, and each set to contain 20 beasts; that is, 60 beasts in all. Suppose, moreover, that, by irregular management, each of these beasts acquires only ½ lb. less of live weight every day than they would under proper management, this would make a loss of 30 lbs. a day of live weight, which, over 180 days, the duration of the fattening season, will make 5,400 lbs. of live weight, or (according to the common rules of computation) 3,240 lbs., or 231 stones of beef, which, at 6s. the stone (not a high price), show a deterioration of £69 6s. in the value of the whole herd at the end of the season. The question, then, resolves itself into this, Whether it is more for your interest to lose this sum annually, or make your cattle-man attend to your beasts according to a regular plan, any form of which it is in your own power to adopt and pursue?

(1237.) What I have narrated above applies to the ordinary mode of feeding cattle, but extraordinary means are sometimes applied to attain a particular object. You may have, for instance, a pair of very fine oxen which you are desirous of exhibiting at a particular show, not altogether for the sake of gaining the premium offered, but partly for the honor of carrying off the prize from contemporaries. In this case they should have a hammel comfortably fitted up for themselves; that is, possessing all the means of satisfying their wants, both of food and shelter. Your ingenuity should be taxed to devise means that will anticipate every desire; and this you will be the better able to do after you have determined on the sort of food you wish to support them upon. If, regardless of expense, you will present a choice of food, there should be a trough for sliced Swedish turnips—a manger for bean-meal—another for bruised oats—a third for broken oil-cake*—a rack for hay—and a trough for wa-

[* The parts of this disquisition on rearing and feeding cattle on turnips which may seem not to possess practical information or value for the American husbandman, may yet be read with entertainment as affording a familiar view of the details of the most important branch of agricultural economy in a country famed for its advancement in the arts as well of tillage as of manufacture.

Few problems can be of more consequence to a great number of farmers, than the cheapest and best mode of fattening stock. There is a sufficient number of our farmers engaged in it render it a matter of national importance. It opens, as observed by an able writer and practical farmer, a wide field for calculation and inquiry as to the cost per pound, of putting on weight according to the food the animal is fed on.

There is, no doubt, a vast difference in the action of food, in producing increased weight, depending upon its quality and description, the mode in which it is administered, the temper and breed of the animal, and, above all, whether the creature is placed in a cold, damp, and exposed situation, (to which many of our farmers give little or no attention,) or in nice, comfortable, dry and warm quarters.

On this subject we particularly recommend the reader to be on the look-out for, and to read

ter; for water at will I conceive essential when so much dry food is administered. Then there should be abundance of straw for litter and warmth, and a regular dressing of the skin every day, to keep it both clean and healthy, as *fat* oxen can reach but very few parts of their bodies with their tongue. So much for winter treatment. In summer they should get cut clover in lieu of the turnips and hay, and all the other auxiliaries to the dry materials and straw, as already stated. But all these will not avail to attain your object, if constant attention be not given, and everything conducted with the utmost regularity in regard to time. True, they get as much as they can eat, but then what they eat should be administered with judgment. It will not suffice to set an adequate portion of each sort of food daily before them, to be taken at will; one or more kinds should be given at stated times, that each may possess the freshness of novelty and variety—not all at one time, but every one at such a time as one or both the animals may incline most to have. All these considerations demand attention, and afford exercise to the judgment. Oxen, when thus fattened, cannot travel any distance on foot; they must be conveyed on carriages built for the purpose, and even on these, if the distance is great, they will fall off in condition, as the confinement in, and motion of, the carriage proving irksome, prevent animals taking their food so heartily as they would do at home. I knew a 3-year-old-off bull that lost 30 stones live weight on being carried partly by steam-ship and partly by railway to a show.

(1238.) The *names* given to cattle at their various ages are these: A new-born animal of the ox tribe is called a *calf*, a male being a *bull-calf*, and a female a *quey-calf*, *heifer-calf*, or *cow-calf*, and a castrated male gets the name of *stot-calf*, or more commonly, simply a *calf*. The term calf is applied to all young cattle until they attain a year old, when they are called *year-olds* or *yearlings*, saying *year-old bull*, *year-old quey* or heifer, *year-old stot*; *stirk* is applied to both a young ox and quey, and *stot* in some places means a bull of any age. In another year they are named *2-year-old bull*, *2-year-old quey* or *heifer*, *2-year-old stot* or *steer*. In England females are called *stirks* from calves to 2-year-old, and the males *steers*. The next year they are called *3-year-old bull*; females, in England, from 2 to 3-year-old, *heifers*, in Scotland *3-year-old queys*, and when they are kept for breeding, and bear a calf at that age, they get the name of *cows*, the same as in England, and the males *3-year-old stots* or *steers*. Next year the *bulls* are *aged*, the *cows* retain that name ever after, and the *stots* or *steers* are *oxen*, which they continue to be to any age they are kept. A cow or quey that has been served by the bull is said to be *bulled*, and are then *in calf*, and from that circumstance are called in England *in calvers*.

---

attentively, a PRIZE ESSAY ON FAT AND MUSCLE, that we shall give in an early number, perhaps in our next, which will be the last of the Second Volume.

An important point of the question, says the writer referred to, and one to which Mr. Stephens does not seem to have adverted, is the comparative *worth of the manure* from the various materials used for feeding. It seems to be admitted, that there is a well grounded preference for that from richly fed animals, and we doubt not that in the farther progress of the application of science to the subject, we shall have an accurately graduated scale of the intrinsic value of manures, from every kind of food, vegetable and animal—from dry wheat straw to oil-cake, and from fish to fat mutton.

The extent to which oil-cake is used as food for beasts in England is entirely justified on the ground of the additional value it imparts to the manure. This is one of the resources for feeding our animals and our land that American Farmers seem as yet not to have studied or understood with the care we may suppose it deserves from the extent to which it is practiced in other countries. *Ed. Farm. Lib.*

A cow that has either *missed* being in calf, or has *slipped* calf, is said to be *eill;* and one that has gone dry of milk is called a *yeld-cow.* A cow giving milk is a *milch cow.* When 2 calves are born at one birth, they are *twins;* if three, *trins.* A twin bull and quey calf are called *free martins,* in which case the quey never produces young, but has no marks of a hybrid or mule. *Cattle, black cattle, horned-cattle,* and *neat-cattle,* are all generic names for the ox tribe, and the term *beast* is used as a synonym. An ox that has no horns is said to be *dodded* or *humbled.* An aged bull that is castrated is called a *segg;* and a quey that has had the ovaries obliterated, to prevent her breeding, is called a *spayed heifer* or *quey.*

(1239.) Cows are kept on every species of farm, though for very different purposes. On *carse* and *pastoral* farms they are merely useful in supplying milk to the farmer and his servants. On *dairy* farms, they afford butter and cheese for sale. On some *farms near large towns,* they chiefly supply milk for sale. And on *farms of mixed husbandry,* they are kept for the purpose of breeding young stock.

(1240.) On carse and pastoral farms, cows receive only a few turnips in winter, when they are dry, and are kept on from year to year; but where the farmer supplies milk to his work-people, as a part of wages, they are disposed of in the yeld state, and others in milk, or at the calving, bought in to supply their place, and these receive a large allowance of turnips, with perhaps a little hay. On these farms, little regard is paid to the breed of the cow, the fact of being a good milker being the only criterion of excellence.

(1241.) On true dairy farms, the winter season is not a favorable one for making butter and cheese for sale; for do what you like to neutralize the effect of the usual rooted green crops on these products, and especially butter, they remain unpalatable to the taste. The cows are therefore in calf during this season, and receive the treatment described above until the period of calving in spring.

(1242.) *In and near* large towns, the dairy-man must always have milk to supply his customers, and it is his interest to render the milk as palatable as possible. For the purpose of maintaining the supply, he buys cows at all seasons, just calved or about to calve. He disposes of the calves, without attempting to fatten them; and to render the milk he sells palatable, he cooks all the food partaken of by the cows. When the cows run dry, they are fattened for the butcher, and not allowed to breed again.

(1243.) The cows in the public dairies in Edinburgh are supported in winter on a variety of substances, namely, turnips, brewers' and distillers' grains called draff, dreg, malt comins, barley, oats, hay-seeds, chaff, cut hay. One or more of these substances, with turnips, are cooked together, and the usual process in doing this and administering the cooked food, is as follows:—Turnips, deprived of tops and tails, and washed clean, are put into the bottom of a boiler, and covered near its top with a quantity of malt comins, cut hay, hay-seeds, chaff, or barley, or more than one of these, as the articles can be procured. Water is then poured into the boiler sufficient to boil them, and a lid placed upon it. After being thoroughly boiled and simmered, the mess is put into tubs, when a little pounded rock-salt is strewed over it, and chopped into a mash with a spade. As much dreg is then poured upon the mash as to make it lukewarm, and of such a consistence as a cow may drink up. From 1 to 1½ stable-pailfulls of this mixture—from 40 to 60 pints imperial—according to the known appetite of the cow, is then poured into the trough belonging to each. The trough is afterward removed and cleaned, and the manger is ready for the reception of fodder—hay or straw. This mess is given 3 times a day, *after* the cows have been milked, for dairy-men understand that animals should not be disturbed while eating their food. The times of milking are 6 A. M., 12 noon, and 7 P. M. The sweet milk and cream obtained by these means, and received direct from the dairy, are pretty good. The former sells in Edinburgh at 1d., and the latter at 1s. the imperial pint. Dr. Cleland states the price of sweet milk in Glasgow at 1½d. the imperial pint.

(1244.) It will be observed that none of the articles usually given to cows are so expensive as oil-cake, cabbages, kohl-rabi, or cole-seed. These products were employed by the late Mr. Curwen in his experiments to ascertain the cost of raising milk for supplying the poor, and the results show they left him very little profit.*

(1245.) There is little milk in winter on a farm which supports cows for breeding stock, being only derived from one or two cows that are latest of calving in spring. All the spare milk may probably be eagerly bought by cotters who have no cows; but should that not be the case, a little butter may be made once in ten days or a fortnight, which if not palatable for the table may be used in making paste, and other culinary purposes. A little saltpetre, dissolved in water, certainly modifies the rank taste of turnips in both butter and milk.

(1246.) Cattle are fed on other substances than turnips, either with themselves or in conjunction with turnips. Oil-cake and potatoes are the most common substances used for this purpose. Linseed-oil and linseed have been recommended, and many are fed at distilleries on *draff* and *dreg*, as the refuse of distillation are termed; and these are sold to the farmers for the purpose of feeding. Oats, barley-meal, and bean-meal, have also been pressed into the service of feeding cattle.

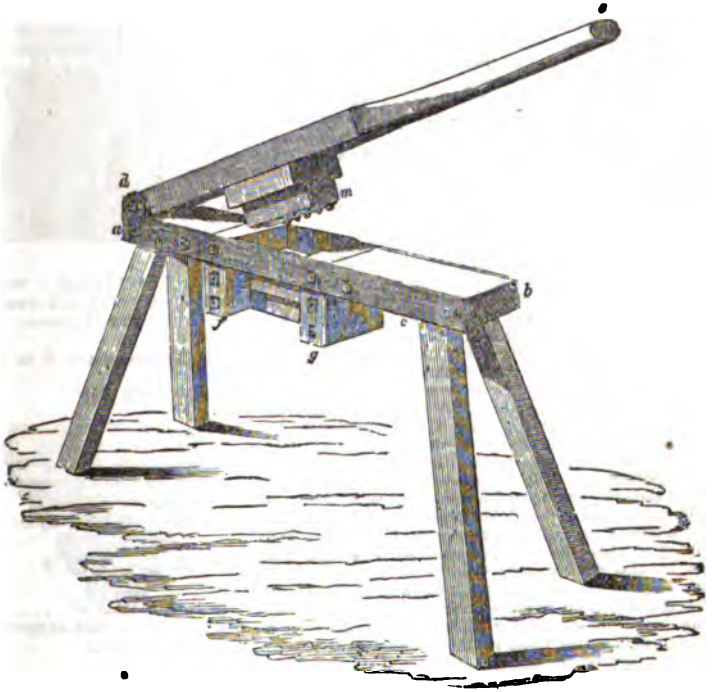
(1247.) The *potatoes used in feeding cattle* are either the common kinds known in human food, or others raised on purpose, such as the yam and ox-noble; and they are given either alternately with turnips, or together. In feeding cattle with potatoes of any kind, and in any way,

* Curwen's Agricultural Hints (990)

there is considerable risk of flatulency and choking. To prevent the latter, the potatoes should be smashed with a hammer, or with an instrument like a pavior's rammer, and though juice should come out in the operation, no loss is incurred, as it is considered of no service in feeding. To prevent flatulence from potatoes is no easy matter; but a friend of mine used a plan which completely answered the purpose, which was mixing cut straw with the broken potatoes. The straw obliging the cattle to chew every mouthfull before being swallowed, may prevent such a large quantity of gas being generated in the paunch as bruised potatoes alone would do, and it is this gas which occasions that distressing complaint called *hoven*. A farm-steward, who had considerable experience in feeding cattle on potatoes on a led-farm, always placed as many potatoes, whole, before cattle as they could consume, and they never swelled on eating them, because, as he conjectured, and perhaps rightly, they do not eat them so greedily when in their power to take them at will, as when doled out in small quantities. This fact confirms the propriety of mixing cut straw among potatoes that are given in small quantities, in order to satisfying the appetite, and filling the paunch with unfermentable matter. The only precaution required in giving a full supply of potatoes is to give only a few and frequently at first, and gradually to increase the quantity.

(1248.) *Oil-cake* has been long and much employed in England for the feeding of cattle, and it is making its way in that respect into Scotland It consists of the compressed husks of linseed after the oil has been expressed from it, and is formed into thin oblong cakes. The cakes are broken into pieces by a machine described in fig. 264. Cattle are never entirely fed on oil-cake, but in conjunction with other substances, as turnips, potatoes, cut hay, or cut straw. When given with cut hay or straw, an ox will eat from 7 to 9 lbs. of cake a-day, and the hay or straw induces rumination, which the cake itself is not likely to do. When given with other substances, as turnips or potatoes, 3 lbs. or 4 lbs. a-day will suffice. A *mixture* of oil-cake and cut meadow-hay

Fig. 259.



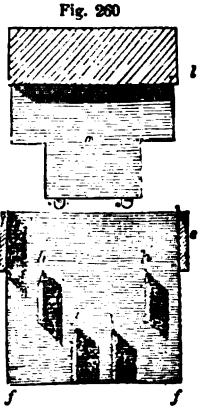
THE LEVER TURNIP-SLICER FOR CATTLE.

forms a very palatable and nutritious food for oxen, and is a favorite one in England. Oil-cake costs from £7 to £10 a ton.

(1249.) [*Turnip-slicers for Cattle.* In the description formerly given of machines for cutting turnips for sheep, that described in (1145) may be again adverted to, fig. 250, the wheel turnip-cutter. This machine is equally well adapted to slice for cattle as for sheep, and is frequently fitted up to slice for cattle only. More frequently it is finished as described with the cross-cutters, fig. 252, and when wanted to slice for cattle, the *cross-cutters* are removed. This is easily accomplished, by first lifting the slicing-knives from the disk of fig. 250, then unscrewing all the nuts of the cross-cutters, and removing them from their places. The slicing-knives are then again placed as before, and the machine is prepared to cut the turnips into plain slices. This machine costs from £4. 4s. to £5.

(1250.) *Lever Turnip-slicer.* One of the cheapest and most efficient turnip-slicers is represented in fig. 259. It was brought before the Highland and Agricultural Society of Scotland by Mr Wallace of Kirkconnell, as an improvement on a preëxisting machine of the same kind.* It has since undergone some farther improvements in the hands of James Slight and Company, Edinburgh; and for the purpose of regular and perfect slicing of turnips, it may be held as as the best and cheapest now employed. The machine as produced by Mr. Wallace, is represented in fig. 259; where *a b* is the stock or sole of the machine, about 34 inches long, 6 inches broad, and 2 inches in thickness. The sole is in 2 pieces connected by an iron bar or strap *a c*, which is repeated on the opposite side, and the whole bolted together, as in the figure. The 2 pieces forming the sole are separated longitudinally from each other, so as, with the two side-straps of iron, to form a rectangular opening of 9 inches by 6 inches, bounded on the two ends by the parts of the sole, and on the two sides by the side straps, which, to the extent of the opening, are thinned off to a sharp edge, and thus form the two exterior cutters *d*, *e*, as seen in fig. 260, which is a transverse section through the cradle of the machine. The sole is supported at a hight of 2 feet upon 4 legs, fig. 259, and the lever *d e* is jointed at *d* by means of a bolt passing through it and the ears of the side-straps, as seen at *d*. The lever is 4 feet in length, its breadth and thickness equal to that of the sole, but is reduced at the end *e* to a convenient size for the hand. Two cutter blocks *f* and *g* are appended to the sole by mortice and tenon, and farther secured by the bolts which pass through the side-strap at that place. Into these blocks the remaining cutters *h h* and *i i*, fig. 260, are inserted in corresponding pairs, and also secured by bolts; the cutters thus arranged form a cradle-shaped receptacle, into which the turnip is laid to be sliced. The lever *d e* is armed with a block of wood *m*, loosely fitted to the cradle; and its lower face is studded with iron knobs, the better to prevent the turnip sliding from under it. The transverse section *d e f f*, fig. 260, shows the position of six cutters *d e*, *h h*, and *i i*, as inserted in the wooden block *d e f f*; and *k l* is the lever, seen in section, with the block *m* attached.

Fig. 260

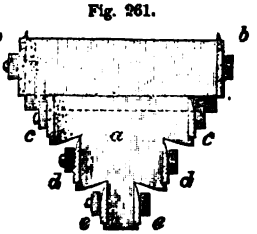


TRANSVERSE SECTION SHOWING THE POSITION OF THE CUTTERS.

(1251.) The late improvement by Messrs. Slight and Company consists in the application of cast-iron knife-blocks, which give greater strength to the machine, and a more ready and secure fixture of the interior knives, and of introducing 8 cutters instead of 6, which makes a more convenient size of slice. Fig. 261 is a section of the cradle, as it appears with the cast-iron knife-block; *a* is the body of the block which is attached to the sole through the medium of a flange behind, and fixed by bolts. The external cutters *b b* are a part of the side straps, as before; and the interior cutters are fixed in pairs, *c c*, *d d*, and *e e*, by their respective bolts passing through the cutters and the block.

(1252.) In using this machine the workman takes hold of the lever at *e*, fig. 259, with the right hand, and having raised it sufficiently high, he, with the left hand, throws a turnip into the cradle. The lever is now brought down by the right hand, which, with a moderate impetus, and by means of the block *m*, sends the turnip down upon the cutters, through the openings of which it passes while the cutters are dividing it, and the whole falls away in perfectly uniform slices. In most cases, it is found more convenient to have a boy to throw in the turnips, and this will somewhat expedite the work. One advantage of this turnip-slicer—and it is an important one—is that, with unerring certainty, it cuts every slice of uniform thickness; the slab-slices, indeed, may of course vary, but all are free of the smallest portion of waste. Its cheapness also is of importance, especially when it is considered that, in a given time, it will slice weight for weight of turnips with the most elaborate machine in use, the power applied being also equal. The price is 28s. to 30s. It is also extremely portable, and can be carried about by one person. An objection has been urged to this slicer, namely, that the turnips must all be put into it one by one; and it is perhaps unnecessary to remark that this objection applies to all turnip-slicers. For though the hopper of some may be capable of containing a number of turnips at one time, yet that number may be considered as having been deposited there individually. The price of the lever turnip-slicer for sheep, as in fig. 245, is £3 10s.

Fig. 261.



THE SECTION OF THE IMPROVED CRADLE.

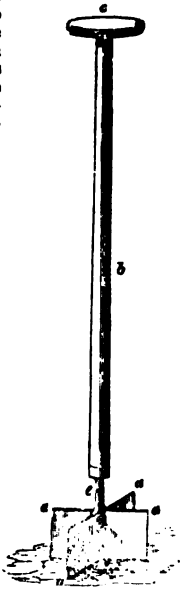
(1253.) *Cross Turnip-cutter.* There is another very simple and useful turnip-cutter, which is frequently used when thin slicing is thought of less importance, but is more especially useful where the cooking system is adopted for either cows or horses, thin slicing being in such cases not called for. This instrument is represented in fig. 262. The cutting part of it consists of 2 steel-edged blades, 8 inches in length and 4 inches in depth. They are slit half-and-half at their middle point, so as to penetrate each other, standing at right angles, forming the *cross-cutter*, *a a a a*. They are then embraced in a four-split palm, and riveted. The palm terminates in a short shank *e*, which is again inserted into the hooped end of a wooden handle *b*, 3 feet in length, which is finished with a crosshead *c*. The price of this instrument is 8s. 6d. The mode of using it is obvious. It is held by the hand in a vertical position; and when placed upon a turnip, one

* Prize Essays of the Highland and Agricultural Society.

thrust downward cuts it into quarters. This instrument is also varied in its construction, being sometimes made with 3 and even with 4 blades, dividing the turnip into 6 or into 8 portions.

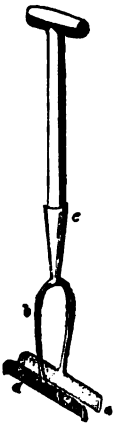
(1254.) Another individual form of the same species is represented by fig. 263. It has two blades *a a*; but they, instead of crossing, stand parallel to each other, and therefore divide the turnips into three portions, resembling slices, of considerable thickness, the middle one being 1¼ inches thick. In the construction of this cutter, a blunted stud is formed at the extremities of each blade, and there projects below the cutting edge about ¼ inch, serving as guards to save the cutting edges from receiving injury when they have passed through the turnip, or otherwise striking any hard surface. These guards, it may be remarked, would form a useful addition to all this class of cutters. The arms *b* of the blades rise to a hight of 9 inches, widening upward to 3¼ inches, to give freedom to the middle slice to fall out. The two arms coalesce above, and are then formed into the socket *c*, to receive the handle, which—as in the cross-cutter, fig. 262—terminates in a crosshead.

Fig. 262.



THE HAND TURNIP-CHOPPER, WITH CROSS BLADES.

Fig. 263.



THE HAND TURNIP CHOPPER, WITH PARALLEL BLADES.

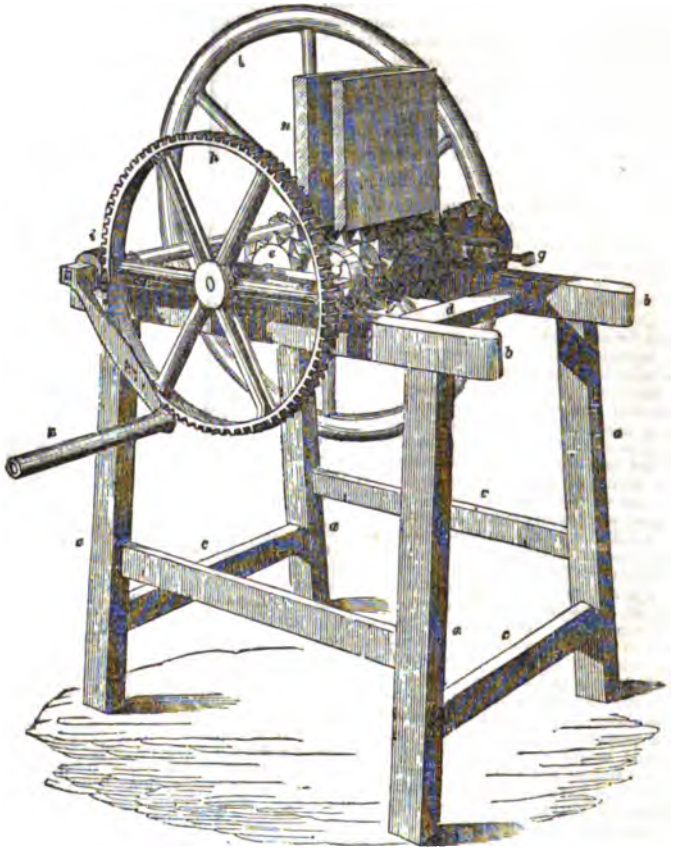
(1255.) *Oil-cake Breaker.*—Machines for preparing oil-cake for more easy mastication by cattle or sheep are made in a variety of forms. One of those forms is similar in principle to that of the early bone-crushing machines; namely, a revolving axle, armed with several series of teeth, which are so arranged as to pass in succession through the interstices of a line of strong teeth or prongs, against which the cakes lies, and is reduced to fragments by the successive action of the revolving teeth. Of this form there are various modifications, all serving the same purpose with nearly equal success.

(1256.) A different form of the machine, and which is held superior in the principle of its construction, is here exhibited in fig. 264, which is a view of the machine in perspective, wherein *a*, *a*, *a*, *a*, are the four posts of a wooden frame, on which the machinery is supported. The frame is 39 inches in length and 20 inches in width over the posts at top, the hight being 33 inches. *b b* are two top-rails, 34 inches in length, and the scantling of their timbers should not be less than 2½ inches square. The posts are supported toward the bottom by the four stay-rails *c*, *c*, *c*; and the top-rails are held in position by cross-rails *d*, one only of which is seen in the figure. Of the machinery, the acting parts consist of 2 rollers, studded all over with pyramidal knobs or teeth. These are arranged in zones upon each roller, and having a smooth space or zone between each of the knobbed zones; the knobs of the one roller corresponding to the smooth space in the other. The rollers *e* and *f* are constructed with an axle or shaft, that of the first *e* being 25 inches long, and of the second *f* 23 inches, and each 1½ inches square. Journals are formed upon these shafts, to run in the bearings which are placed on the top-rails *b b*, as afterward described. In this figure, *g g* are two pinching screws, which serve to regulate the distance at which the rollers are to work and, consequently, the degree of coarseness to which the cake is to be broken. The wheel *h*, of 20 inches diameter, is placed upon the shaft of the roller *e*, and the pinion *i*, of 3 inches diameter, with its shaft, and the winch-handle *k*, act upon the wheel *h*, giving a very considerable mechanical advantage to the power which is applied to the machine. The fly-wheel *l* is likewise placed upon the shaft of the pinion *i*, and is requisite in this machine to enable the power to overcome the unequal resistance of the work. On the farther end of the shaft of each of the rollers, there is mounted a wheel of 4½ inches diameter, for the purpose of carrying both rollers at the same speed. These wheels, one of which is seen at *m*, are formed with long teeth, to admit of the roller *f* approaching to or receding from the other, which is stationary *in place*. A feeding hopper *n* is placed over the line of division of the two rollers; it is 16½ inches long, 3 inches wide, and 14 inches deep. In forming the hopper, two upright pieces, 3 inches by 2 inches, are bolted to the inside of the top-rail, their position being between the shafts of the 2 rollers, and these form the ends of the hopper. They are then boarded on each side, which completes the machine. The hopper is here represented in section, the near portion of it being supposed entirely removed, in order to exhibit more distinctly the construction of the rollers.

(1257.) Fig 265 is a farther illustration of the construction of the rollers being a transverse section of the two, *a a* are the shafts, the shaded part *b* one of the plain disks which go to form the smooth zones on the body of the roller; it is 4 inches diameter and 1 inch thick; *c* is one of the knobbed disks, its body being of the same diameter and thickness as the former; but having the 4-sided pyramidal knobs set around it, the diameter, measuring to the apex of the knobs, is extended to 6 inches. One roller for the machine here described requires 5 plain and 6 knobbed disks, beginning and ending with a knobbed disk. In the other the arrangement is reversed, bringing out the alternation of the plain and knobbed zones before alluded to as more distinctly represented in fig. 266, which is a plan of part of the rollers, *c c* being two of the knobbed disks, and *b b b* three of the plain.

(1258.) Fig. 267 represents one of the bearings or plummer-blocks for the journals of the rollers, *a* is the bed of the plummer-block, *b* and *c* the brass bushes, and *d* the cover. The bush *b*, which corresponds to the roller *e*, fig. 264, is always stationary, while *c*, which is acted upon by the

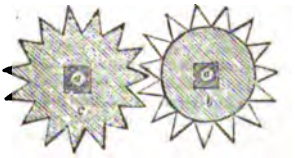
Fig. 264.



THE OIL-CAKE BREAKER.

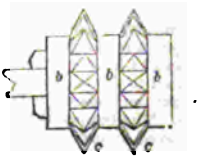
screw, is advanced toward, or withdrawn from, *b*, as the size to which the cake is to be broken may require. These plummer-blocks are bolted down to the top-rails of the frame, to which also the separate bearings of the pinion-shaft are likewise bolted.

Fig. 265.



THE TRANSVERSE SECTION OF THE ROLLERS.

Fig. 266.

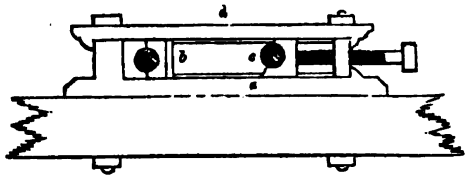


THE PLAN OF PART OF A ROLLER.

(1259.) It may be proper to remark here that the machine now described is of a good medium size, and with a man to drive and a boy to feed in the cakes, it will break about half a ton in an hour. The price is from £4 to £4 10s. The amount of its performance can be augmented or diminished to only a small extent, for as its feed is necessarily confined to one cake at a time, the only change that can be made on its production must depend upon the celerity of its motions. Hence it is one of those machines that cannot easily be adapted to *large* and to *small* establish-

ments with any view, in this latter case, to amelioration of form; for the almost only means of doing so must be by giving it a quicker or slower motion, which can only affect the expense of construction to a very small amount, so small as hardly to be appreciable. In addition to what is

Fig. 267.



PART OF THE TOP-RAIL, WITH PLUMMER BLOCK.

shown of this machine in fig. 264, the rollers are frequently covered with a movable wooden case, which gives a more tidy appearance to it, and, moreover, it is always desirable that the frame below should contain a *shoot* formed of light boarding, that will receive the broken cake from the rollers, and deliver it at one side of the machine into a basket or other utensil in which it can be removed to the feeding stations.—J. S.]

(1260.) Mr. Brodie, Abbey Mains, East Lothian, made an experiment on feeding cattle, from October, 1836, to June, 1837, on different kinds of food. There were 4 lots of cattle, consisting of 5 each. The first lot was fed on turnips and straw, which, being the usual treatment, formed the standard of comparison. The second lot had half the weight of turnips and 30 lbs. of oil-cake a day. A third lot was fed on the last quantity of turnips and bean-meal and bruised oats. And the fourth had distillery grains and ground beans. The value of the cattle, when put up to feed, was £11 a piece, and they were of the Aberdeenshire polled breed. This is a summary of the cost of feeding:

Lot 1. White turnips at 8s. 4d., Swedes at 12s. 6d. per ton, cost	£53	9	10
Average cost of each beast per week	0	6	3
Lot 2. Turnips as above, oil-cake, £7 15s. per ton, cost	£48	16	0
Average cost of each beast per week	0	5	9
Lot 3. Turnips as above, bean-meal 5s., bruised oats 3s. 6d per bushel, cost	£58	8	1
Average cost of each beast per week	0	6	8
Lot 4. Turnips and bean-meal, as above, draff 4s. 6d. per quarter, dreg 2s. 6d. per puncheon, cost	£63	3	2
Average cost of each beast per week	0	7	9

The ultimate results are as follows:

Lots.	Live weight.	Beef.		Tallow.		Hide.	
	sts.	sts.	lbs.	sts.	lbs.	sts.	lbs
1.	536	283	3	36	10	27	13
2.	552	295	10	41	6	29	6
3.	517	280	7	37	2	26	13
4.	545	280	0	36	11	25	7

"Upon the whole," concludes Mr. Brodie, "it is evident, by these experiments, that feeding with turnips as an auxiliary has been the most advantageous mode of using turnips, as, by the above statement, it is apparent that if the cattle of the first lot had only been allowed half the quantity of turnips which they consumed, and had got oil-cake in lieu of the other half, as was given to the second lot, the expense of their keep would have been lessened £4 13s., and from superior quality of beef, their value would have been increased £10, making together £14 13s."* Three remarks occur to me to make on the progress of this experiment; the first is, that if the cattle had been sold on the 7th April, 1837, when they were adjudged by competent farmers, they would not have repaid the feeder his expenses, as the prime cost of lot first, with the cost of feeding to that time, amounted to £95 1s. 8d., and they were only valued at £82; lot second cost £90 12s., and they were valued at £88 10s.; lot third cost £93 4s., and were valued at £77; and lot fourth cost £97 4s. 5d., and their value was only £81 10s. And this is almost always the result of feeding cattle, because *ripeness* only exhibits itself toward the *end of the feeding season*, and it is only after that state of condition is indicated that the quality of the meat improves so rapidly as to enhance its value so as to leave a profit. As with sheep so with cattle; with good beasts the inside is first filled up before the outside indicates fineness. Another remark is, that this result should be a useful hint to you to weigh well every consideration before disposing of your fattening beasts in the middle of the feeding season. The last remark I have to make is, that the cattle of lot first, continuing to receive the same sorts of food they had always been accustomed to, throve more rapidly at first than the beasts in the other lots, but afterward lost their advantage; thereby corroborating the usual experience of stock not gaining condition immediately on a change of food, even of a better kind, such as from turnips to grass.

(1261.) Mr. Mowbray of Cambus, in Clackmannanshire, made experiments in the winter of 1839–40 on feeding cattle with other than the ordinary produce of the farm, but as the cattle were

* Quarterly Journal of Agriculture, vol. viii.

not all sold at the same time I need not relate the details; and I mention the experiments for the sake of some of the conclusions that may be deduced from them. It would appear that cattle may be fed on turnips and hay as cheaply as on turnips and straw, for this reason, that when straw is given as fodder, more turnips are consumed, and, therefore, when turnips are scarce, hay may be used with advantage. It also appears that cattle may be fed cheaper on distillery refuse of draff and dreg than on turnips and straw, but then the food obtained from the distillery requires more time to bring cattle to the same condition, which in some circumstances may be an inconvenience.*

(1262.) *Linseed-oil* has been successfully employed to feed cattle by Mr. Curtis of West Rudham, in Norfolk. The mode of using the oil is this: First ascertain how much cut straw the oxen, intended to be fed, will consume a week, then sprinkle the oil, layer upon layer, on the cut straw, at the rate of 1 gallon per week per ox. The mixture, on being turned over frequently, is kept 2 days before being used, when a slight fermentation takes place, and then the oil will scarcely be discerned, having been entirely absorbed by the straw, which should of course be the best oat straw. This mixture, when compared with oil-cake, has stood its ground. The cost of the oil is not great, its average price being about 34s. the cwt. of 12¼ gallons, a gallon of fine oil weighing 9.3 lb., which makes the feeding of an ox cost only 2s. 10d. per week.†

(1263.) Mr. Curtis has fed cattle for upward of 20 years upon what he calls *green malt*, which consists of steeping light barley "for 48 hours in soft water, when the water is let off and the barley is thrown into a round heap, in a conical form, till it gets warm and begins to sprout freely. It is then spread out and turned over repeatedly as it grows. The only care required is, that the sprout or future blade does not get cut off, as the malt will then lose much of its nutritious quality." He finds this substance, which costs with its labor 1s. a stone, preferable to oats at 10d. in their natural state.‡

(1264.) A method of feeding cattle has been adopted by Mr. Warnes, Jr., Trimingham, Norfolk, which, in a manner, combines both the substances used by Mr. Curtis, and deserves attention. The substances consist of linseed-meal and crushed barley. The barley may either be used malted, that is, in a state of "green malt," as designated by Mr. Curtis, or crushed flat by bruising cylinders. Crushed oats, boiled peas and bean flour may all be substituted for the barley, and used with the linseed meal. The mode of making this compound is thus recommended by Mr. Warnes: "Put 168 lbs. of water into an iron cauldron or copper or boiler, and as soon as it boils, not before, stir in 21 lbs. of linseed meal; continue stirring it for 5 minutes; then let 63 lbs. of the crushed barley be sprinkled by the hand or one person upon the boiling mucilage, while another rapidly stirs and crams it in. After the whole has been carefully incorporated, which will not occupy more than 5 minutes, cover it closely down and throw the furnace door open. Should there be much fire, put it out. The mass will continue to simmer, from the heat of the cauldron, till the barley has entirely absorbed the mucilage. The work is then complete, and the food may be used on the following day. When removed into tubs, it must be rammed down to exclude the air, and to prevent its turning rancid. It will be seen that these proportions consist of 3 parts of barley to one of linseed, and of 2 parts of water to 1 of barley and linseed included. Also, that the weight of the whole is 13 stones when put into the cauldron; but after it has been made into compound and become cold, it will be found in general reduced to something less than 15 stones, which will afford 1 bullock for a fortnight 1 stone per day, containing 1¼ lbs. of linseed. It will keep a long time if properly prepared. The consistency ought to be like that of clay when formed for bricks." In regard to the nutritive properties of this compound Mr. Warnes testifies thus: "The last of my experimental bullocks for 1841 was disposed of at Christmas at 8s. 6d. per stone. He weighed 60 stones 5 lbs.. of 14 lbs. to the stone, and cost £7 17s. 6d. thirteen months previously; so that he paid £17 10s. for little more than one year's keeping. His common food was turnips or grass; 14 lbs. a day of barley or peas compound were given him for 48 weeks, and an unlimited quantity the last 5 weeks; when, considering the shortness of that time, his progress was perfectly astonishing, not only to myself, a constant observer, but to many graziers and butchers who had occasional opportunities of examining him. Altogether the weight of compound did not exceed 2 tons 4 cwts., at a cost of only £3 16s per ton."‖

(1265.) This successful result obtained by Mr. Warnes shows that cattle may be *profitably* fed on prepared food, though the results of several experiments which have been made by farmers in Scotland lead to an opposite conclusion; yet Mr. Warnes's statement contains no comparison, for it is quite possible that the nutritious materials employed by him, namely, linseed-meal and bruised barley, would have fed a bullock equally well in their naturally cold state as when cold, after being cooked warm. As to the expediency of cooking food for cattle, Mr. Warnes goes so far in opinion as to say that "neither oil nor linseed should be used in a *crude* state, but formed into mucilage by being boiled in water;" but this opinion was evidently given when the results obtained by Mr. Curtis on feeding cattle with linseed-oil in a crude state, were unknown to him; for although he admits "that linseed-oil will fatten bullocks, experience has placed beyond a doubt. Among the fattest beasts ever sent to the London market from Norfolk was a lot of Scotch heifers, grazed (?) on linseed-oil and hay." Yet he adds: "But the quantity given per day, the cost per head, or anything relative to profit or loss, I never heard." I should therefore like to see a comparison instituted between the nutritive properties of linseed-meal and bruised barley, or peas or bean-meal, in their ordinary state, and after they had been boiled and administered either in a hot or cold state, and also between the *profits* arising from both. Until this information is obtained, we may rest content with the results obtained by some very accurate experiments, conducted by eminent farmers, on the same food administered in a warm and in a cold state, and which go to prove that food is *unprofitably* administered to cattle in a *cooked* state. I shall now lay some statements corroborative of this conclusion before you.

‖ Warnes's Suggestions on Fattening Cattle.

(1266.) The first I shall notice, though not in detail, are the experiments of Mr. Walker, Fortygate, East Lothian. He selected, in February, 1833, 6 heifers of a cross between country cows and a Short-Horn bull, that had been on turnips, and were advancing in condition, and divided them into 2 lots of 3 heifers each, and put one lot on raw food and the other on steamed, and fed them three times a day—at daybreak, noon and an hour before sunset. The food consisted of as many Swedes as they could eat, with 3 lbs. of bruised beans and 20 lbs. of potatoes, ¼ stone of straw and 2 ounces of salt to each beast. The three ingredients were mixed together in a tub placed over a boiler of water, and cooked by steaming, and the bruised beans were given to the lot on raw food at noon, and one-half of the potatoes in the morning and another half in the afternoon. It was soon discovered that the lot on the cooked food consumed more turnips than the other, the consumption being exactly 37 cwt. 16 lbs., while, when eaten raw, it was only 25 cwts. 1 qr. 14 lbs., the difference being 55 lbs. every day, which continued during the progress of the experiment for 3 months.

(1267.) Steers were experimented on as well as heifers, there being 2 lots of 2 each. They also got as many Swedish turnips as they could eat, but had 30 lbs. of potatoes and 4½ lbs. bruised beans, 2 ounces of salt, and ¼ stone of straw each, every day.

(1268.) The cost of feeding the heifers was as follows:

	Cwts.	qrs.	lbs.			
3 heifers on *steamed* food:						
Consumed of Swedish turnips,	37	0	16, at 4d. per cwt.	£0	12	4½
.. .. Potatoes	3	3	0, at 1s. 3d. ..	0	4	8
.. .. Beans, 1 bushel	0	2	7	0	3	0
.. .. Salt				0	0	0½
Coals and extra labor				0	2	0
Cost of 3 heifers 1 week, or 7s. 4½d. per week each				£1	2	1½
3 heifers on *raw* food:						
Consumed of Swedish turnips,	25	1	14, at 4d. per cwt.	£0	8	6½
.. .. Potatoes, beans and salt, as above				0	7	8½
Cost of 3 heifers 1 week, or 5s. 5d. each per week				£0	16	3
2 stots on *steamed* food:						
Consumed of Swedish turnips,	28	2	0, at 4d. per cwt.	£0	7	10
.. .. Potatoes	3	3	0, at 1s. 3d. ..	0	4	8
.. .. Beans	0	2	7	0	3	0
.. .. Salt				0	0	0½
Coals and extra labor				0	1	6
Cost of 2 stots for 1 week, or 8s. 6½d. each per week				£0	16	0½
2 stots on *raw* food:						
Consumed of Swedish turnips,	17	2	0, at 4d. per cwt.	£0	5	10
.. .. Potatoes, beans and salt, as above				0	7	8½
Cost of 2 stots for 1 week, or 6s. 9½d. each per week				£0	13	6½

(1269.) The following table shows the progress of condition made by the heifers and stots:

Cattle.	Average live weight of 3 at commencement of feeding.	Average live weight of 3 at end of feeding.	Average increase of live weight in 3 months.	Average dead weight of beef.	Average weight of tallow.	Average weight of hide.	Average weight of offal.
	Sts.	Sts. lbs.	Sts. lbs.	Sts. lbs.	Sts. lbs.	Sts. lbs.	Sts. lbs.
Heifers on steamed food,	74	90 0	16 0	50 0	7 11	3 12	26 9
Heifers on raw food,	74	89 3	15 0	50 1	8 4	4 4	26 10
Stots on steamed food,	84	103 4	19 0	56 19	8 11	5 12	28 3
Stots on raw food.	90	106 5	15 0	58 6	8 8	5 4	30 4

(1270.) The comparative profits on cooked and raw food stand thus:

Live weight of heifers, when put to feed on *steamed* food, 74 sts.=42 sts. 4 lbs. beef, at 5s. 6d. per stone, sinking offal	£11	12	7
Cost of keep 12 weeks 5 days, at 7s. 4½d. per week	4	19	0
Total cost	£16	11	7
Live weight of the same heifers, when finished feeding on steamed food, 90 sts.=50 sts. 2 lbs., at 6s. 6d. per stone, sinking offal	16	9	1½
Loss on steamed food on each heifer	£0	2	6½
Live weight of 1 heifer, when put to feed on *raw* food, 74 sts.=42 sts. 4 lbs. beef, at 5s. 6d. per stone, sinking offal	£11	12	7
Cost of keep 12 weeks 5 days, at 5s. 5d. per week	3	8	10½
Total cost	£15	1	5½
Live weight of the same heifer when finished feeding on raw food, 89 sts. 3 lbs.=50 sts. 1 lbs., at 6s. 6d. per stone, sinking offal	16	5	5½
Profit on raw food on each heifer	£1	4	0

Live weight of 1 stot when put up to feed on *steamed* food, 84 sts.=50 sts. 4 lbs., at 5s. 6d. per stone, sinking offal	£13	4	0
Cost of keep 12 weeks 5 days, at 8s. 6½d. per week	5	8	4
Total cost	£18	12	4
Live weight of the same stot after being feed on steamed food, 104 sts. 7 lbs.=56 sts. 10 lbs., at 6s. 6d. per stone, sinking offal	18	8	7½
Profit on each stot on steamed food	£0	3	8½
Live weight of 1 stot when put on *raw* food, 90 sts.=51 sts. 6 lbs., at 5s. 6d. per stone, sinking the offal	£14	2	10½
Cost of 12 weeks 5 days' keep, at 6s. 9½d. per week	4	6	1
Total cost	£18	8	11½
Live weight of the same stot after being fed on raw food, 106 sts. 7 lbs.=58 sts. 6 lbs., at 6s. 6d. per stone, sinking offal	18	19	9½
Profit on each stot on raw food	£0	10	10

(1271.) The facts, brought out in this experiment, are these: It appears that turnips lose weight on being steamed. For example, 5 tons 8 cwts. only weighed 4 tons 4 cwts. 3 qrs. 16 lbs. after being steamed, having lost 1 ton 3 cwts. 12 lbs. or 1-6 of weight; and they also lost 1-5 of bulk when pulled fresh in February; but on being pulled in April the loss of weight in steaming decreased to 1-6. Potatoes did not lose above 1-50 of their weight by steaming, and none of their bulk. The heifers on steamed food not only consumed a greater weight of fresh turnips, in the ratio of 37 to 25, but after allowing for the loss of steaming, they consumed more of the steamed turnips. Thus, after deducting 1 5 from 37 cwts. 16 lbs.—the weight lost in steaming them—the balance, 29 cwts. 2 qrs. 17 lbs., is more than the 25 cwts. 1 qr. 14 lbs. of raw turnips consumed, by 4 cwts. 1 qr. 3 lbs. All the cattle, both on the steamed and raw food, relished salt; so much so, that when it was withheld, they would not eat their food with the avidity they did when it was returned to them.

(1272.) Steamed food should always be given in a fresh state—that is, new made; for, if old, it becomes sour, when cattle will scarcely touch it, and the sourer it is they dislike it the more. "In short," says Mr. Walker, "the quantity they would consume might have been made to agree to the fresh or sour state of the food when presented to them. . . . We are quite aware that to have done a large quantity at one steaming would have lessened the expense of coal and labor, and, also, by getting sour before being used, saved a great quantity of food; but we are equally well aware that, by so doing, we never could have fattened our cattle on steamed food."

(1273.) An inspection of the above table will show that both heifers and stots increased more in live-weight on steamed than on raw food; the larger profit derived from the raw food arising solely from the extra expense incurred in cooking the food. It appears, however, that a greater increase of tallow is derived from raw food. The results appear nearly alike with heifers and stots of the same age; but if the stots were of a breed possessing less fattening properties than cross-bred heifers—and Mr. Walker does not mention their breed—then they would seem to acquire greater *weight* than heifers, which I believe is the usual experience. The conclusion come to by Mr. Walker is this: "We have no hesitation in saying that, in every respect, the advantage is in favor of feeding with raw food. But it is worthy of remark that the difference in the consumption of food arises on the turnips alone. We would therefore recommend every person wishing to feed cattle on steamed food to use potatoes, or any other food that would not lose bulk and weight in the steaming process, as there is no question but, in doing so, they would be brought much nearer to each other in the article of expense of keep. . . . Upon the whole, we freely give it as our opinion that steaming food for cattle will never be attended with beneficial results under any circumstances whatever, because it requires a more watchful and vigilant superintendence during the whole process than can ever be delegated to the common run of servants, to bring the cattle on steamed food even upon a footing of equality, far less a superiority, to those fed on raw food."*

(1274.) One of the stots that had been fed on raw and another on steamed food were kept and put to grass. In their external condition no one was capable of judging how they had been fed. They were put to excellent grass on the 20th May, and the stot on raw food gained condition until 20th July, when, perhaps, the pasture may have begun to fail. That on steamed food fell off to that time 3 stones live weight. On 20th August both were put on cut grass, and both improved, especially the one that had been on steamed food, until the 18th October, when both were put on turnips, on which both became alike by the 10th November, relatively to what they were at the beginning of the season; that is, the stot that had been on raw food increased from 106 to 120 stones, and the other from 106 to 118 stones, live weight.

(1275.) Similar results as to profit were obtained by the experiments of Mr. Howden, Lawhead, East Lothian. "To me," he says, "it has been most decidedly shown that preparing food in this way [by steaming] is anything but profitable. Local advantages—such as fuel and water being at hand—may enable some others to steam at less expense; but in such a situation as mine, I am satisfied that there will be an expense of 10s. a head upon cattle incurred by the practice. A single horse-load of coals, carriage included, costs me 10s.; and exactly 6 cart-loads were required and used in preparing the food for cattle, equal to 6s. 8d. each, and probably as much more would not be an over-estimate for the additional labor in the 3 months." A few facts, worthy of attention, have been brought to light by Mr. Howden's experiment. It seems that raw potatoes and water will make cattle fat—a point which has been questioned by some of our best farmers. Potatoes, beans and oats, taken together, will feed cheaper, in reference to time, than turnips or potatoes separately; and from this fact may be deduced these, namely, that potatoes, when used alone, to pay their expense, would require the beef fed by them to fetch 4d. per lb.;

* Prize Essays of the Highland and Agricultural Society, vol. x.

turnips alone, 3½d.; and potatoes and corn together, 3d., and at the same time yielding beef of finer quality. There is a curious fact to be observed in the table given by Mr. Howden. Of 6 heifers, 1 in a lot of 3 weighed 1022 lbs.; and another, in another lot of 3, weighed also 1022 lbs., on 5th March, when both were put up to be experimented on; and on the 5th June following both were of the same weight, namely, 1176 lbs., both showing exactly an increase of 154 lbs.; both being supplied with the same *weight* of food, namely, 140 lbs. of turnips, to the one given raw, to the other cooked. This is a remarkable coincidence; but here it ends, and the superiority of cooked food becomes apparent; for the beef of the heifer fed on raw turnips weighed 5 sts. 12 lbs. and its tallow 5 sts. 10 lbs.; whereas, the beef of the one fed on steamed turnips weighed 44 sts. 4 lbs., and its tallow 6 sts. 22 lbs. How is this to be accounted for? Partly, no doubt, in the cooking of the food; but partly, I should suppose, from the state of the animal indicated by its hide, the thinner one of the heifer fed on steamed turnips weighing 3 sts. 10 lbs., showing a greater disposition to fatten—that is, to lay on more rapidly the valuable constituents of beef and tallow—than the thicker hide of the other heifer fed on raw turnips, which weighed 4 sts. 4 lbs. It is but justice, however, to the raw turnips to mention a fact to which Mr. Howden adverts. The turnips appropriated to the experiment were, it seems, stored against a wall, one store having a northern and the other a western aspect; but whether from aspect, or dampness, or other cause, those intended to be eaten *raw* had fermented in the store awhile before being observed, and thus, becoming unpalatable, of the 18 tons 15 cwts. stored, about 2½ tons were left unconsumed; so that, in fact, the heifers upon raw turnips did not receive so much food, or in so palatable a state as those on the steamed. It seems steaming renders tainted turnips somewhat palatable, while it has a contrary effect on tainted potatoes, the cattle preferring these raw. Turnips require a longer time to steam, and according to Mr. Howden's experience, they lose ¼ or 1-10 more of their weight than potatoes.* You may observe, from the state of the turnips in the store, the injudiciousness of storing them *against a wall*, as I have before observed (1019).

(1276.) Mr. Boswell of Kingcausie, in Kincardineshire, comes to the same conclusion in regard to the unprofitableness of feeding cattle on cooked food. He says, "It appears that it is not worth the trouble and expense of preparation to feed cattle on boiled or steamed food; as, although there is a saving in food, it is counterbalanced by the cost of fuel and labor, and could only be gone into profitably where food is very high in price and coal very low." His experiments were made on 10 dun Aberdeenshire horned cattle, very like one another, and their food consisted of the Aberdeen yellow bullock-turnips and Perthshire red potatoes. The 5 put on raw food weighed alive 228 stones 11 lbs., and the other 5 on cooked food 224 stones 6 lbs. imperial. When slaughtered, the butcher considered both beef and tallow "to be perfectly alike." Those fed on raw food cost £32 2s. 1d., and those on cooked £34 5s. 10d., leaving a balance of expense of £2 3s. 9d. in favor of the former. The opinions of feeders of cattle are not alike on all points. Thus, Mr. Boswell says, "The lot on raw consumed much more food than those on steamed," a fact directly the reverse of that stated by Mr. Walker in (1266). "Twice a week, on fixed days," he continues, "both lots got a small quantity of the tops of common heath, which acted in the way of preventing any scouring; in fact, turnip-cattle seem very fond of heather as a condiment." . . . "The dung of the steamed lot was from first to last in the best state, without the least appearance of purging, and was free of that abominable smell which is observed when cattle are fed on raw potatoes, or even when a portion of their food consists of that article. Another fact was observed, that after the steamed lot had taken to their food, they had their allowance finished sooner than the raw lot, and were therefore sooner able to lie down and ruminate." There is a curious fact mentioned by Mr. Boswell regarding a preference and dislike shown by cattle for turnips in different states. "When *raw* turnips and potatoes were put into the stall at the same time, the potatoes were always eaten up before a turnip was tasted; while, on the other hand, steamed turnips were eaten in preference to steamed potatoes."†

(1277.) Some curious and interesting facts have been arrived at by Mr. Stephenson, Whitelaw, East Lothian, in his experience of feeding cattle. They are detailed by him in a paper on feeding different lots of cattle, not with cooked and raw food, but with different sorts of food in a raw state. He divided a number of cattle into 3 lots, containing 6 in each lot, and fed one on oil cake, bruised beans, and bruised oats, in addition to whatever quantity of turnips they could eat, and potatoes for the last few days of the experiment; another lot received the same sort of food, with the exception of the oil-cake; and the third lot was fed entirely on turnips. The live weights of the lots varied considerably from 486 to 346½ imperial stones. I need not detail the particulars of the experiment, which was conducted from November, 1834, to March, 1835, for 17 weeks, as they present nothing remarkable; but their results are worthy of your attention.

(1278.) Each beast in the lot that got oil-cake cost, in 17 weeks, £5 2s. 7d., or 6s. per week; in the lot fed on corn, £3 17s., or 4s. 6d. per week; and in that fed entirely on turnips, £1 18s. 7½d., or 2s. 3d. a week. Estimating the value of the fed beef at 6s. 6d. per imperial stone, there was a *loss* of 12½ per cent. sustained on the lot fed on oil-cake; a *gain* of 8½ per cent. on that fed on corn; and a *gain* of 22 per cent. on that fed entirely on turnips.

(1279.) This was the cost incurred for producing every 1 lb. of increase of live weight, the lot fed on oil cake increasing from 486 to 594 stones; that on corn from 443 to 544 stones; and that on turnips from 346½ to 395½ stones.

The oil-cake cost 4 9-10 pence to produce 1 lb. of live weight.

.. corn	.. 3 9-10	..	..	..	..
.. turnips	.. 4 4-10	..	..	..	..

It thus appears that the joint agency of corn and turnips produces 1 lb. of live weight at the cheapest rate of the three modes adopted.

---

* Prize Essays of the Highland and Agricultural Society, vol. x.

† Ibid., vol. x.

(1280.) Another conclusion come to from the data supplied by this experiment is, that it took—

90 lbs. of turnips to produce	1 lb. of live weight.
40 lbs. of potatoes	
8 7-10 lbs. of corn	
21 8-10 lbs. of oil-cake	

And the cost of doing this was as follows:

90 lbs. of turnips, at 4d. per cwt.....	3 2-10d.	per 1 lb. of live weight.
40 lbs. of potatoes, at 1s. 6d. per cwt.....	6 4-10d.	.. ..
8 7-10 lbs. of corn at 3s. 3d. per bushel of 60 lbs.....	5 7-10d.	.. ..
21 8-10 lbs. of oil-cake, at ¾d. per lb. or £7 per ton.....16 3-10d.		.. ..

Could these results be proved to be *absolutely* correct, there would be no difficulty of assigning the degree of profit to be derived from employing any of these substances in the feeding of cattle. Is not the inquiry, however, of as much importance, even in a national point of view, as to deserve investigation at some sacrifice of both cost and trouble?

(1281.) You should not suppose that cattle consume food of any sort in a uniform ratio; for see actual results. The lot that was fed entirely on turnips increased in the first 32 days of the experiment only 8 stones, whereas the same beasts, in 46 days immediately preceding those on which the experiment began, increased 48¼ stones; and in one 8 days of the 46 they consumed 160 8-10 lbs. each of white globe turnips every day, and increased 1 lb. of live weight for every 65 4-10 lbs. of turnips consumed. The 90 lbs. taken above as the quantity of turnips required to produce 1 lb. of live weight is therefore not absolute, but assumed as a medium quantity, for it will happen that 1,000 lbs. will not produce 1 lb. of live weight. What the circumstances are which regulate the tendencies of cattle to fatten, are yet unknown. The fact is, cattle consume very different quantities of turnips in different states of condition, consuming more when lean, in proportion to their weight, than when fat. A lean beast will eat twice, or perhaps thrice, as many turnips as a fat one, and will devour as much as ¼ part of his own weight every day, while a very fat one will not consume 1-10. I had a striking example of this one year, when I bought a very lean 2-year-old steer, a cross betwixt a Short-Horn bull and Angus cow, for £6 in April; and he was a large-boned, thriving creature, but his bones were cutting the skin. He was immediately put on Swedish turnips; and the few weeks he was on them, before being turned to grass, he could hardly be satisfied, eating three times as much as the fat beasts in the same hammel. He was grazed in summer, and fed off on turnips and sold in April following for 17 guineas. Some stots of Mr. Stephenson's, in November, eat 2 7-10 lbs. for every stone of live weight they weighed; the year after the quantity decreased to 1 9-10 lbs., and after the experiment was included, when their live weights were nearly doubled, they consumed only 1 5-10 lbs.

(1282.) The object which Mr. Stephenson had in conducting the experiment the results of which are narrated above, were fourfold: 1. To compare cattle fed partly on oil-cake with those which had none; 2. To compare those fed partly on corn with those which had none; and 3. To compare those fed solely on turnips with those which had different sorts of food. The results were, that oil-cake is an unprofitable food for cattle, that corn yields a small profit, that turnips are profitable, and that when potatoes can be sold at 1s. 6d. per cwt. they are also unprofitable. "When any other food than turnips," observes Mr. Stephenson, "is desired for feeding cattle, we would recommend bruised beans as being the most efficient and least expensive; on this account we would prefer bruised beans alone to distillery offal. As regards linseed-cake, or even potatoes, they are not to be compared to beans." . . . "We give it as our opinion, that whoever feeds cattle on *turnips alone* will have no reason, on the score of *profit*, to regret their not having employed more expensive auxiliaries to hasten the fattening process. This opinion has not been rashly adopted, but has been confirmed by a more extended and varied experience in the feeding of cattle than has fallen to the lot of most men." 4. Another object he had in these experiments was, to ascertain whether the opinion is correct or otherwise, that cattle consume food in proportion to their weights. On this subject Mr. Stephenson says "that cattle consume food something nearly in proportion to their weights, we have very little doubt, *provided they have previously been fed in the same manner, and are nearly alike in condition.* Age, sex, and kind have little influence in this respect, as the quantity of food consumed depends much on the length of time the beast has been fed, and the degree of maturity the animal has arrived at—hence the great difficulty of selecting animals to be experimented upon. To explain our meaning by an example, we would say that 2 cattle of the same weight, and which had been previously kept for a considerable time on similar food, would consume about the same quantity. But, on the contrary, should 2 beasts of the same weight be taken, the one fat and the other lean, the lean beast would perhaps eat twice, or perhaps thrice, as much as the fat one—more especially if the fat one had been for some time previously fed on the same food, as cattle eat gradually less food until they arrive at maturity, when they become stationary in their appetite." . . . "We shall conclude," he says, "by relating a singular fact," and a remarkable one it is, and worth remembering, "that *sheep* on turnips will consume nearly in proportion to *cattle*, weight for weight, that is, 10 sheep of 14 lbs. a quarter, or 40 stones in all, will eat nearly the same quantity of turnips as an ox of 40 stones; but turn the ox to grass, and 6 sheep will be found to consume an equal quantity. This great difference may perhaps," says Mr. Stephenson, and I think truly, "be accounted for by the practice of sheep cropping the grass much closer and oftener than cattle, and which, of course, prevents its growing so rapidly with them as with cattle."*

(1283.) Still another question remains to be considered in reference to the feeding of cattle in winter, which is, whether they thrive best in *hammels* or in *byres at the stake?* The determination of this question would settle the future construction of steadings; for, of course, if more profit were certainly yielded to the farmer to feed his cattle in hammels than in byres, not only would

* Prize Essays of the Highland and Agricultural Society, vol. xii.

no more byres be erected, but those in use converted into hammels; and this circumstance would so materially change the form of steadings, as to throw open the confined courts, embraced within quadrangles, to the influence of the sun, at the only season these receptacles are required, namely, in winter. Some facts have already been decided regarding the comparative effects of hammels and byres upon cattle. Cattle are much cleaner in their persons in hammels than in byres. No doubt they *can* be kept clean in byres, but not being so, there must be some difficulty incidental to byre-management, and it consists, I presume, in the cattle-man finding it more laborious to keep the beasts clean in a byre, than in hammels; otherwise the fact is not easily to be accounted for, for he takes no *special* care to keep beasts in hammels clean. Perhaps when cattle have liberty to lie down where they please they may choose the driest, because the most comfortable spot; whereas, in a byre, they must lie down upon what they cannot see behind them. There is another advantage derived from hammels; the hair of cattle never scalds off the skin, and never becomes short and smooth, but remains long and mossy, and all licked over, and washed clean by rain, until it is naturally *cast* in spring, and this advantage is felt by cattle when sent to market in winter, where they can withstand much more wet and cold than those which have been fed in byres. A third advantage is, that cattle from hammels can travel the road without injury to their feet, being accustomed to be so much upon their feet, and to move about. It has been alleged in favor of byres, that they accommodate more cattle on the same space of ground, and are less expensive to erect at first than hammels. That in a given space more beasts are accommodated in byres there is no doubt, and there is as little doubt that more beasts are put in a byre than should be; but I have great doubts that it will cost more money to accommodate a given number of cattle in the hammel than in the byre system; because hammels can be constructed in a temporary form of wood and straw, and make beasts very comfortable at a moderate charge, whereas byres cannot be formed in that fashion; and even in the more costly form of roofs and walls, the shedding of hammels requires, comparatively to a byre, but a small stretch of roof; and it is well known that it is the roof and not the bare masonry of the walls that constitute the most costly part of a steading. I have seen a set of hammels, having stone and lime walls, and feeding-troughs, and a temporary roof, erected for £1 for every beast it could accommodate, and no form of byre could be built at that cost. But all these advantages of hammels would be of trifling import, if it can be proved by experience that cattle afford larger profits on being fed in byres; and unless this superiority is established in regard to either, the other is undeserving of preference. How then, stands the fact? Has experiment ever tried the comparative effects of both on anything like fair terms? Mr. Boswell of Balmuto, in Fifeshire, and of Kingcausie, in Kincardineshire, has done it; and it shall now be my duty to make you acquainted with the results.

(1284.) To give as much variety to this experiment as the circumstances would admit, it was conducted both at Balmuto and Kingcausie, and the beasts selected for it were of different ages, namely, 2 and 3-year-olds. At Balmuto 4 three-year-olds were put in close byres, and 4 in open hammels, and the same number of 2-year-olds were accommodated in a similar manner at Kingcausie. Those at Kingcausie received turnips only, and of course straw; at Balmuto a few potatoes were given at the end of the season, in addition to the turnips. The season of experiment extended from 17th October, 1834 to 19th February, 1835. The results were these:—

			St.	lb.
The 4 hammel-fed 2-year-olds at Kingcausie gained of live weight			45	8
.. 4 .. .. 3-year-olds at Balmuto			45	0
			91	8
	Sts.	lbs.		
.. 4 byre-fed 2-year-olds at Kingcausie gained of live weight,	32	7		
.. 4 .. 3-year-olds at Balmuto	36	0		
			68	7
Gain of live weight by the hammel-fed,			23	1

This is, however, not all gain, for the hammel-fed consumed more turnips, the Aberdeen yellow bullock, than the byre-fed.

	Tons.	cwts.	qrs.	lbs.
Those at Kingcausie consumed more by	1	7	2	6
And those at Balmuto	2	4	3	22
Total more consumed,	3	12	2	0

In a pecuniary point of view, the gain upon the hammel-fed was this:—23 stones 1 lb. live weight, = 13¾ stones beef, at 6s. per stone, gives £4 2s., from which deduct the value of the turnips, at 4d. per cwt., £1 4s. 2d., leaving a lance of £2 7s. 10d.

(1285.) It is a prevalent opinion among farmers, that young cattle do not lay on weight so fast, as old. But this experiment contradicts it; for the 2-year-olds in the hammels at Kingcausie gained 44 stones 22 lbs., on their united weights of 320 stones 7 lbs., in the same time that the 3-year-olds in the hammels at Balmuto, weighing together 350 stones, were of gaining 46 stones. Besides, the young beasts in the hammels at Kingcausie gained over those in the byre 12 stones 15 lbs., while the older cattle in the hammels at Balmuto gained over those in the byre only 10 stones. So that, in either way, the young cattle had the advantage over the older.

(1286.) Mr. Boswell observes that "hammels ought never to be used unless when the climate is good, and the accommodation of courts dry and well sheltered; and, above all, unless when there is a very large quantity of litter to keep the cattle constantly clean and dry." Shelter is essential for all sorts of stock in any situation, and the more exposed the general condition of the farm is, the more *need* there is of shelter; but be the situation what it may, it is, in my opinion, quite possible to render any hammel sheltered enough for stock, not by the distribution of planting, but by temporary erections against its weather-side; and these means will be the more

effectual when the hammel is placed facing the meridian sun, which it should be in every case If these particulars are attended to, and a rain-water spout placed along the eave in front to prevent the rain from the roof falling into the court, and an open drain, with convenient gratings, connected with all the courts, is properly made, the quantity of straw required will not be inordinate as I have myself experienced when farming dry turnip-soil. Mr. Boswell's testimony in favor of hammels is most satisfactory: it is this. "From the result of my own experiment, as well as the unanimous opinion of every agriculturist with whom I have conversed on the subject, I feel convinced that there is no point more clearly established than that cattle improve quicker, or, in other words, *thrive better in open hammels* than in close byres."*

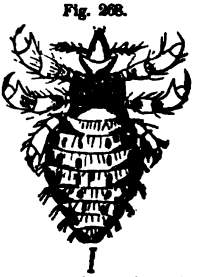
(1287.) I have dwelt the longer on the subject of feeding cattle, because of its great importance to the farmer, and because of the uncertainty sometimes attending its practice to a profitable issue: and there is no doubt that whether it leaves a profit or not depends entirely on the mode in which is prosecuted. Many are content to fatten their cattle in any way, or because others do so, provided they know they are not actually losing money by it, but if they do not make their cattle in the ripest state they are capable of being made, they are, in fact, losing part of their value. But how are they you may ask, best to be made ripe? There lies the difficulty of the case, and it must be attended with much difficulty before a man of the extensive experience in fattening cattle as Mr. Stephenson, would express himself in these words: "We have had great experience in feeding stock, and have conducted *numbers of experiments* on that subject with all possible care, both in weighing the cattle alive, and the whole food administered to them and in every experiment we made *we discovered something new*. But we have seen enough to convince us that, were *the art of feeding better understood, a great deal more beef and mutton might be produced from the same quantity of food* than is generally done." So far should such a declaration deter you from fattening cattle, it should rather be a proof of the wideness of the field that is still open for you to experiment in.

(1288.) There are but few *diseases* incidental to cattle in a state of confinement in winter, these being chiefly confined to the skin, such as the affection of *lice*, and to accidents in the administration of food, as *hoven* and *obstruction of the gullet* may be termed.

(1289.) *Lice.* When it is known that almost every species of quadruped found in the country, and in a state of nature, is inhabited by one or more pediculidæ, sometimes peculiar to one kind of animal, at other times ranging over many, it will not excite surprise that they should also occur on our domestic ox. Indeed, domestication and the consequences it entails, such as confinement, transition from a low to a higher condition, high feeding, and an occasional deviation from a strictly natural kind of food, seem peculiarly favorable to the increase of these parasites. Their occurrence is well known to the breeder of cattle, and to the feeder of fat cattle; and they are not unfrequently a source of no small annoyance to him. Unless when they prevailed to a great extent, they are probably not the cause of any positive evil to the animal, but, as their attacks are attended with loss of hair, an unhealthy appearance of the skin, and their presence is always more or less unsightly, and a source of personal annoyance to cattle, they may much impair the animal's look, which, when it is designed to be exhibited in the market, is a matter of no small consequence. As an acquaintance with the appearance and habits of these creatures must precede the discovery and application of any judicious method of removing or destroying them. I shall describe the species now which are the most common and noxious to the ox, and afterward to the other domestic animals of the farm. They may be divided into two sections, according to a peculiarity of structure, which determines the mode in which they attack an animal, namely, those provided with a mouth formed for sucking, and such as have a mouth with two jaws formed for gnawing. Of the former there are 3 species, which are very common, attacking the ox, the sow, and the ass.

(1290.) *Ox-louse (Hæmatopinus surysternus)*, fig. 268. It is about 1 or 1½ lines in length, as seen by the line below the figure, the head somewhat triangular, and of a chesnut color, the eyes pale brown, antennæ pale ochre-yellow, thorax darker chesnut than the head, with a spiracle or breathing-hole on each side, and a deep furrow on each side anteriorly; the shape nearly square, the anterior line concave, abdomen broadly ovate, grayish-white, or very slightly tinged with yellow, with 4 longitudinous rows of dusky horny excrescences, with 2 black curved marks on the last segment; legs long and strong, particularly the 2 fore-pairs, the color chesnut; claws strong and black. This may be called the common louse that infests cattle. It is most apt to abound on them when tied to the stall for winter feeding; and a notion prevails in England that its increase is owing to the cattle feeding on straw. The fact probably is, that it becomes more plentiful when the animal is tied up, in consequence of its being then less able to rub and lick itself, and the creature is left to propagate, which it does with great rapidity, comparatively undisturbed. It generally concentrates its forces on the mane and shoulders. As the parasite is suctorial, if it is at all the means of causing the hair to fall off, it can only be by depriving it of the juices by which is nourished, which we can conceive to be the case when the sucker is inserted at the root of the hair; but it is more probable that the hair is rubbed off by the cattle themselves, or is shorn off by another louse to be just noticed. The egg or nit is pear-shaped, and may be seen attached to the hairs.

Fig. 268.



THE OX-LOUSE, HÆMATOPINUS SURYSTERNUS.

(1291.) *Ox-louse (Trichodectes scalaris)*, fig. 269.—This parasite is minute, the length seldom exceeding ¼ a line. The head and thorax are of a light rust color, the former of a somewhat obcordate shape, with two dusky spots in front; the third joint of the antennæ longest, and spindle-shaped (in the horse-louse, *Trichodectes equi*, that joint is clavate); abdomen pale, tawny, pubes-

* Prize Essays of the Highland and Agricultural Society, vol. xi.

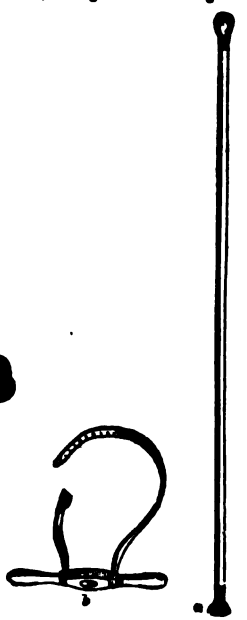
cent, the first 6 segments with a transvere dusky or rust-colored stripe on the upper half, a narrow stripe of the same color along each side, and a large spot at the hinder extremity; legs, pale tawny. Plentiful on cattle; commonly found about the mane, forehead, and rump, near the tail-head. It is provided with strong mandibles, with two teeth at the apex, and by means of these it cuts the hairs near the roots with facility. Both these vermin are destroyed by the same means as the sheep-louse (1156).

Fig. 296

THE OX-LOUSE, TRICHODECTES SCALARIS.

(1292.) *Choking.*—When cattle are feeding on turnips or potatoes, it occasionally happens that a piece larger than will enter the gullet easily, is attempted to be swallowed, and obstructed in its passage. The accident chiefly occurs to cattle receiving a limited supply of turnips, and young beasts are more subject to it than old. When a number of young beasts in the same court only get a specified quantity of turnips or potatoes once or twice a day, each becomes apprehensive, when the food is distributed, that will not get its own share, and therefore eats what it can with much apparent greediness, and not taking sufficient time to masticate, swallows its food hastily. A large piece of turnip, or a small potato, thus easily escapes beyond the power of the tongue, and, assisted as it is by the saliva, is sent to the top of the gullet, where it remains. Cattle that project their mouths forward in eating, are most liable to choke. When turnips are sliced and potatoes are broken, there is less danger of the accident occurring even among young cattle. The sight of the obstruction, its consequent effects, and remedial measures for its removal, are thus described by Professor Dick. "The obstruction usually occurs at the bottom of the pharynx and commencement of the gullet, not far from the lower part of the larynx, which we have seen mistaken for the foreign body. The accident is much more serious in ruminating animals than in others, as it immediately induces a suspension of that necessary process, and of indigestion, followed by a fermentation of the food, the evolution of gases, and all those frightful symptoms which will be noticed under the disease *hoven*. The difficulty in breathing, and the general uneasiness of the animal, usually direct at once to the nature of the accident, which examination brings under the cognizance of the eye and hand. *No time must be lost in endeavoring to afford relief*; and the *first* thing to be tried is, by gentle friction and pressure of the hand upward and downward, to see and rid the animal of the morsel. *Failing in this*, we mention first the great virtue we have frequently found in the use of mild lubricating fluids, such as warm water and oil, well boiled gruel, &c. The gruel is grateful to the animal, which frequently tries to gulp it, and often succeeds. Whether this is owing to the lubrication of the parts, or the natural action superinduced, it is unnecessary to inquire; but the fact we know, that a few pints of warm gruel have often proved successful in removing the obstruction. *If this remedy should be ineffectual*, the foreign body may perhaps be within the reach of the small hand which a kind dairy-maid may skillfully lend for the purpose. *If this good service cannot be procured*, the common probang must be used, the cup-end being employed. Other and more complicated instruments have been invented, acting upon various principles—some, for example, on that of bruising the obstructing body; and the use of these requires considerable skill. *Disappointed in all*, we must finally have resource to the knife."* You may try all these remedies, with the exception of the knife, with perfect confidence. The friction, the gruel, the hand, and the probang, I have successfully tried; but the use of the knife should be left to the practical skill of the veterinary surgeon.

Fig. 270. Fig. 271



THE MOUTH-PIECE FOR THE PROBANG. THE PROBANG.

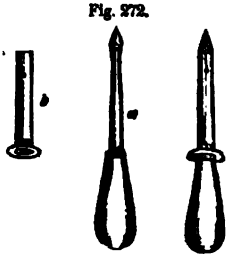
(1293.) The common *probang* is represented in fig. 271, *a* being the cup-end, which is so formed that it may partially lay hold of the piece of turnip or potato, and not slip between it and the gullet, to the risk of rupturing the latter, and being of larger diameter than the usual state of the gullet, on pressing it forward distends the gullet, and makes room for the obstructing body to proceed to the stomach. Formerly the probang was covered with cane, but is now with leather, which is more pliable. It is used in this manner: Let the piece of wood, fig. 270, be placed over the opened mouth of the animal as a bit, and the straps of leather attached to it buckled tightly over the neck behind the horns, to keep the bit steady in its place. The use of the bit is, not only to keep the mouth open without trouble, but to prevent the animal injuring the probang with its teeth, and it offers the most direct passage for the probang toward the throat. Let a few men seize the animal on both sides by the horns or otherways, and let its mouth be held projecting forward in an easy position, but no fingers introduced into the nostrils to obstruct the breathing of the animal, nor the tongue forcibly pulled at the side of the mouth. Introduce now the cup-end *a* of the probang, fig. 271, through the round hole *b* of the mouth-piece, fig. 270, and push it gently toward the throat until you feel the piece of the turnip obstructing you; push then with a firm and persevering hand, cautioning the men, previous to the push, to hold on firmly, for the

* Dick's Manual of Veterinary Science.

passage of the instrument may give the animal a little pain, and cause it to wince and even start away. The obstruction will now most likely give way, especially if the operation has been performed before the parts around it began to swell; but if not, the probang must be used with still more force, while another person rubs with his hands up and down upon the distended throat of the beast. If these attempts fail, recourse must be had to the knife, and a veterinary surgeon sent for instantly.

(1294.) *Hoven.*—The hoven in cattle is the corresponding disease to the gripes or batts in horses. The direct cause of the symptoms is undue accumulation of gases in the paunch or large stomach, which, not finding a ready vent, causes great pain and uneasiness to the animal, and, if not removed in time, ruptures the paunch and death ensues. The cause of accumulation of the gases is indigestion. "The structure of the digestive organs of cattle," says Professor Dick, "renders them peculiarly liable to the complaint, while the sudden changes to which they are exposed in feeding prove exciting causes. Thus, it is often witnessed in animals removed from confinement and winter feeding to the luxuriance of the clover field; and in house-fed cattle, from the exhibition of rich food, such as peas-meal and beans, often supplied to enrich their milk. We have already mentioned that it sometimes proceeds from obstructed gullet. The symptoms bear so close a resemblance, both in their progress and termination in rupture and death, to those so fully described above, that we shall not repeat them. The treatment mostly corresponds, and it must be equally prompt. The mixture of the oils of linseed and turpentine is nearly a specific."* The recipe is, linseed-oil, raw, 1 lb.; oil of turpentine, from 2 to 3 oz.; laudanum, from 1 to 2 oz., for one dose. Or hartshorn, from ½ to 1 oz., in 2 pints imperial of tepid water. In cases of pressing urgency, from 1 to 2 oz. of tar may be added to ½ pint of spirits, and given diluted, with great prospect of advantage. These medicines are particularly effective in the early stage of the disease, and should therefore be tried on the first discovery of the animal being affected with it. Should they not give immediate relief, the probang may be introduced into the stomach, and be the means of conveying away the gas as fast as it is generated; and I have seen it successful when the complaint was produced both by potatoes and clover; but I never saw an instance of hoven from turnips, except from obstruction of the gullet. The trial of the probang is useful to show whether the complaint arises from obstruction or otherwise, for should it pass easily down the throat, and the complaint continue, of course the case is a decided one of hoven. Placing an instrument, such as in fig. 270, across the mouth, to keep it open, is an American cure which is said never to have failed. But the gas may be generated so rapidly that neither medicines nor the probang may be able to prevent or convey away, in which case the apparently desperate remedy of *paunching* must be had recourse to. "The place for puncturing the paunch," directs Professor Dick, "is on the left side, in the central point between the lateral processes of the lumbar vertebra, the spine of the ileum, and the last rib. Here the *trochar* may be introduced without fear. If air escape rapidly, all is well. The canula may remain in for a day or two, and, on withdrawal, little or no inconvenience will usually manifest itself. If no gas escape, we must enlarge the opening freely, till the hand can be introduced into the paunch, and its contents removed, as we have sometimes seen, in prodigious quantities. This done, we should close the wound in the divided paunch with 2 or 3 stitches of fine catgut, and carefully approximate and retain the sides of the external wound, and with rest, wait for a cure, which is often as complete as it is speedy."† To strengthen your confidence in the performance of this operation, I may quote a medical authority on its safe effects, in the human subject, even to the extent of exposing the intestines as they lay in the abdomen. "I should expect no immediately dangerous effects from opening the abdominal cavity. Dr. Blundell has stated that he has never, in his experiments upon the rabbit, observed any marked collapse when the peritoneum was laid open, although in full expectation of it. The great danger to be apprehended is from inflammation, and the surgeon, of course, will do all in his power to guard against it."‡ I once used the trochar with success in the case of a Skibo stot which had been put on potatoes from turnips, and as he was in very high condition, took a little blood from him, and he recovered very rapidly. In another yard I lost a fine 1-year-old Short-Horn quey by hoven, occasioned by potatoes. Oil and turpentine were used, but as the complaint had remained too long, before it was noticed by myself, late at night, the medicine had no effect. The probang went down easily, proving there was no obstruction. The trochar was then thrust in, but soon proved ineffectual, and as I had not the courage to use the knife to enlarge the opening the trochar had made, and withdraw the contents of the paunch with the hand, the animal sank and was immediately slaughtered. The remedies cannot be too soon applied in the case of hoven.

Fig. 272.



THE TROCHAR.

(1295.) The *trochar* is represented in fig. 272. It consists of a round rod of iron *a*, 5 inches in length, terminating at one end in a triangular, pyramidal-shaped point, and furnished with a wooden handle at the other. The rod is sheathed in a cylindrical cover or case *b*, called the canula, which is open at one end, permitting its point to project, and furnished at the other with a broad, circular flange. The canula is kept tight on the rod by means of a slit at its end nearest the point of the rod, which, being somewhat larger in diameter than its own body, expands the slit end of the canula until it meets the body, when the slit collapses to its ordinary size, and the canula is kept secure behind the enlarged point as at *c*. On using the trochar, in the state as seen by *c*, it is forced with a thrust into the place pointed out above, through the skin into the paunch; and on withdrawing the rod by its

* Dick's Manual of Veterinary Science. † Ibid.

‡ Stephens on Obstructed and Inflamed Hernia.

handle—which is easily done, notwithstanding the contrivance to keep it on—the canula is left in the opening, to permit the gas to escape through its channel. On account of the distended state of the skin, the trochar may rebound from the throat; and in such an event, a considerable force must be used to penetrate the skin.

(1296.) The *fardlebound* of cattle and sheep is nothing more than a modification of the disease in horses called stomach-staggers, which is caused by an enormous distension of the stomach. "In this variety, it has been ascertained," says Professor Dick, "that the *maniplies* are most involved, its secretions are suspended, and its contents become dry, hard, and caked into one solid mass. Though the constipation is great, yet there is sometimes the appearance of a slight purging, which may deceive the practitioner."* The remedial measures are, first, to relieve the stomach by large drenches of warm water, by the use of the stomach-pump. Searching and stimulating laxatives are then given, assisted by clysters, and then cordials.

(1297.) *Warts* and *angle-berries* are not uncommon excrescences upon cattle. They are chiefly confined to the groin and belly. I have frequently removed them by ligature with waxed silk thread. Escharotics have great efficacy in removing them—such as alum, bluestone, corrosive sublimate.

(1298.) *Encysted tumors* sometimes appear on cattle, and may be removed by simple incision, having no decided root or adhesion. I had a 2-year-old Short-Horn quey that had a large one upon the front of a hind foot, immediately above the coronet, which was removed by simple incision by a veterinary surgeon. What the true cause of its appearance may have been, I cannot say; but the quey, when a calf, was seen to kick a straw-rack violently with the foot affected, and was lame in consequence for a few days; after which, a small swelling made its appearance upon the place, which, gradually enlarging, became the loose and unsightly tumor which was removed.

(1299.) A gray-colored scabby eruption, vulgarly called the *ticker*, sometimes comes out on young cattle on the naked skin around the eye-lids, and upon the nose between and above the nostrils. It is considered a sign of thriving, and no doubt it makes its appearance most likely on beasts that are improving from a low state of condition. It may be removed by a few applications of sulphur ointment.

(1300.) In winter, when cows are heavy in calf, some are troubled with a complaint commonly called a *coming down of the calf-bed*. A part of the womb is seen to protrude through the vaginal passage when the cow lies down, and disappears when she stands up again. It is supposed to originate after a very severe labor. Bandages have been recommended, but, in the case of the cow, they would be troublesome, and indeed are unnecessary; for if the litter is made firm and higher at the back than the front part of the stall, so as the hind-quarter of the cow shall be higher than the fore when lying, the protrusion will not occur. I had a cow that was troubled with this inconvenience every year, and as she had no case of severe labor in my possession, I did not know whether, in her case, it was occasioned by such a circumstance; but it seemed to give her no uneasiness, when the above preventive remedy was resorted to.

(1301.) It not unfrequently happens to cattle in large courts, and more especially to those in the court nearest the corn-barn, that an oat-chaff gets into one of their eyes in a windy day. An irritation immediately takes place, causing copious watering from the eye, and, if the chaff is not removed, a considerable inflammation and consequent pain soon ensue, depriving the sufferer of the desire for food. To have it removed, let the animal be firmly held by a number of men, and as beasts are particularly jealous of having anything done to their eyes, a young beast even will require a number of men to hold it fast. The fore-finger should then be gently introduced under the eye-lid, pushed in as far as it can go, and being moved round along the surface of the eye-ball, is brought round to its original position, and then carefully withdrawn and examined, to see if the chaff has been removed along with it, which it most likely will be; but if not, repeated attempts will succeed. A thin handkerchief around the finger will secure the extraction at the first attempt. Fine salt or snuff have been recommended to be blown into the eye when so affected, that the consequent increased discharge of tears may float away the irritating substance; but the assistance of the finger is less painful to the animal, and sooner over, and, as it is an operation I have frequently performed with undeviating success, I can attest its efficacy and safety.

33. DRIVING AND SLAUGHTERING CATTLE.

"Frisk, dance and leap, like full-fed beasts, and even
Turn up their wanton heels against the Heaven;
Not understanding that this pleasant life
Serves but to fit them for the butcher's knife."
FLAVEL.

(1302.) It is requisite that cattle which have been disposed of to the dealer or butcher, or are intended to be driven to market, should undergo a preparation for the journey. If they were immediately put to the road to travel, from feeding on grass or turnips, when their bowels are full of

* Dick's Manual of Veterinary Science.

indigested vegetable matter, a scouring might ensue, which would render them unfit to pursue their journey; and this complaint is the more likely to be brought on from the strong propensity which cattle have to take violent exercise on feeling themselves at liberty from a long confinement. They in fact become *light-headed* whenever they leave the hammel or byre, so much so that they actually "frisk, dance and leap," and their antics would be highly amusing, were it not for the apprehension they may hurt themselves against some opposing object, as they seem to regard nothing before them. I remember seeing a dodded Angus stot let out of a byre running so recklessly about that at length he came at full speed with his head against the wall of the steading, and was instantly felled to the ground. Before any one could run to his assistance he sprang upon his feet and made off again at full speed, holding his head high and tail on end, as if he felt proud of having done a feat which no one else could imitate. With distended nostrils and heaving flanks he appeared dreadfully excited; but on being put into his byre he soon calmed down. On being let out for the first time cattle should be put awhile into a large court, or on a road well fenced with inclosures, and guarded by men, to romp about. Two or three times of such liberty will make them quiet; and, in the mean time, to lighten their weight of carcass, they should get hay for a large proportion of their food. These precautions are absolutely necessary for cattle confined in byres, otherwise accidents may befall them on the road, where they will at once break loose. Even at home serious accidents sometimes overtake them, such as the breaking down of a horn, casting off a hoof, spraining a tendon, bruising ribs, and heating the whole body violently; and, of course, when any such ill luck befalls, the animal affected must be left behind, and become a drawback upon the value of the rest, unless kept on for some time longer.

(1303.) Having been prepared for the road, the *drover*—who may be your own shepherd, or a hired professional drover—takes the road very slowly for the first two days, not exceeding 7 or 8 miles a day. At night, in winter, they should be put into an open court and supplied with hay and water and a very few turnips; for if the turnips are suddenly withdrawn from them, their bellies will become what is termed *clinged*, that is, shrunk up into smaller dimensions—a state very much against a favorable appearance in a market. After the first two days they may proceed faster, say 12 or 13 miles a day if very fat, and 15 if moderately so. When the journey is long and the beasts get faint in travel, they should get corn to support them. In frosty weather, when the roads become very hard, they are apt to become *shoulder-shaken*, an effect of founder; and if sleet falls during the day, and becomes frozen upon them at night, they may become so chilled as to refuse food, and shrink rapidly away. I had a lot of 12 Angus oxen so affected on their road to Glasgow, when overtaken in an unexpected storm in May, that I could scarcely recognize them in the market. Cattle should, if possible, arrive the day before in the neighborhood of a distant market, and be supplied with a good feed of turnips and hay, or grass, to make them look fresh and fill them up again; but if the fair is only a short distance, they can travel to it early in the morning.

(1304.) In driving cattle the drover should have *no dog*, which will only annoy them. He should walk either before or behind, as he sees them disposed to proceed too fast or loiter on the road; and in passing carriages the leading ox, after a little experience, will make way for the rest. In other respects their management on the road is much the same as that of sheep, though the rate of traveling is quicker. Accommodation will

be found at night at stated distances along the road. On putting oxen in a ferry-boat the shipping of the first one only is attended with much trouble. A man on each side should take hold of a horn, or of a halter made of any piece of rope, should the beast be hornless, and other two men, one on each side, should push him up behind with a piece of rope held between them as a breaching, and conduct him along the plank into the boat, which, if it have low gunwales, a man will require to remain beside him until one or two more of the cattle follow their companion, which they will most readily do. In neglecting this precaution in small ferry-boats, I have seen the first beast leap into the water, and then it was difficult to prevent some of the rest doing the same thing from the quay.

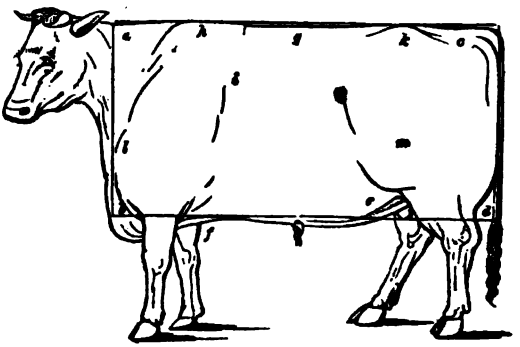
(1305.) Whatever time a lot of cattle may take to go to a market, they should never be *overdriven*. There is great difference in management in this respect among drovers. Some like to proceed on the road quietly, slowly, but surely, and to enter the market in a placid, cool state. Others, again, drive smartly along for some distance and rest to cool awhile, when the beasts will probably get chilled and have a staring coat when they enter the market; while others like to enter the market with their beasts in an excited state, imagining them then to look gay; but distended nostrils, loose bowels and reeking bodies, the ordinary consequences of excitement, are no recommendations to a purchaser. Good judges are shy of purchasing cattle in a heated state, because they do not know how long they may have been in it, and, to cover any risk, will give £1 a head below what they would have bid for them in a cool state. Some drovers have a habit of thumping at the hindmost beast of the lot with his stick while on the road. This is a reprehensible practice, as the flesh, where thumped, will bear a red mark after the animal has been slaughtered, the mark getting the appropriate name of *blood-burn*, and the flesh so affected will not take on salt, and is apt to putrefy. A touch upon the shank, or any tendonous part, when correction is *necessary*, is all that is required; but the voice, in most cases, will answer as well. The flesh of overdriven cattle, when slaughtered, never becomes properly firm, and their tallow has a soft, melted appearance.

(1306.) A few large oxen in a lot look best in a market on a position rather above the eye of the spectator. When a large lot is nearly alike in size and appearance, they look best and most *level* on a flat piece of ground. Very large fat oxen never look better than on ground on the same level with the spectator. An ox, to look well, should hold his head in a line with the body, with lively ears, clear eye, dewy nose, a well-licked hide, and stand firmly on the ground on all his feet. These are all symptoms of high health and good condition. Whenever you see an ox shifting his standing from one foot to another, he is *foot-sore*, and has been far driven. When you observe him hanging his head and his eyes watering he feels ill at ease inwardly. When his coat stares he has been overheated some time, and got a subsequent *chill*. All these latter symptoms will be much aggravated in cattle that have been fed in a byre. You may discover when a beast has been fed at the stake with the seal or baikie, by observing a fretted and callous mark on the *top* of the neck immediately behind the ears; by the hoofs being rather overgrown at the points; by marks of dung, or at least much resting, upon the outside of the hams; and very frequently by the remains of lice upon the tail-head and top of shoulder, their scurf remaining, or the hair shorn off altogether.

(1307.) In all *customs relating to markets* it is the same with cattle as with sheep (1167). And an ox puts on fat precisely in the same manner as a sheep (1169).

(1308.) In *judging* cattle the procedure is somewhat different from that of sheep, inasmuch as the hair of cattle not hiding their form so effectually as wool does that of sheep, the *eye* is more used than the hand; indeed, in the case of ripe fed cattle, the eye alone is consulted. The hand as well as the eye is brought into use in judging of *lean* cattle to lay on to grass or to fatten on turnips; and when we come to consider that matter in summer and autumn, I shall let you know the use of the hand in determining the qualities essential to a good *lean* beast. Meantime our business is with fat beasts; and although judging them by the eye is not a difficult thing in itself, it is rather difficult to describe in words. With the assistance, however, of the accompanying figures, I hope you will obtain some useful hints toward acquiring a knowledge of the art. When you look at the *near* side of a *ripe* ox in profile—and this is the side usually chosen to begin with—whatever be its *size*, imagine its body to be embraced within a rectangled parallelogram, as in fig. 273; and if the ox is filled up in all

Fig. 273.

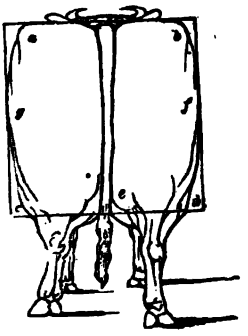


THE SIDE VIEW OF A WELL FILLED-UP FAT OX.

points, his carcass will occupy the parallelogram *a b c d* as fully as in the figure; but, in most cases, there will be deficiencies in various parts—not that *all* the deficiencies will occur in the same animal, but different ones in different animals. The flank *e*, for instance, may be shrunk up, and leave a space there to the line; or the brisket *f* may descend much farther down than is represented; or the rump *c* may be elevated much above the line of the back; or the middle of the back *g* may be much hollowed below the line; or the top of the shoulder *h* may be much elevated above it; or a large space may be left unfilled in the hams above *d*. Then a similar survey should be made behind the animal; the imaginary line should inscribe it also within it the perimeter of a rectangled parallelogram, though of different form from the other, as represented in fig. 274, where the breadth of the hook-bones, *a* and *b*, is maintained as low as the points *c* and *d*; and the *closing* between the legs at *e* is also well filled up. This figure gives a somewhat exaggerated view of the appearance of a fat ox behind; but still it gives the form of the *outline* which it should have. Then go in front of the ox, and there imagine the outline of the body at the shoulder, inscribed within a rectangled parallelogram *a b c d*, fig. 275, of exactly the same dimensions as the one in fig. 274. The shoulder, from *a* to *b*, is apparently of the same breadth as across the hook-bones, from *a* to *b*, fig. 274. The off-side of the animal may of course be expected to be similar in outline to the near side. Having thus

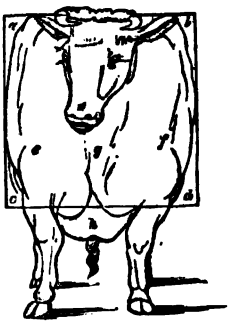
obtained an idea of the outline which a fat ox should have, let us now attend to the filling up of the area of the parallelogram.

Fig. 274.



THE HIND VIEW OF A WELL FILLED-UP FAT OX.

Fig. 275.



THE FRONT VIEW OF A WELL FILLED-UP FAT OX.

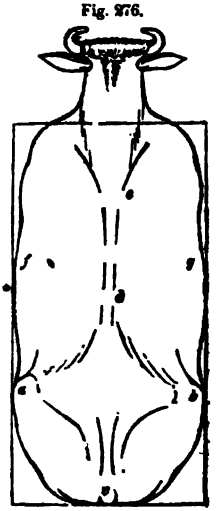
(1309.) On looking again at the near-side view, fig. 271, observe whether the ribs below and on each side of *g* are rounded, and nearly fill up the space between the more projecting points *h* and *k*, that is, between the shoulders and the hook. Observe also whether the shoulder *h* is flat, somewhat in the same plane as *g*, or more rounded and prominent; and whether the space behind the shoulder, at *i*, is hollow or filled up. Observe, again, whether the shoulder-point *l* is projecting and sharp, or rounded off; and whether the neck, between *a* and *l*, is flat and sunk, or sweeps finely in with the shoulder. Observe yet more, whether the muscles at *m* are thin and flat, or full and rounded; and whether the hook-bone *k* projects or sinks in, or appears to connect itself easily with the rump *c* on the one hand, and with the ribs *g* on the other. With all these alternative particulars before you, they should be arranged in the following manner, to constitute *points* in perfection.

(1310.) The line from the shoulder to the hook, from *h* to *k*, fig. 273, should be parallel to the back-bone. The space on each side of *g*, along the ribs from *g* to *h*, and along the loin from *g* to *k*, does not fall in with the line *h* and *k*, but should be a little nearer, and almost as high as the back-bone, with a rounding fall of the ribs down the side of the animal. The loin, from *k* to *g*, should be perfectly flat above, on the same level as the back-bone, and drop down on this side, in connection with the utmost rounding of the ribs. The point of the hook *k* should just be seen to project, and no more; and the space between it and the rump *c* should gradually sweep round to the narrower breadth of the pelvis, as seen from *a* to *c* or *b* to *c* in fig. 276. *i* is placed at the utmost bend of the ribs, along which a straight line should touch every point through *i*, from the front of the shoulder to the buttock. The triangular space comprehended within *a h l* should gradually taper from the shoulder-point to the head. A straight line from *l*, the shoulder-point, should touch every spot from it to *m*. The line of the back should be straight from *a* to *c*; the tail should drop perpendicularly from *c* to *d*; and the belly should sweep level, not high at *e* nor dropping at *f*. There are thus three straight lines along the side of a fat ox, from *a* to *c*, one through *i*, and from *l* to *m*. Proceeding behind the animal to fig. 274, the space between the hooks, from *a* to *b*, should be level, but a little rounded off at both ends, and the bone at the top of the tail only being allowed to project a *little* upward. The muscles on each side

below the hooks, at *g* and *f*, when fuller than the hooks, is no *deformity*, but should they be no fuller, they are right. The muscles at *c* and *d*, down the side of the hams, are allowed to sweep gradually toward the hock joints of the legs. The *closing* at *e* should be well filled up to furnish the rounds fully, but freely, for *packed* rounds prevent easy motion of the hind legs. Sometimes the tail is hid in a channel left by the muscles between *e* and *f*, but this is not usually the case. On going to the front view, fig. 275, the shoulder-top between *a* and *b* should be filled out with a natural round, and the muscles below it upon the shoulder-blades should always project farther than the breadth of the shoulder-top, and in this respect the fore-quarter differs from the hind, where the muscles below the hooks seldom project beyond them. The shoulder-points *e* and *f* should not be prominent, but round off with the muscles of the neck toward *g* where the round of the front of the neck falls from the head to the breast where the upper part of the brisket *h* meets it, and projecting a little in front, is rounded below and forms the lowest part of the body of a fat ox, and should be well filled out in breadth to spread the fore-legs asunder. The fore-legs are usually farther apart than the hind, but the hind at times, when the *shaw* or *cod* is large and fat, is as much and even more apart.

(1311.) The objectionable deviations from these points are as follows: In fig. 273, a hollow back at *g* is bad, showing weakness of the back-bone. A high shoulder-crest at *h* is always attended with a sharp thin shoulder, and has the effect of bringing the shoulder-tops *a* and *b*, fig. 275, too close together. A long distance between *g* and *k* makes the loins hollow, and gives to a beast what is called a *washy* appearance, and is always attended with a liability to looseness in the bowels. This washiness is generally attended with an inordinate breadth of hooks, from *a* to *b*, fig. 274, and causes them to project much beyond the muscles below. A sharp projecting hook is always accompanied with flat ribs at *g*, fig. 273, and ribs when flat give the animal a hollow side, which bears little flesh, the viscera being thrown down into the cavity of the belly, which droops considerably below the line; but in the event of the muscles of the abdomen having a greater weight to bear, they become thicker and stronger, and, accordingly, the flesh there becomes less valuable, and it has also the effect of thinning away the thick flank *e*. Flatness of rib is also indicative of hollowness of the space behind the shoulder, so much so, indeed, that the animal seems as if it had been gripped in too firmly there. As the flesh is taken away from the shoulder-blade by a sharp shoulder and hollow ribs, so the shoulder-joint *l* projects the more, and causes a thinness of the neck between *a* and *l*. The rump-bone, at *c*, frequently rises upward, thereby spoiling the fine straight line of the back; and whenever this happens, the rump between *k* and *c* wants flesh and even becomes hollow, thereby much deteriorating the value of the hind-quarter. A projecting hook *k* also thins away the muscles about *m*, and behind it to the rounds; and this again is followed by an enlargement of the openings at the closing *e*, fig. 274. Whenever the shoulder becomes thin and narrow, when viewed in front, as in fig. 275, the shoulder-points *e* and *f* are wider than from *a* to *b*, and while this effect is produced above, the

Fig. 276.



THE BACK VIEW OF A WELL-FILLED FAT OX.

brisket *h* below becomes less fat, and permits the fore-legs to stand nearer each other. A greatly commendatory point of a fat ox is a level broad back from rump to shoulder, because all the flesh seen from this position, as is endeavored to be represented by fig. 276, is of the most valuable description; where the triangular space included between *a*, *b*, *c*, is the rump; the triangular space between *a*, *b*, *d*, the loin; and the space between *d* and *e*, deflecting on both sides toward *f* and *g*, the ribs, the value of all which parts are enhanced the more nearly they all are on a level with each other. All that I have endeavored to describe, in these paragraphs, of the points of a fat ox, can be judged of alone by the eye, and most judges never think of employing any other means; but the assistance derived from the hand is important, and in a beginner cannot be dispensed with.

(1312.) The first point usually *handled* is the end of the rump at the tail-head, at *c*, fig. 273, although any fat here is very obvious, and sometimes attains to an enormous size, amounting even to deformity. The hook-bone *k* gets a touch, and when well covered, is right; but should the bone be easily distinguished, the rump between *k* and *c* and the loin from *k* to *g* may be suspected, and, on handling these places, the probability is that they will both be hard, and deficient of flesh. To the hand, or rather to the points of the fingers of the right hand, when laid upon the ribs *g*, the flesh should feel soft and thick and the form be round when all is right, but if the ribs are flat the flesh will feel hard and thin, from want of fat. The skin, too, on a rounded rib, will feel soft and mobile, the hair deep and mossy, both indicative of a kindly disposition to lay on flesh. The hand then grasps the flank *e*, and finds it thick, when the existence of internal tallow is indicated. The cod is also fat and large, and on looking at it from behind seems to force the hind legs more asunder than they would naturally be. The palm of the hand laid along the line of the back from *c* to *h* will point out any objectionable hard piece on it, but if all is soft and pleasant, then the shoulder-top is good. A hollowness behind the shoulder at *i* is a very common occurrence; but when it is filled up with a layer of fat, the flesh of all the fore-quarter is thereby rendered very much more valuable. You would scarcely believe that such a difference could exist in the flesh between a lean and a fat shoulder. A high narrow shoulder is frequently attended with a ridged back-bone, and low-set narrow hooks, a form which gets the appropriate name of *razor-back*, with which will always be found a deficiency of flesh in all the upper part of the animal, where the best flesh always is. If the shoulder-point *l* is covered, and feels soft like the point of the hook-bone, it is good, and indicates a well-filled neck-vein, which runs from that point to the side of the head. The shoulder-point, however, is often bare and prominent. When the neck-vein is so firmly filled up as not to permit the points of the fingers into the inside of the shoulder-point, indicates a well tallowed animal; as also does the filling-up between the brisket and inside of the fore-legs, as well as a full, projecting, well-covered brisket in front. When the flesh comes down heavy upon the thighs, making a sort of double thigh, somewhat like the shape at *d* and *e*, fig. 274, it is called *lyary*, and indicates a tendency of the flesh to grow on the lower instead of the upper part of the body. These are all the *points* that require *touching when the hand is used*; and in a high-conditioned ox, they may be gone over very rapidly.

(1313.) Cattle are made to fast before being slaughtered, as well as sheep. The time they should stand depends on the state of the animal on its arrival at the shambles. If it has been driven a considerable distance in a proper manner, the bowels will be in a tolerably empty state, so that

12 hours may suffice, but if full and just off its food, 24 hours will be required. Beasts that have been overdriven, or much struck with sticks, or are in any degree infuriated—or *raised*, as it is termed—should not be immediately slaughtered, but allowed to stand on dry food, such as hay, until the symptoms disappear. While such precautions are certainly necessary to preserve meat in the best state, we can scarcely credit the loss there must be incurred every year in Smithfield market in London, by the injuries sustained by the animals being driven through the streets of an immensely peopled metropolis. The state of many of the animals in the market on a Monday morning is truly pitiable. "The loss to the grazier," says a writer who advocates the removal of the market to the suburbs, "is in the difference in value of his sheep or cattle, when they arrive in the neighborhood of the metropolis, and when offered for sale in Smithfield after intense suffering from hard blows, driving over the stones, from hunger, thirst, fright, and the compressed state in which they are constrained to be packed; the sheep and beasts the whole time, from their raised temperature, clouding the atmosphere of Smithfield with dense exhalations from their bodies. The London butcher, carrying on a respectable trade, will at all times, when he enters the market, reject such cattle or sheep as are what is termed in a *mess;* that is, depressed, after excitation by being overlaid or overdriven, or such as have been more than usually troublesome in getting into the market, and, consequently, will be in a more worried and exhausted condition. It is to be observed that all animals brought into Smithfield, especially on the Monday's market-day, are more or less in the condition above described." He goes on to state that "a calculation has been made, that 512,000 serious and extensive œdematous bruises are, in the course of one year, discovered on cattle after they are slaughtered. The pain these bruises must occasion to the cattle, and the loss to the butcher or the public, is exclusive of those parts of the animal which suffer most from the conduct of the drovers, namely, the head, especially the nasal organs, and concussions of the brain by blows on the horns, besides the more acute suffering from blows on the hocks." The beef consumed in London, in 1836, amounted to 9½ millions of stones, which, at 6s. a stone, gives a total value of £2,850,000; and if its deterioration is taken only at half a farthing per pound, the annual loss sustained by the bruises of cattle alone will amount to £69,270 16s.*

(1314.) Cattle are slaughtered in a different manner from sheep, and the mode differs in different countries. In the great abbatoirs at Montmartre, in Paris, they are slaughtered by bisecting the spinal cord of the cervical vertebræ; and this is accomplished by the driving of a sharp-pointed chisel between the second and third vertebra, with a smart stroke of a mallet, while the animal is standing, when it drops, and death or insensibility instantly ensues, and the blood is let out immediately by opening the blood-vessels of the neck. The plan pursued in this country is, first to bring the ox down on his knees, and place his under-jaw upon the ground, by means of ropes fastened to his head and passed through an iron ring in the floor of the slaughter-house. He is then stunned with a few blows from an iron ax made for the purpose, on the forehead, the bone of which is usually driven into the brain. The animal then falls on its side, and the blood let out by the neck. Of the two modes the French is apparently less cruel; for some oxen require many blows to make them fall; I once witnessed an ox receive nine blows before he fell. I have heard it alleged by butchers that the separation of the spinal cord pro-

* The Question of the Smithfield Market Fully Considered. (1068)

ducing a general nervous convulsion throughout the body, prevents the blood flowing so rapidly and entirely out of it as when the ox is stunned in the forehead. The skin is then taken off to the knees, when the legs are disjointed, and also off the head. The carcass is then hung up by the tendons of the hough, on a stretcher, by a block and tackle, worked by a small winch, which keeps good what rope it winds up by a wheel and rachet.

(1315.) Every farm on which sheep are killed should have a proper slaughter-house, such as is seen at fig. 1, Plate I. at *y*, the ground-plan of which may be seen in fig. 2, plate II., where it is represented to be 10 feet by 9 feet, a space too small when cattle are slaughtered, but it is very rare that an ox is slaughtered on a farm, except when one is so that is likely to be lost by some acute disease, in which contingency the animal is slaughtered in the straw-barn and hung up by the baluks; but it is quite easy, when the slaughter-house is fitting up, to have a block and tackle and small winch, erected at a convenient corner, to be used on such occasions. The floor should be laid with clean-droved pavement, and have a decided slope to the side at which the drain is made to take away the dirty water occasioned by cleaning, which it should always be thoroughly. The walls should also be plastered, and a ventilator placed on the roof, to maintain a draft of air. The site chosen for the slaughter-house should be in a cool place, away from the sun's influence in summer, for in a heated apartment meat never becomes firm. A locked closet is useful to hold the knives, steel, and stretchers, and the outer door provided with a good thumb-latch and lock and key; the key, of course, always to remain in the farm-house until needed.

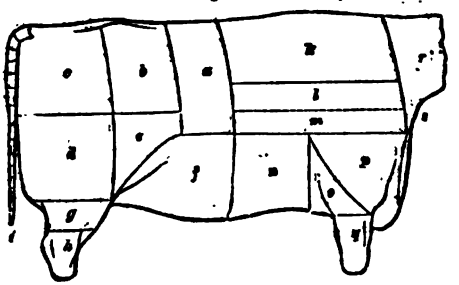
(1316.) It is the shepherd's duty to act the part of butcher on a farm. He should learn to slaughter gently, dress the carcass neatly and cleanly, in as plain a manner as possible, without *flourishes*, as the figures incised on the membraneous skin are called, and separate the valuable from the worthless portion of the entrails, keeping the loose fat by itself, and hang up the skin in a suitable place to dry. It is his duty also to keep the slaughter-house neat and clean.

(1317.) After the carcass has hung 24 hours, it should be cut down by the back-bone, or chine, into two *sides*. This is done either with the saw or chopper; the saw making the neatest job in the hands of an inexperienced butcher, though it is the most laborious, and with the chopper is the quickest, but by no means the neatest plan, especially in the hands of a careless fellow. In London the chine is equally divided between both sides, while in Scotland one side of a carcass of beef has a great deal more bone than the other, all the spinous processes of the vertebra being left on it. The bony is called the *lying* side of the meat. In London the divided processes in the fore-quarter are broken in the middle when warm, and chopped back with the flat side of the chopper, and this has the effect of thickening the fore and middle ribs considerably when cut up. The London butcher also cuts the joint above the hind knee, and, by making some incisions with a sharp knife, cuts the tendons there, and drops the flesh of the hind-quarter on the flanks and loins, which causes it to cut up thicker than in the Scotch mode. In opening the hind-quarter he also cuts the aitch-bone or pelvis through the center, which makes the rump look better. Some butchers in the north country score the fat of the *closing* of the hind-quarter, which has the effect of making that part of both heifer and ox look like the udder of an old cow. There is far too much of this scoring practiced in Scotland, and ought to be abandoned, and let the pieces have more their natural appearance.

(1318.) In cutting up a carcass of beef the London butcher displays great expertness; he not only discriminates between the qualities of its different parts, but can cut out any piece to gratify the taste of his customers. In this way he makes the best use of the carcass, realizes the largest value for it, while he gratifies the taste of every grade of customers. A figure of the Scotch and English modes of cutting up a carcass of beef will at once show you their difference, and on being informed where the valuable pieces lie, you will be enabled to judge whether the oxen you are breeding or feeding possess the properties that will enable you to demand the highest price for them.

(1319.) The Scotch mode of cutting up a carcass of beef is represented

Fig. 277.



THE SCOTCH MODE OF CUTTING UP A CARCASS OF BEEF.

in fig. 277, and these are the names of the different pieces of meat:

In the hind-quarter.		*In the fore-quarter*	
a, The sirloin, or back sey.		*k*, The spare rib or fore sey.	
b, .. hook-bone.		*l*, .. runner,	large and small.
c, .. buttock,	the rump.	*m*, .. runner,	
d, .. large round		*n*, .. nicholes.	
e, .. thick flank.		*o*, .. brisket.	
f, .. thin flank.		*p*, .. shoulder-lyar.	
g, .. small round.		*q*, .. nap or shin.	
h, .. hough.		*r*, .. neck.	
i, .. tail.		*s*, .. sticking piece.	

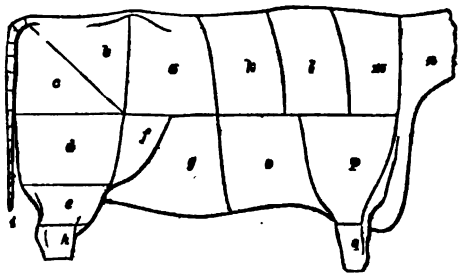
a the surloin is the principal roasting-piece, making a very handsome dish, and is a universal favorite. It consists of two portions, the Scotch and English sides, the former is the one above the lumbar bones, and is somewhat hard in ill-fed oxen; the latter consists of the muscles under these bones, and are generally covered with fine fat, and are exceedingly tender. The better the beast is fed the larger is the under muscle, better covered with fat, and more tender to eat; *b* the hook-bone and *c* the buttock are cut up for steaks, beef-steak pie, or minced collops, and both these, along with the sirloin, fetch the highest price; *d* is the large round, and *e* the small round, both well known as excellent pieces for salting and boiling, and are eaten cold with great relish; *h* the hough is peculiarly suited for boiling down for soup, having a large proportion of gelatinous matter. Brown soup is the principal dish made of the hough, but its decoction forms an excellent *stock* for various dishes, and will keep in a state of jelly for a considerable time. The synovial fat, skimmed off in boiling this piece, and poured upon oatmeal, seasoned with pepper and salt, constitutes the famous *fat brose* for which Scotland has long been celebrated. In the making, this brose should not be much stirred, and the oatmeal left among the fat gravy in small, dry lumps. It was of this piece that the old favorite soup of Scotland, called *skink*, was made. *e* is the thick and *f* the thin flank both excellent pieces for salting and boiling; *i* is the tail,

and insignificant as it may seem, it makes a soup of very fine flavor. Hotel-keepers have a trick of seasoning brown soup, or rather beef-tea, with a few joints of tail, and passing it off for genuine ox-tail soup. These are all the pieces which constitute the hind-quarter, and it will be seen that they are valuable both for roasting and boiling, not containing a single coarse piece. In the fore-quarter is *k*, the spare rib or fore-sey, the six ribs of the back end of which make an excellent roast, and when taken from the side opposite to the *lying* one, being free of the bones of the spine, makes a large one; and it also makes excellent beef-steaks and beef-steak pie. *l* and *m* are the two runners, and *n* the nine-holes, make salting and boiling pieces; but of these, the nine-holes is much the best, as it consists of layers of fat and lean without any bone; whereas the fore parts of the runners have a piece of the shoulder-blade in them, and every piece connected with that bone is more or less coarse-grained; *o* the brisket eats very well boiled fresh in broth, and may be corned and eaten with boiled greens or carrots; *p* the shoulder-lyar is a coarse piece, and fit only for boiling fresh to make into broth or beef-tea; *q* the nap or shin, is analogous to the hough of the hind-leg, but not so rich and fine, there being much less gelatine in it; *r* the neck makes good broth, and the sticking-piece *s* is a great favorite with some epicures, on account of the pieces of rich fat in it. It makes an excellent stew, as also sweet barley broth, and the meat eats well when boiled in it. These are all the pieces of the fore-quarter, and it will be seen that they consist chiefly of boiling-pieces, and some of them none of the finest, the roasting-piece being confined to the six ribs of the spare-rib *k*, and the finest boiling-piece, corned, only to be found in the nine-holes *n*.

(1320.) In some of the largest towns of Scotland a difference of 1d. per lb. may be made between the roasting and boiling pieces, but in most towns, and in the country villages, all the pieces realize the same prices, and even the houghs and shins fetch 3d. per lb.

(1321.) In the English mode the pieces are cut up somewhat differently,

Fig. 278.



THE ENGLISH MODE OF CUTTING UP A CARCASS OF BEEF

especially in the fore-quarter. Fig. 278 shows this mode, and it consists of the following pieces:

In the hind-quarter.

a, The loin.
b, .. rump.
c, .. aitch-bone.
d, .. buttock.
e, .. hock.
f, .. thick flank.
g, .. thin flank.
h, .. shin.
i, .. tail.

In the fore-quarter.

k, The fore rib.
l, .. middle rib.
m, .. chuck rib.
n, .. clod, and sticking, and neck.
o, .. brisket.
p, .. leg-of-mutton piece.
q, .. shin.

a, the loin, is the principal roasting piece; *b*, the rump, is the favorite steak-piece; *c*, the aitch-bone, the favorite stew; *d*, the buttock, *f*, the thick flank, and *g*, the thin flank, are all excellent boiling pieces when corned; *e*, the hock, and *h*, the shin, make soup, and afford *stock* for various purposes in the culinary art; and *i* is the tail for ox-tail soup—a favorite English luncheon. In the curious case of assessing damages against the Bank of England for removing the famous Cock eating-house in Threadneedle-street, it was produced in evidence, that, in the 3 years 1837–8–9, there had been 13,359 ox-tails used for soup; and as 36 tails make 10 gallons of soup, there had been served up 59,369 basins, at 11d. the basin, making the large amount of £2,720 13s. 4d. for this article alone.* These are all the pieces in the hind-quarter, and it will be seen they are valuable of their respective kinds. In the fore-quarter, *k*, the fore rib, *l*, middle rib, and *m*, chuck rib, are all roasting pieces, not alike good; but in removing the part of the shoulder-blade in the middle rib, the spare-ribs below make a good broil or roast; *n*, the neck, makes soup, being used fresh, boiled, and the back end of the brisket *o* is boiled corned, or stewed; *p*, the leg-of-mutton piece, is coarse, but is as frequently stewed as boiled; *q*, the shin, is put to the same uses as the shin and hock of the hind-quarter. On comparing the two modes of cutting up, it will be observed that in the English there are more roasting pieces than in the Scotch, a large proportion of the fore-quarter being used in that way. The plan, too, of cutting the line between *b* and *c*, the rump and aitch-bone in the hind-quarter, lays open the steak-pieces to better advantage than in the Scotch buttock, *c*, fig. 277. Extending the comparison from one part of the carcass to the other, in both methods, it will be seen that the most valuable pieces—the roasting—occupy its upper, and the less valuable—the boiling—its lower part. Every beast, therefore, that lays on beef more upon the upper parts of its body is more valuable than one that lays the same quantity of flesh on its lower parts.

(1322.) The relative values of the pieces differ much more in London than in Scotland. The rumps, loin and fore ribs fetch the highest price; then come the thick flank, buttock and middle rib; then the aitch-bone, thin flank, chuck-rib, brisket and leg-of-mutton piece; then the clod, sticking and neck; and last of all the legs and shins. In actual pecuniary value, the last may bear a proportion of only one-fourth of the highest price.

(1323.) Of the qualities of beef obtained from different breeds of cattle, I believe there is no better meat than from the West Highland breed for fineness of grain, and cutting up into convenient pieces for family use. The Galloways and Angus, when fattened in the English pastures, are great favorites in the London market. The Short-Horns afford excellent steaks, being thick of flesh, and the slice deep, large and juicy, and their corned flanks and nineholes are always thick, juicy and well mixed. The Herefords are somewhat similar to the Short-Horns, and the Devons may pernaps be classed among the Galloways and Angus, while the Welsh cannot be compared to the West Highland. So that, taking the breeds of Scotland as suppliers of good beef, they seem to be more valuable for the table than those of England. Any beef that I have seen of Irish beasts is inferior, but the cattle derived from Britain, fed on the pastures of Ireland, afford excellent meat. Shetland beef is the finest grained of all, but the pieces are very small.

(1324.) In regard to the proportion of beef and tallow generally obtained from cattle, Dr. Cleland states that of 14,566 head of cattle sold in the Glasgow market in 1822, averaging exactly

* John Bull, 16th January, 1841.

44 stones imperial, each yielded 5¼ stones, which is exactly ¼ of the weight of beef.* From 4 of the oxen experimented on by Mr. Stephenson, and which were slaughtered at the same time, these results were obtained:

Cattle.	Live weight.	Beef.		Tallow.		Hide.		Other offals.	
Nos.	Sts.	Sts.	lbs.	Sts.	lbs.	Sts.	lbs.	Sts.	lbs.
1.	112	66	2	8	10	5	11	32	5
2.	100	58	6	7	7	4	12	29	3
3.	108	62	3	9	0	4	12	26	13
4.	109	62	4	9	4	5	12	31	8

The proportion of tallow to beef is here nearer 1-7 than ¼ over the whole beasts; and there is another result worth attending to, which is that of Nos. 2 and 3, which had the same weight of hide, namely, 4 sts. 12 lbs.; No. 3 must have had the finest skin and touch, for its superiority in every respect is apparent, both in weight of tallow, which was 9 sts. to 7 sts. 7 lbs.; in weight of beef, which was as 62 sts. 3 lbs. to 58 sts. 6 lbs.; and in lightness of other offals, which were as 26 sts. 13 lbs. is to 29 sts. 3 lbs. Besides difference in quality of the same weight of hide, a lighter hide, under similar circumstances, will produce the same results as those above. For example: of two of the heifers fed by Mr. Howden on raw and steamed food, which afforded the same live weight when put up to feed, namely, 1022 lbs., and the same live weight after the experiment was concluded, namely, 1176 lbs., one had a light hide, that is, 52 lbs. weight, and the other a heavier one, 60 lbs., and the light one was accompanied with 620 lbs. of beef and 96 lbs. of tallow, while the heavier hide was associated with only 572 lbs. of beef and 80 lbs. of tallow. All these proportions very nearly indicate the tallow at 1-7 of the beef; but sometimes the proportion of tallow is very much greater and much less. I had a young Short-Horn cow which slipped her second calf, and was fed when she became dry, which was in November, and in May following was sold to the late Mr. Robert Small, flesher, Dundee, when she yielded 72½ stones of beef and 27 stones of tallow, being in the ratio of 2¾ to 1. On the other hand, Lord Kintore's large ox that was exhibited at the Highland and Agricultural Society's Show at Aberdeen in 1834 only yielded 16 sts. 7 lbs. of tallow, from 173 sts. 4 lbs of beef; being in the ratio of 10¼ to 1.† There are, perhaps, not sufficient data in existence to determine the true proportion of offal of all kinds to the beef of any given fat ox; but approximations have been made which may serve the purpose until the matter is investigated by direct experiment, under various circumstances. The dead weight bears to the live weight a ratio varying between .571 and .605 to 1; and on applying one or other multiple to the cases of the live weight, you will find a pretty correct approximation. The tallow is supposed to be 8-100 of the live weight, so that the multiple is the decimal of .08. The hide is supposed to be 5-100 of the live weight, so, to obtain its weight, a multiple of .05 should be used. The other offals are supposed to bear a ratio of about ¼ of the live weight, so that the multiple of .28 is as near as can be proposed under existing experience.‡

(1325.) *Beef* is the staple animal food of this country, and it is used in various states—fresh, salted, smoked, roasted, and boiled. When intended to be eaten fresh, "the *ribs* will keep the best, and with care will keep 5 or 6 days in summer, and in winter 10 days. The middle of the *loin* is the next best, and the *rump* the next. The *round* will not keep long, unless salted. The *brisket* is the worst, and will not keep longer than 3 days in summer, and a week in winter."§ In cooking, a piece of beef, consisting of four of the largest ribs, and weighing 11 lbs. 1 oz., was subjected to roasting by Mr. Donovan, and it lost during the process 2 lbs. 6 oz., of which 10 oz. were fat, and 1 lb. 12 oz. water dissipated by evaporation. On dissection, the bone weighed 16 oz., so that the weight of meat fit for the table was only 7 lbs. 11 oz. out of 11 lbs. 1 oz. It appears that when the butchers' price of ribs is 8½d. per lb., the cost of the meat when duly roasted is 11¼d. per lb., and the average loss arising from liquefaction of fat and evaporation of water is 18 per cent. With sirloins, at the price of 8½d. per lb., the meat cost, when roasted, 1s. 1 1-6d. per lb., at a loss of 20½ per cent. A loss of 18 per cent. was also sustained on boiling salted briskets; and on salted flanks at 6d. per lb. the meat cost 7½d. per lb., at a loss of 13 1-5 per cent.§ In regard to the power of the stomach to digest beef, that which is eaten boiled with salt only is digested in 2 hours 45 minutes. Beef, fresh, lean, and rarely roasted, and a beef-steak broiled, takes 3 hours to digest: that fresh and dry-roasted, and boiled, eaten with mustard, is digested in 3 hours and 30 minutes. Lean fresh beef fried takes 4 hours to digest, and old hard salted beef boiled does not digest in less than 4 hours 15 minutes. Fresh beef-suet boiled takes 5 hours 30 minutes to digest.¶

(1326.) The usual mode of preserving beef is by *salting*; and when intended to keep a long time, such as for the use of shipping, it is always salted with brine: but for family use it should be salted dry with good Liverpool salt, without saltpetre; for brine dispels the juice of the meat, and saltpetre only serves to make the meat dry, and give it a disagreeable and unnatural red color. Various experiments have been made to cure beef, with salt otherwise than by hand-rubbing, and in a short space of time; and also to preserve it from putrefaction by other means than salt. Those of Messrs. Payne and Ellmore, of London, consist in putting meat in a copper which is rendered air-tight, and an air-pump then creates a vacuum within it, thereby extracting all the air out of the meat; then brine is pumped in by pressure, which entering into every pore of the meat formerly occupied by the air, is said to place it in a state of preservation in a few minutes. M. Gannal, of France, preserved the carcass of an ox from putrefaction for 2 years by injecting

4 lbs. of saline mixture into the carotid artery. Whether any such contrivance can be made available for family purposes seems doubtful. Up to the 10th October, 1842, salted beef imported was subject to a duty of 12s. per cwt.; since that date both salted and fresh pay a duty of 8s. per cwt. from foreign countries, and 2s. from British possessions. Up to that period the importation of live stock was prohibited, by the same act; bulls and oxen can now be imported from foreign countries at £1 each, and from British possessions, 10s.; cows, 15s. and 7s. 6d.; calves, 10s. and 5s.; sheep, 3s. and 1s. 6d., and lambs, 2s. and 1s. each.* Salted beef cured with wood smoke is converted into a ham, and very highly relished. The tierce of salted beef for the navy contains 300 lbs., consisting of 38 pieces of 8 lbs. each.

(1327.) Cattle are useful to man in various other ways than affording food from their flesh, their offals of tallow, hides, and horns, forming extensive articles of commerce. Of the *hide*, the characteristics of a good one for strong purposes are strength in its middle or *butt*, as it is called, and light on the edges or *offal*. A bad hide is the opposite of this, thick in the edges and thin in the middle. A good hide has a firm texture, a bad one loose and soft. A hide improves as the summer advances, and it continues to improve after the new coat of hair in autumn until November or December, when the coat gets rough from the coldness of the season, and the hide is then in its best state. It is surprising how a hide improves in thickness after the cold weather has set in. The sort of food does not seem to affect the quality of the hide; but the better it is, and the better cattle have been fed, and the longer they have been well fed, even from a calf, the better the hide. From what has been said of the effect of weather upon the hide, it seems a natural conclusion that a hide is better from an ox that has been fed in the open air than from one fed in a byre. Dirt adhering to a hide injures it, particularly in byre-fed animals; and anything that punctures a hide, such as *warbles* arising from certain insects, is also injurious. The best hides are obtained from the West Highland breed of cattle. The Short-Horns produce the thinnest hides, the Aberdeenshire the next, and then the Angus. Of the same breed, the ox affords the strongest hide; but as hides are applied to various uses, the cows, provided it be large, may be as valuable as an ox's. The bull's hide is the least valuable. Hides are imported from Russia and South America; and the number imported in 1838 was 301,890. The duty on hides, by the new Tariff, is 6d. per cwt. for dried and 3d. for wet.

(1328.) Hides, when deprived of their hair, are converted into leather by infusion of the astringent property of bark. The old plan of tanning used to occupy a long time; but such was the value of the process, that the old tanners used to pride themselves in producing a substantial article. More recent discoveries have prompted tanners to hasten the process, much to the injury of the article produced. Strong infusions of bark make leather brittle; 100 lbs. of skin, quickly tanned in a strong infusion, produce 137 lbs. of leather; while a weak infusion produces only 117¼, the additional 19¾ lbs. serving only to deteriorate the leather, and cause it to contain much less textile animal solid. Leather thus highly charged with tannin is so spongy as to allow moisture to pass readily through its pores, to the great discomfort and danger of persons who wear shoes made of it. The proper mode of tanning lasts a year or a year and half, according to the quality of the leather wanted, and the nature of the hides. A perfect leather is recognized by its section, which should have a glistening marbled appearance, without any white streaks in the middle.† Leather is applied to many important purposes, being made into harness for agricultural and other uses. It is used to line the powder magazines of ships-of-war; to make carding-machines for cotton and other mills; belts to drive machinery; to make soles of shoes; and, when japanned, to cover carriages. Calves' leather is used in bookbinding. The duty on tanned hides is now fixed at £10 per £100 value. The hair taken off hides in tanning is employed to mix with plaster, and is surreptitiously put into a hair-mattresses. The duty imposed on foreign cattle hair is 6d. per cwt.

(1329.) "The principal substances of which *glue* is made," says Dr. Ure, "are the paring of ox and other thick hides, which form the strongest article; the refuse of the leather-dresser; both afford from 45 to 55 per cent. of glue. The tendons, and many other offals of slaughter-houses, also afford materials, though of an inferior quality, for the purpose. The refuse of tanneries—such as the ears of oxen, calves, sheep, &c.—are better articles: but parings of parchment, old gloves, and in fact animal skins in any form, uncombined with tanning, may be made into glue."‡

(1330.) *Ox-tallow* is of great importance in the arts. Candles and soap are made of it, and it enters largely into the dressing of leather and the use of machinery. Large quantities are annually imported from Russia. Of the exports from St. Petersburgh, consisting of 4¼ millions of poods, at least 3¼ millions are exported to this country, at the value of £2,306,150, at £35 per ton.‖ Of the quantity imported in 1837, 1,294,000 cwts. were retained for home consumption. Ox-tallow consists of 76 parts of stearine and 24 of oleine out of the 100. The duty on tallow by the new Tariff is 3s. 2d. per cwt. from foreign countries, and 3d. per cwt. from the Colonies.

(1331.) The *horns* of oxen and sheep are used for many purposes. "The horn consists of two parts: an outward horny case, and an inward conical-shaped substance, somewhat intermediate between indurated hair and bone," called the *flint* of the horn. "These two parts are separated by means of a blow on a block of wood. The horny exterior is then cut into three portions by means of a frame-saw. The lowest of these, next the root of the horn, after undergoing several processes by which it is rendered flat, is made into combs. The middle of the horn, after being flattened by heat and its transparency improved by oil, is split into thin layers, and forms a substitute for glass in lanterns of the commonest kind. The tip of the horn is used by the makers of knife-handles and of the tops of whips, and for other similar purposes. The interior, or core of the horn, is boiled down in water. A large quantity of fat rises to the surface; this is put aside, and sold to the makers of yellow soap. The liquid itself is used as a kind of glue, and is purchased by the cloth-dresser for stiffening. The bony substance which remains behind is then sent

‡ Ibid., art. *Glue*.
‖ McCulloch's Dictionary of Commerce, art. *Tallow*.

to the mill, and, being ground down, is sold to the farmers for manure. Besides these various purposes to which the different parts of the horn are applied, the clippings which arise in comb-making are sold to the farmers at about 1s. per bushel. The shavings which form the refuse of the lantern-makers are sold as manure."* Horn, as is well known, is easily rendered soft and pliant in warm water; and by this, and the property of adhesion like glue, large plates of horn can be made by cementing together the edges of small pieces rendered flat by a peculiar process, as a substitute for glass. For this purpose, the horns of goats and sheep are preferred, being whiter and more transparent than those of any other animal. Imitation of tortoise-shell can be given to horn by the use of various metallic solutions. Horn, also, when softened, can be imprinted with any pattern by means of dies.† The duty on horns is 1s. per ton, and on hoofs £1 per £100 value.

34. TREATMENT OF FARM-HORSES IN WINTER.

"But loose betimes, and through the shallow pond
Drive the tired team, and bed them snug and warm;
And with no stinting hand their toil reward."

GRAHAM.

(1332.) With the exception of a few weeks in summer, farm-horses occupy their stable all the year round. It is situate at O, fig. 3, Plate III., where it is seen with two doors and two windows in front, and surmounted with two ventilators on the roof. Its plan may be seen at O, fig. 4, Plate IV., where it is represented as containing 12 stalls. The fitting-up of the stable in all its particulars of stalls, floor, and accommodation, having already been fully dilated on when treating of the steading, from (23) to (34), more seems unnecessary to be said in regard to these particulars in this place.

(1333.) Farm-horses are under the immediate charge of the plowmen, one of whom works a pair, and keeps possession of them generally during the whole period of his engagement. This is a favorable arrangement for the horses, as they work much more steadily under the guidance of the same driver, than when changed into the hands of different; and it is also better for the plowman himself, as he will perform his work much more satisfactorily to himself, as well as his employer, with horses familiarized to him than strange ones. In fact, the man and his horses must become acquainted before they can understand each other; and when the peculiarities of each party are mutually understood, work becomes more easy, and of course greater attention can be bestowed upon it. Some horses show great attachment to their driver, and will do whatever he desires without hesitation; others show no particular regard; and the same difference may be remarked of plowmen toward their horses. Upon the whole, however, there seems to be a very good understanding in this country between the plowman and his horses; and, indeed, independently of this, I believe there are few masters disposed to allow their horses to be ill treated, because there is no occasion for it; for horses which have been brought up upon a farm, in going through the same routine of work every year, become so well acquainted with what they have to do in every department of work, that should a misunderstanding arise between them and their driver, you may safely conclude that the driver is in the wrong.

(1334.) The treatment which farm-horses usually receive in winter is this: The plowmen, when single, get up and breakfast before daybreak, and by that time go to the stable, where the first thing they do is to take

* Babbage on the Economy of Machinery and Manufactures. † Ure's Dictionary of the Arts, art. *Horn*.

out the horses to the water.* While the horses are out of the stable the rest of the men take the opportunity of cleansing away the dung and soiled litter made during the night, into the adjoining court-yard K, fig. 3, Plate III., with their shovels (fig. 149), wheelbarrow and besoms. While the horses are absent usually one of the plowmen supplies each corn-box with corn from the corn-chest. It is not an unusual practice to put the harness on while the horses are engaged with the corn; but this should by no means be allowed. Let the horses enjoy their food in peace, as many of them, from sanguine temperament or greed, cannot divest themselves of the feeling that they are about to be taken away from their corn, if worked about during the time of feeding. The harness can be quickly enough put on after the feed is eaten, as well as the horses curried and brushed and the mane and tail combed. A very common practice, however, is to dress the horses while eating, which should not be allowed. A better plan in all respects is to let the horses eat their corn undisturbed, and then dress and harness them afterward, and it has the advantage of allowing them a little time between eating their corn and going out to work, which, if of a violent nature, undertaken with a full stomach, may bring on an attack of *batts* or colic.† The plan which I have just described is intended to apply to single men who live together, and who have their own victuals to cook. But should the plowmen be married men the best arrangement for them is to go to the stable when they rise, water the horses, clean the stable, corn the horses, bind them up, and, shutting the door, leave them in quiet to eat their food as long as they themselves are in taking their breakfast, which by that time should be made ready by their wives. On returning to the stable after breakfast the horses should then be dressed, combed and harnessed, when they will come out quite fresh and clean to go to yoke and after their feed has been a little time in their stomachs.

[* It can nowhere, we trust, be unseasonable to exhort the farmer to give attention, habitually, to the *treatment* of all domestic animals, and more especially to those to whose labor he owes the fruits and profits of his industry. Common humanity, to say nothing of Christian benevolence, demands, and the more especially as all power of complaint is denied them, that every animal that works should be not only *suitably and well fed*, but that it should be saved from suffering by thirst; that its skin be kept clean and in good condition, which a few minutes' use of the curry-comb and brush will effect, and that its eyes and feet should be often examined and protected from injury; while a sore back or gall on any part of the body should be deemed a disgrace to master as well as man. Trite and commonplace as this word in their favor may appear, we cannot withhold it, in view of so much neglect in working animals as we see committed on many farms that fall under our observation; for whether we speak of it or not, we never visit or pass a farm without noticing these things. Those whose benevolence does not move them thus to care for the feelings of the humblest beast in their employment should yet be prompted to look after their comfort, as well in the stable as the field—whether in or out of harness—by the consideration that a sufficiency of substantial food, personal care and kind treatment always beget proportionate willingness and efficiency—as much or even more with the brute than with the human. For ourselves, we take the occasion to reiterate our persuasion that the almost universal preference for the horse over the ox and mule, as a beast of labor and burden, has its origin, in a great measure, in—[alas! not *bygone*] ages of war and barbarism, which made power and fleetness identical; and that with a vast saving of national wealth these more economical animals might and ought to be substituted for the short-lived and perishable horse. *Ed. Farm. Lib.*]

[† We well remember, when residing in Baltimore, to have been within an ace of killing one of the best geldings we ever straddled, by giving him a brisk eight-mile an-hour canter immediately after he had swallowed his oats. As soon as he took the spur we knew there was something wrong; and, turning back at the end of the first mile, scarcely got him in his stall before he was prostrate and swollen like an inflated bladder. By dint of hard rubbing and the prompt use of enemas he was fortunately saved for some years more of gallant service. *Ed. Farm. Lib.*]

(1335.) Men and horses continue at work until 12 noon, when they come home, the horses to get a drink of water and a feed of corn and the men their dinner. Some keep the harness on the horses during this short interval, but it should be taken off to allow both horses and harness to cool, and at any rate the horses will be much more comfortable without it, and it can be taken off and put on again in a few seconds; and, besides, the oftener the men are exercised in this way they will become the more expert. When the work is in a distant field, rather than come home between yokings, it is the practice of some farmers to feed the horses in the field out of the nose-bags; and the men to take their dinners with them, or be carried to them in the field by their own people. This plan may do for a day or two in good weather on a particular occasion; but it is by no means a good one for the horses, for no mode so effectual for giving them a chill could be contrived than to cause them to stand on a head ridge for nearly an hour on a winter day, after working some hours. A smart walk home can do them no harm, and if time is pressing for the work to be done, let the horses remain a shorter time in the stable. The men themselves will feel infinitely more comfortable to get dinner at home. There is a practice in England connected with this subject that I think highly objectionable, which is, doing a day's work in one yoking. For a certain time horses, like men, will work with spirit, but if made to work beyond that time they not only lose strength, but their very spirit is wrung out of them, and in the latter part of the time will do their work in a careless manner. Horses thus kept for 7 or 8 hours upon the stretch at work must be injured in their constitution, or, if able to withstand it, it must be either at the expense of bad work executed at the latter part of the yoking, or of curtailment of hours of a full day's work, or of extraordinary feeding, either of which expedients is no compensation for bad management. Common sense tells a man that it is much better for a horse to be worked a few hours smartly, and have his hunger satisfied before feeling fatigue, when he will again be able to proceed with fresh vigor, than to be worked the same number of hours without feeding. I can see no possible objection that can be offered to horses receiving a little rest and food in the middle of a long day's work, but I see many and serious ones to their working all day long without rest and food. Suppose, then, that men and horses come home at midday, the usual dinner-hour of agricultural laborers, the first thing to be done is to give the horses a drink at the pond on the way to the stable; and there should then be no washing of legs. From the water the horses proceed to the stable, where the harness is taken off; and as the men then have nothing else to do, every man gets the corn from the steward at the corn-chest for his own horses in nose-bags, or in a small corn-trough or box which each man keeps for the purpose. Of these two sorts of things for carrying the corn in the stable I prefer the trough, as being most easily filled and emptied of corn. The horses are bound up, the stable door shut, and the men go to their own houses to dinner, which should be in readiness for them. After dinner they proceed to the stable, when the horses will be found to have finished their feed, and when a small quantity of fodder may be thrown before them fresh from the straw-barn, for at this time of year farm-horses get no hay. The men may have a few minutes to converse until 10 minutes to 1 P. M., when they should give the horses a slight wisp down, put on the harness, comb out their tails and manes, and be all ready to put on the bridles the moment 1 o'clock arrives, which is announced by the steward.*

[* In our country, in the towns generally, the "ten-hour system," as it is called, prevails, while in the country the practice is to be up by daylight, winter and summer, and to labor until dark,

(1336.) The afternoon yoking is short, not lasting longer than sunset, which at this season is before 4 P. M., when the horses are loosened out of yoke and brought home. After drinking again at the pond they are gently passed through it to wash off any mud from their legs and feet, which they can hardly escape collecting in winter. But in washing the men should be prohibited wetting their horses above the knees, which they are most ready to do should there be any mud upon the thighs and belly; and to render this prohibition effectual, I have expressly stated, when speaking of the construction of a horse-pond (125), that it should not be made deeper at any part than will take a horse to the knee. There is danger of contracting inflammation of bowels or colic in washing the bellies of horses in winter; and to treat mares in foal—which they will be at this time of year—in this way is little short of madness. If the feet and shanks are cleared of mud, that is all that is required in the way of washing in winter. On the horses entering the stable and having their harness taken off, they are well strapped down by the men with a wisp of straw. Usually two wisps are used, one in each hand; but I am sure the work is much better done with one, shifting the hand as occasion requires, and directing the attention to one place at a time. A couple of wisps may very properly be taken to rub down the legs and clean the pasterns, rendering them as dry as a moderate length of time will admit. All this is done not quite in the dark, for there is still a glimmer of twilight in the western horizon, but too much in the dark to allow its being well done. After the horses are rubbed down, the men proceed to the straw-barn and bundle each 4 windlings of fodder-straw, one to be given to each horse just now, and the other two to be put above the stalls across the small fillets *p*, fig. 7, which run along the stable for the purpose.

(1337.) When 8 P. M. arrives, the steward, provided with light in a lantern, summons the men to the stable to give the horses a grooming for the night and their suppers. The sound of a horn, or ringing of a bell, are the usual calls on the occasion, which the men are ready to obey. I may here remark in passing, that the sound of a horn is pleasing in a calm winter night, and I never hear it without its recalling to my mind the goatherds' horns in Switzerland, pouring out their mellow and prayer-like strains at sunset, the time for gathering the flocks together from the mountain sides, on their way to the folds in the neighboring village. Lights are placed at convenient distances in the stable to let the men see to groom the horses. The grooming consists first in currying the horse with the curry-comb, to free him of all dirt that may have adhered to the skin during the day, and which has now become dry and flies off. A wisping of straw removes the roughest of the dirt loosened by the curry-comb. The legs ought to be thoroughly wisped, not only to make them clean, but dry of any moisture that may have been left in the evening, and at this time the feet should be picked clear by the foot-picker of any dirt adhering around between the shoe and the foot. The brush is then used to remove the remaining and finer portions of dust, from which, in its turn, it is cleared by a few rasps of the curry-comb. The wisping and brushing, if done with some force

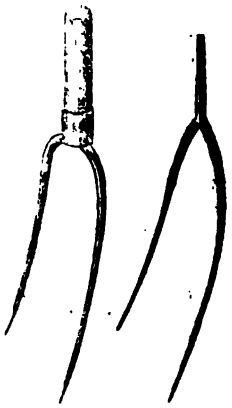
---

with the usual intervals for meals. But while mechanics in town, under a vigilant boss, are at work, they keep working all the time; not so with men hired by the day at the *public* expense to work *and to vote!* In the country, too, if a stage drives along the road, you will see a man stop his plow and a whole gang let fall their hoes or axes to look at the passer-by, as if they had never seen a stage or a horseman before.

In the South the slaves "knock off" for two hours at midday in very hot weather, but being almost universally *tasked*, where the work will admit of it, they generally get through in less than ten hours. *Ed. Farm. Lib.*]

and dexterity, with a combing of the tail and mane, should render the horse pretty clean; but there are more ways than one of grooming a horse, as may be witnessed by the skimming and careless way in which some plowmen do it. It is true that the rough coat of a farm-horse is not easily cleaned, and more especially in a work-stable where there is much dust floating about and no horse-clothes in use; but rough as it is, it may be *clean* though not *sleek*; and it is the duty of the steward to see that the grooming is done in an efficient manner. A slap of the hand upon the horse will soon let you know whether there is any loose dust in his hair. Attendance at this time will give you an insight into the manner in which farm-horses ought to be cleaned and generally treated in the stable. The straw of the bedding is then shaken up with a fork such as in fig. 279. This figure has rather longer prongs, and is too sharp for a *stable fork*, which is most handy for shaking up straw when about 5 feet in length, and least dangerous of injuring the legs of the horses by puncture when blunt. The united prongs terminate at their upper end in a sort of spike or tine, which is driven into a hooped ash shaft, as better seen in fig. 280, which is a steel-pronged fork of the form used in Lincolnshire, and is an excellent instrument for working among straw. This mode of mounting a fork is much better than with socket and nail, which are apt to become loose and catch the straw. The horses then get their feed of oats, after which the lights are removed and the stable-doors barred and locked by the steward, who is custodier of the key. In some stables a bed is provided for a lad, that he may be present to relieve any accident or illness that may befall any of the horses; but where the stalls are properly constructed, there is little chance of any horse strangling himself with the collar, or any becoming sick where a proper ventilation is established.

Fig. 279. Fig. 280.



THE COMMON FORK. THE LINCOLNSHIRE STEEL FORK.

(1338.) In winter it is usual to give farm-horses a mash, once, at least, and sometimes thrice a week. The mash consists of either steamed potatoes, boiled barley or oats, mixed sometimes with bran, and sometimes seasoned with salt. The articles are prepared in the boiler *b'* in the boiling-house U, fig. 4, Plate IV., in the afternoon by the cattle-man or a field-worker, or any other person appointed to do it, and put into tubs, into which it is carried to the stable by the men, and dealt out in the troughs used to carry the corn to the horses, with a shovel. It is warm enough when the hand can bear the heat. The quantity of corn put into the boiler is usually as much as that given raw, and in preparation swells out considerably, so that the mash acquires considerable bulk. The horses are exceedingly fond of mash, and when the night arrives for its being dealt out, show unequivocal symptoms of impatience until they receive it. The quantity of raw oats given to farm-horses, when on full feed, is 3 lippies a day, by measure and not by weight; but taking horse-corn at almost the highest figure of 60 lbs. per firlot, each feed will weigh 3¾ lbs., the daily allowance amounting to 11¼ lbs.; but the lippy-measure, when the corn is dealt out, is most frequently not struck, but heaped, or at least hand-waved, so that the full allowance will weigh even more than this. As horses work only 7 or 8 hours a day in winter, their feeding is lessened to perhaps 2 full feeds a day or 7½ lbs., divided into three portions, namely, a full feed

in the morning, ½ feed at midday, and ½ feed at night; and on the nights the mash is given, the evening ½-feed of oats is saved. One season, as a mash, I tried steamed potatoes, with salt alone, of which the horses were excessively fond, and received three times a week, and on which they became very sleek in the skin and fat, notwithstanding much heavy work; but in spring, when the long day field-work was resumed, they seemed to me to be all affected with shortness of wind. Have cooked potatoes necessarily this effect upon horses? I may mention that oats, when desired to be cooked, must be *boiled*, as steaming only burns the outside, and does not penetrate into the interior, having somewhat the effect of kiln-drying. Oats, in fact, and barley too, must be macerated to be cooked, and to do this effectually *warm* water must be used.

(1339.) I have often thought that the usual careless manner of placing the lights in the stable in the evening is highly dangerous to the safety of the building; and yet, in the most crowded and dirty stables, no accidents of fire almost ever happen. Sometimes the candle is stuck against a wall by a bit of its own melted grease; at other times it hangs by a string from the roof in an open lantern, set apparently on purpose to light straws. A good stable lantern is still a desideratum; and it should be made to hold a candle, and not an oil-lamp, as being the most cleanly mode of light for carrying about; and if the candle could be made to require no snuffing it would be perfect. A common tin lantern, with a horn glass, is what is commonly in use to carry the candle in the air; but when it gets blackened with smoke in the inside, it is of little use to give light outside. I have seen a globe lantern of glass made very strong for use on board of ship, but it has an oil-lamp. I observe Messrs. Palmer and Company, London, advertising a "weather *candle*-lamp for *safety*, and for use in *wind* and *rain*, and which requires *no snuffing*." The candle costs 8½d. per lb., and burns 5 hours for 1d. I have not seen this lamp, but judging from its figure, and if the glass is made strong enough, it would seem to answer the purpose, and is certainly not dear. If safe, it might be taken into the straw-barn, hammels, &c. at night.

(1340.) This is the usual routine of the treatment of farm-horses in winter, and when followed with some discernment in regard to the state of the weather, is capable of keeping them in health and condition. The horses are themselves the better of being out every day; but the species of work which they should do daily must be determined by the state of the weather and the soil. In very wet, frosty, or snowy weather, the soil cannot be touched; but then threshing and carrying corn to market may be conducted to advantage, and the dung from the courts may be taken out to the fields in which it is proposed to make dung-hills. This latter piece of work is best done when the ground is frozen hard. When heavy snow falls, nothing can be done out of doors with horses, except threshing when the machine is impelled with horse-power. In a very rainy day, the horses should not go out, as everything about them, as well as the men, become soaked; and before both or either can be again made comfortable, the germs of serious disease may be laid in both. When it is fair above, on the other hand, however cold the air or wet the soil, some of the sorts of out-door work mentioned above may be done by the horses; and it is better for them to work only one yoking a day than to stand idle in the stable. Work-horses soon show symptoms of impatience when confined in the stable even for a day, on Sundays, for example; and when the confinement is much prolonged, they even become troublesome. When such occasions happen, which they do in continued snow-storms, with the ground covered deep, the horses should be ridden out for some time every

day, and groomed as carefully as when at work. Exercise is necessary to prevent thickening of the heels, a shot of grease, or a common cold. Fat horses, when unaccustomed to exercise, are liable to molten grease.

(1341.) It is an advisable plan for a farmer to breed his own horses; and, on a farm which employs 6 pairs, two mares might easily bear foals every year, and perform their share of the work at the same time, without injury to themselves. The advantage of breeding working stock at home is, that, having been born and brought up upon the ground, they not only become naturalized to the products of its particular soil, and thrive the better upon them, but also become familiarized with every person and every field upon it, and are broken into work without trouble or risk. The two mares should work together, and be driven by a steady plowman; and their work should almost always be confined to plowing, particularly in winter and spring, when they are big with young, for the shaking in the shafts of a cart is nothing in their favor. In driving home turnips, and leading out dung in winter, over most probably not the smoothest of roads, mares in foal should not be employed, their driver rather plowing with them, when that operation can be performed, or assisting the other men at their carts with manual labor.

(1342.) Supposing, then, that one or two mares bear foals every year, the young horses, their produce, consisting of foals, year-olds, and two-year-olds, should be accommodated in the steading N, figs. 3 and 4, Plates III. and IV., according to age, where there are more than one of the same age, the older being apt to knock about the younger; but where one only of every age is brought up, they may be placed together for the sake of companionship, as horses are very social animals, and they learn to accommodate themselves to one another's tempers. Where blood foals are bred as well as draft, they should have separate hammels, the latter being too rough and overbearing, but the bloods generally contrive to obtain the mastery. Young horses never receive any grooming, and are even seldom handled; but they should all be accustomed to be led in a halter from their youngest period.

(1343.) The food usually given to young horses in winter is oat-straw for fodder, and a few oats; and where they are wintered among the young cattle in the large court K, they have the chance of a few pickings of corn from the corn-barn, or the refuse of hay from the litter of the work-horse stable, and then they seldom get corn. The fact is, young horses are generally unjustly dealt with; they are too much stinted of nourishing food, and the consequences established by the treatment are a smallness of bone which deprives them of requisite strength for their work, and a dullness of spirits which renders their work a burden to them. I speak of what I have seen of the way in which a large proportion of the farm-horses of this country are brought up when young. Their treatment seems to be derived from the opinion that very little nourishing meat should be given to young horses. Instead of this, they should receive a stated allowance of corn—and if bruised, so much the better—according to their ages; and when a mash is given to the work-horses, the young ones should always have a share. Should a mash be grudged as being too extravagant for young horses, they should get Swedish turnips or potatoes every day; for some moist food is requisite with dry fodder and corn.

(1344.) The names usually given to the different states of the horse are these: The new-born young is called a *foal*, a male one being a *colt foal* and a female a *filly foal*. After being weaned, the foals are called *colt* or *filly*, according to the sex, which the male retains until broken in for work, when he is a *gelding* or *horse*, which he retains all his life; and the

filly is then changed into *mare*. When the colt is not castrated, he is an *entire colt;* which name he retains until he serves mares, when he is a *stallion* or *entire horse*. A mare, when served, is said to be *covered by* or *stinted to* a particular stallion; and after she has borne a foal, then she is a *brood-mare*, until she ceases to bear, when she is a *barren mare* or *eild mare;* and when dry of milk, she is said to be *yeld*. A mare, while bearing a foal, is said to be *in foal*.*

(1345.) You have seen that though cattle gain weight when fed on cooked food, compared to others fed on the same substances in a raw state; yet the expense of cooking counterbalances any advantage gained in weight, and it is therefore inexpedient to undertake the trouble of it. These results might have been anticipated from the peculiar functions of the stomach of the ox; for he *chews the cud*, that is to say, he masticates the food, as he takes it into his mouth in a very imperfect manner, rendering it only so small as to be able to swallow it with some degree of force, in which state it reaches the paunch or first stomach; where, if it decomposes immediately and generates gas, it produces the disease of the *hoven*, which has been spoken of already (1294). But should it not decompose—which is the usual condition of the food—it is again brought up to the mouth, and undergoes a thorough mastication, after which it is swallowed and finds its way to the stomach, which contains the gastric juice, there to be digested for the purpose of being assimilated into the system. Now, all that we can do for the ox in cooking his food, is to save him the trouble of chewing the cud, and to put the food into that state in which it is at once fit to be acted upon by the gastric juice. In doing this, we attempt to imitate and enter into competition with a complicated natural process, and, as might be expected in the circumstances, exhibit our inferiority. In the state, however, in which cooked food is presented to the ox, chewing the cud is not altogether saved him, as the straw which he chooses to eat undergoes that operation, and therefore assists in keeping that important function in exercise. It is doubtful that the ox would retain his wonted good health, were we able entirely to suspend the action of that function in him; and it is therefore questionable policy to attempt it to a farther degree than to reduce his food so small as to render it fit to enter the paunch, with still less mastication than he would have to give it in its ordinary state.

(1346.) The case, however, of the horse is very different. His is a single or simple stomach, which must be filled at once with well-masticated food, before the gastric juice can act upon it in a proper manner; and should any food which enters it in an insufficiently masticated state, escape beyond the influence of the juice into the bowels, it may decompose there, generate gas, and produce the analogous disease of *hoven* in cattle, namely, flatulent colic or *batts*. To render food in such a state at first as shall save the horses the trouble of mastication, is, therefore, to do him a good service; and hence, cooked food is in a proper state for feeding a horse, and it has also been proved to be economical. Still, the cooking will be carried to an injurious degree, if it shall, by dint of ease of deglutition, prevent the flow of the sufficient quantity of saliva into the stomach which is necessary to complete digestion—"the quantity of which," says Professor Dick, "is almost incredible to those who have not had an opportunity of ascertaining it, but which the following fact will testify. A black horse had received a wound in the parotid duct, which became fistulous. When his jaws were in motion in the act of eating hay, I had the curiosity to collect in a glass measure the quantity which flowed during 1 minute, by a stop watch; and it amounted to nearly 2 drachms more than 2 oz. in that time. Now, if we calculate that the parotid gland on the opposite cheek poured into the mouth the same quantity in the same time, and allow that the sublingual and sub-maxillary gland, on each side combined, pour into the mouth a quantity equal to the two parotids, we then have no less than 8 oz. of saliva passing into the mouth of a horse in one minute, for the purpose of softening the food and preparing it for digestion."† Yet it is impossible for any horse to swallow food in the most favorable state it can be made for swallowing, without moving his jaws to a certain degree, and this insures a certain quantity of saliva entering his stomach.

(1347.) But more than this, cooked food may be presented in too nutritious a state for the stomach; and there may be, on the other hand, too little nutriment in the food given; for, "the digestive organs of the horse, like those of the ox," says Professor Dick, "are very capacious, and are evidently intended to take in a large proportion of matter containing a small proportion of nutriment; and if the food upon which they are made to live is of too rich a quality, there is, by the excitement produced, an increase of the peristaltic motion, in order to throw off the superabundant quantity which has been taken into the stomach and bowels. It is necessary to give, therefore, a certain quantity of *bulk, to separate, perhaps, the particles of nutritious matter*, that the bowels may be enabled to act upon it properly. A horse could not live so well on oats, if fed entirely upon them, as when a portion of fodder is given; with them a certain quantity is required. But this may be carried too far, and the animal may have his bowels *loaded* with too large a quantity of unnutritious food;" as witness the nature of the *steep* before alluded to; "and nothing less than such a mass as will render him incapable to perform any active exertion, will be sufficient to afford him even a scanty degree of nourishment. A horse living on straw in a straw-yard be-

[* Some use the foolish expression, *out* of such a horse or stallion, instead of *by* the stallion and *out* of the mare; and, again, they say "My horse was *sired* by Messenger," instead of *got* by Messenger. As John Randolph once observed, they might as well say he was *damn'd* by a particular mare. There are proprieties and technicalities belonging to every sort of business, which should be learned at least by those who follow, or are immediately interested in it.

Ed. Farm. Lib.]

† Quarterly Journal of Agriculture, vol. iii.

comes pot-bellied. Hence it is, that a proper arrangement in the properties and proportions of his food becomes a matter of important consideration."* These and the preceding remarks comprehend all the rationale of feeding both cattle and horses, and, if carefully considered, may conduct you to adopt such an appropriate mixture of materials in your possession as may serve to maintain the strength, good health and condition of your horses, on the one hand, and to do so economically on the other. Meantime, I shall enumerate a few of the attempts that have hitherto been made of making mixtures of food for horses, with the view of ascertaining whether cooked or raw food, in a prepared or natural state, maintains horses in the best order.

(1348.) The most careful set of experiments that have yet been recorded in supporting *farm-horses* on *boiled* and *raw* grain, and on raw grain *prepared* and in a *natural* state, was made by Mr. James Cowie. Halkerton Mains, Kincardineshire. He subjected no fewer than 12 horses to the experiment, dividing them into 3 sets of 4 each, and keeping each set on a separate fare. The horses were weighed on 1st March, when the experiment began, and their weights varied from 9 cwts. 3 qrs. to 12 cwts. 1 qr. 4 lbs.; and they were again weighed on 1st May, at the end of the experiment, and their weights then ranged from 9 cwts. 2 qrs. 23 lbs. to 12 cwts. 1 qr. 14 lbs. Thus the range of weight did vary much at both the periods, though the individual weights did. Their ages ranged from 4 to 12 years.

(1349.) The facts brought out in this experiment were, that the horses fed on *unbruised raw* and on *boiled* grain, gave results so very nearly alike that it seems inexpedient to incur the expense of *cooking* food for horses, as that costs about 1½d. on two feeds for each horse. This is a rather remarkable result, for one should have expected that the *boiled* grain would have had the advantage. *Bruised raw* grain seems the most nourishing, and, in not requiring cooking, of course the most economical mode of feeding work-horses. For, all the horses that had been on *boiled* and *unbruised raw* grain lost 70 lbs. each; and that amount of loss in an animal of 10 cwts. or 12 cwts. is considerable; whereas those which had been on *bruised* grain, though given raw, either gained weight or lost none. And as to the economy of using grain in this state, *besides the cooking*, it is alleged that boiled whole grain passes through the horse undigested as well as raw grain when whole, and that the quantity which thus escapes is equal to 1-6 of what a horse consumes; whereas, the grain that is *bruised* undergoes a considerable degree of digestion at least, before passing away. If the loss is taken at 1-6 on a horse which gets 12 lbs. daily of oats whole, a yearly saving might be effected of about 2 quarters of corn, by giving him 10 lbs. of bruised instead.

(1350.) Many economical forms of mixtures have been recommended for farm-horses, and these are among them:

10 lbs. of chaffed straw, at £1 per ton	1d.
10 lbs. of oats, at 3s. per bushel	9
16 lbs. of turnips, at 10s. per ton	1
Expense of cutting and chaffing	0½
Cost of one horse each day	11½d.
16 lbs. of hay, at 3s. 6d. per cwt.	6d.
5 lbs. of oats, at 3s. per bushel	4½
16 lbs. of turnips, at 10s. per ton	1
Cost of one horse each day	11½d.
28 lbs. of steamed turnips	3½d.
7 lbs. of coals, at 1s. per bushel	1
Expenses of steaming	0½
16 lbs. of straw, at £1 per ton	1½
Cost of one horse each day	6½d.

This last mixture, containing no corn of any kind, is said to "succeed remarkably well, and although the horses perspired considerably while at work, they kept their condition exceedingly well," and has been adopted by some farmers in the South of England, and by Mr. Karkeek, the veterinary surgeon, as having been "highly recommended by several practical farmers."† No doubt, horses can live upon turnips, as well as upon grass, without corn, and they may be said to work upon them: but I quite agree with Mr. Stewart, when he observes: "What the owner might call *work* is not known. In this country, grass alone will not produce workable horses," and the same may more truly be said of turnips and straw. "If food is not given," continues Mr. Stewart, "work cannot be taken. Every man who has a horse has it in his power to starve the animal; but that, I should think, can afford little matter for exultation."‡ Turnips are frequently given to farm-horses in the evening in lieu of a feed of corn, and even in lieu of a hot mash at night; and horses are very fond of Swedish turnips, which, on being washed, are generally set before them whole, unless some of the men take the trouble of cutting them into slices with their knives; but the best way would be to have them sliced on purpose by Wallace's turnip-slicer, fig. 259, which has been already described. Potatoes are given to horses in a raw state, in the same manner as turnips, and they seemed to be relished by them, but not so fondly, in so far as I have observed, as Swedish turnips. But of the sorts of food of the root kind, there is none which gives horses so much delight as the carrot. It is a pity that this root can only be cultivated successfully on very light soil, otherwise it would be worth while to raise as many, at least, as would support the horses, in conjunction with corn, all winter. Stewart says that "for slow-working horses carrots may supply the place of corn quite well, at least for those employed on the farm."‖ They would get fat enough on 70 lbs. of carrots a day, but would want stamina without corn.§ Carrots

* Quarterly Journal of Agriculture, vol. iii.
† Prize Essays of the Highland and Agricultural Society, vol. xiv.
‡ Stewart's Stable Economy. ‖ Ibid.
§ An error has crept into (1031), where the specific gravity of the carrot is stated at 0·018 instead of 0·810 (10·83)

are easily and successfully grown in the Island of Guernsey; but they are not given to horses on account of an allegation that "when on this food their *eyes* are injured." The same writer mentions a similar effect produced by the parsnip at a certain season of the year. "To horses," he says, "parsnips are frequently given, and have the property of making them sleek and fat; but in working they are observed to sweat profusely. If new, and cut sufficiently small, no other ill effect results, except, indeed, at one period of the year, toward the close of February, when the root begins to shoot; if then given, both horses and horned cattle are subject, on this food, to an inflammation in the eye, and epiphora or watery eye; in some subjects, perhaps, producing blindness."* Horses are very fond of bread; a piece of bread, and especially oat cake, will take a horse in the field when a feed of corn cannot. It is quite common in Holland to see travelers at a village inn, take a black loaf and slice it down with a bread-knife in a trough for their horse. Upon the principle of economy, M. Longchamp has proposed to feed the cavalry of France with a bread composed of ¾ of of boiled potatoes and ¼ oatmeal, properly baked in an oven. The usual allowance of oats for a horse, at 10 lbs. costs 13 sous; but 10 lbs. of this bread will only cost 5 sous

(1351.) But independent of all succedanea, which may be given to horses at times as a treat, and as affording a beneficial change of food, there should be a regular feed prepared for farm-horses, which should be administered every day, and any deviation from which should be regarded as a relish or treat. There are two formulæ which I shall give, which have been found to make excellent prepared food for farm-horses, and they may be prepared without much trouble, provided the proper apparatus is erected for the purpose. The first is given in quantity of each day for one horse:

In the morning....	3½ lbs. of oat and bean meal, 11 lbs. of chopped straw,	14½ lbs.
At midday.....	3 lbs. of oat and bean meal, 12 lbs. of chopped straw,	15 ..
At night.....	1½ lbs. of oat and bean meal, 11 lbs. of steamed potatoes. 2 lbs. of chopped straw,	14½ .. 44 lbs.

This quantity is quite sufficient for the strongest farm-horses, and less will be consumed by ordinary ones, but that can be regulated according to circumstances, by withdrawing a little meal and straw, still retaining the proportions. The usual allowance of oats, as you have seen, weighs 11½ lbs. a day, when the grain is of the finest quality; but as horses seldom receive the finest oats, and are usually supplied with what are called common oats, which do not weigh so heavy, the usual allowance may be taken at 10 lbs.; and when hay is given to the horses in spring they eat at least 1½ stones of 22 lbs =33 lbs. every day. This mixture, on the other hand, contains no hay, and only 8 lbs. of oats and bean-meal, or 6 lbs. of barley-meal instead, if more convenient to be given, and 11 lbs. of steamed potatoes, which cannot be estimated at much value on a farm beyond the cost of steaming.† The value of the ordinary and the prepared food can easily be estimated, and it will be found that the prepared is the cheapest, and at the same time better for the horses' health, and equally well for them as to condition and spirit. The mixture is made in this way: The meal and chopped straw are put and mixed together in a tub, and a little salt sprinkled over it. The steamed potatoes are then poured hot into the tub over the straw, and the whole is formed into a mush with a shovel, and let stand awhile to acquire an equal temperature throughout, and to swell the meal into a pulpy state with the potatoes, before being divided out to the horses.

(1352.) A formula is given by Prof. Low, consisting of chopped straw, chopped hay, bruised or coarsely-ground grain and steamed potatoes by weight, in equal parts, with 2 oz. of salt; and of this from 30 lbs. to 35 lbs., or 32½ lbs. on an average, to be given to a horse every day.‡ This mixture, including hay, will be more expensive than the above; and I am doubtful that 35 lbs. of it will satisfy a farm-horse on active work in spring, when he can eat 33 lbs. of unchopped hay a day, without corn.

(1353.) It appears at first sight somewhat surprising that the idea of preparing food for farm-horses should only have been recently acted on; but I have no doubt that the practice of the turf and of the road, of maintaining horses on large quantities of oats and dry rye-grass hay, has had a powerful influence in retaining it on farms. But now that a more natural treatment has been adopted by the owners of horses on fast work, farmers, having now the example of post-horses standing their work well on prepared food, should easily be persuaded that, on slow work, the same sort of food should have even a more salutary effect on their horses. How prevalent was the notion, at one time, that horses could not be expected to do work at all unless there was *hard meat* in them! "This is a very silly and erroneous idea, if we inquire into it," as Prof. Dick truly observes; "for whatever may be the consistency of the food when taken into the stomach, it must, before the body can possibly derive any substantial support or benefit from it, be converted into *chyme*—a pultaceous mass; and this, as it passes onward from the stomach into the intestinal canal, is rendered still more fluid, by the admixture of the secretions from the stomach, the liver and the pancreas, when it becomes of a milky appearance, and is called *chyle*. It is then taken into the system by the lacteals, and in this *fluid*, this *soft* state—*and in this state only*—mixes with the blood and passes through the circulating vessels for the nourishment of the system."‖ Actuated by these rational principles, Mr. John Croall, a large coach proprietor in Edinburgh, now supports his coach-horses on 8 lbs. of chopped hay and 16 lbs. of bruised oats; so does Mr. Isaac Scott, a Postmaster, who gives 10 lbs. or 12 lbs. of chopped hay and 16 lbs. of bruised oats to large horses; and to carry the principle still farther into practice, Captain Cheyne found his post-

* Quayle's Agriculture of the Channel Islands.
‡ Low's Elements of Practical Agriculture.
† Quarterly Journal of Agriculture, vol. iv.
‖ Quarterly Journal of Agriculture, vol. iii.

Horses work well on the following mixture, the proportions of which are given for each horse every day; and this constitutes the second of the formulæ alluded to above:

In the day ..	8 lbs. of bruised oats.	At night ..	22 lbs. of steamed potatoes.
	3 lbs. of bruised beans.		1¼ lbs. of fine barley-dust.
	4 lbs. of chopped straw.		2 lbs. of chopped straw.
	15 lbs.		2 ounces of salt.
			25¼ lbs.

Estimating the barley-dust at 10d. per stone; chopped straw 6d. per stone; potatoes, steamed, at 7s. 6d. per cwt.; and the oats and beans at ordinary prices, the cost of supper was 6d., and for daily food 1s. with cooking, in all 1s. 6d. a horse each day.*

(1354.) [*Hay and Straw-Cutters.*—Machines for chopping hay and straw form now an important article in the class of implements for preparing food for horses and cattle. In England the straw-cutter or chaff-cutter is held, very properly, in high estimation by the farmer, and its value, in an economical point of view, seems to be fully appreciated by all. In Scotland, with all its boasted economy in the various walks of Agriculture, the straw-cutter is but partially employed, and it is chiefly among those farmers who, to a well-established experience superadd scientific skill, that the employment of the straw-cutter, together with the other members of the class of food preparing machines, are brought to bear upon the establishment in a systematic reform. There can be no doubt that ere long the food-preparing system will become as universal among farmers as the threshing-machine is already, and straw-cutters, corn-bruisers and steaming-apparatus will be seen in every well-regulated steading. To the full development of such a system there exists one especial obstacle, which is that defect, in the minds of many men, which prevents their forming a systematic arrangement of any given subject, and from being indifferently qualified to draw conclusions from a series of facts, which individually appear isolated and loosely connected, but which, in the aggregate, are capable of bringing out important results. For example, there are many individuals who may have procured the requisite machinery to have enabled them to follow the system here alluded to, but, owing to the absence of properly organized methods of procedure in the different processes, and losing sight of the advantages to be derived from a proper combination of effects, by viewing only the results in detail, the well-intended trial ends in disappointment, and the machinery set aside as unprofitable; whereas, under proper direction, it would certainly have achieved the object. In using machinery of this kind it should always be borne in mind that the more constantly and regularly it is kept in operation, so much the more productive it will be in saving expense to its proprietor, provided such machinery be of a kind that can be rendered available as a means of saving expense; and, from the nature of things, no machine will be continued in any practice after it has been ascertained to possess only negative properties.

(1355.) Straw-cutters are of very various construction, rising in the perfection and complication of parts, from the simple knife, jointed at one end to a table and wielded by the right hand, as a lever of the second order, chopping the straw or hay that is presented to it by the left. From this simple and primitive form they rise in gradation to a class of elaborate machines, too numerous to be described individually, but out of which the following varieties are selected as appearing most worthy of attention. I shall pass over some of the early machines, which, however ingenious, were unnecessarily complicated; such as those which enjoyed the advantage of a revolving web to carry forward the substance to be cut, and having also the means of moving the substance, not uniformly, but by starts, the progressive action being performed in the interval of the strokes of the cutter, the substance, at the same time, being alternately compressed and relaxed, that is, compressed while the knife is cutting, and relaxed during the progressive stage. Such mechanical appliances are now, for the most part, laid aside, and the machine is proportionally simplified.†

(1356.) The straw-cutting machines now in general use may be arranged under three varieties, and in the order of seniority stand as follows: 1. Those having the cutting-knife or knives attached on the disk of a fly-wheel. 2. Those having the knives placed upon the periphery of a skeleton cylinder; and 3. Those having numerous knives set round the surface of a small solid cylinder. This last being the simplest form of the modern machine I shall place it first in the order of description.

(1357.) *The Canadian Straw-Cutter.*—This machine, as the name implies, is an importation from Canada, a description of it having been sent thence by Mr. Fergusson of Woodhull, now of Fergus, Upper Canada, to the Highland and Agricultural Society, in whose Transactions it was first published‡ but the present figure is taken from the machine as made by James Slight and Company, who have greatly improved the construction of the cutting cylinder. Fig. 281 is a view in perspective of this machine. It consists, first, of a wooden frame, of which *a a a a* are the four posts, 2½ inches square, the front pair 43 inches in hight, and the back pair 36 inches. These are connected by two side-rails, one of which is seen at *b*, and a cross-rail, *c*, which last serves also to support the bottom of the feeding-spout. These rails are 2½ inches deep by 1½

[† Not to have it said that this great work had been impaired in any of its essential parts, and especially in such engravings as are employed to illustrate it, we give all the cuts of machinery, though well aware that some of them have been well supplanted by more economical inventions of our own ingenious countrymen. The presentation of them will be acceptable, too, as we may suppose, to the manufacturers and venders of implements, patrons of this work.

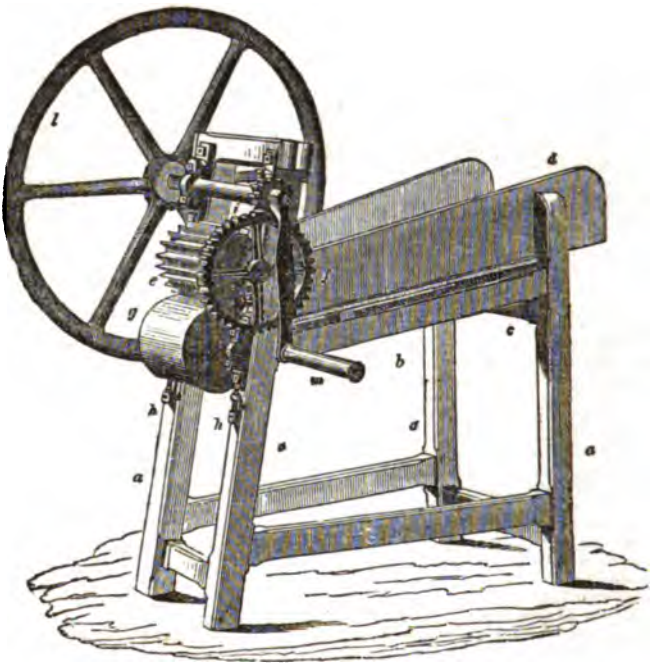
Ed Farm. Lib.]

* Quarterly Journal of Agriculture, vol. iii.

‡ Prize Essays of the Highland and Agricultural Society, vol. xii.

inches in thickness. The posts are farther connected by four light stay-rails below; and the frame, when thus joined, measures 15 inches in width at the front, where the rollers are applied, 22 inches in width behind, and 40 inches in length at bottom, but only 36 inches at the top-rail

Fig. 281.



THE CANADIAN STRAW-CUTTER

measured over all. The feeding-spout, *d*, is 40 inches in length, 9 inches in width within, at the feeding end, and 18 inches behind; the depth is 4 to 6 inches.

(1358.) The acting parts of this straw-cutter consist of the cutting-cylinder *e*, which is 9 inches in length and 6½ inches in diameter to the edge of the cutters. It is armed with 24 cutters or knives; its axle runs in plummer-blocks, bolted upon the posts, and carries likewise the wheel *f* of 9½ inches in diameter. The pressure cylinder *g* is a plain cylinder of hard-wood, beech or elm, turned true upon an iron axle, which runs in plummer-blocks similar to the former. The length of the pressure cylinder is 9 inches, and its diameter 7 to 8 inches; it carries no wheel, but revolves by similar contact with the cutting-cylinder. The pressure-cylinder is furnished with a pair of adjusting screws at *k k*, which act upon the plummer blocks of the cylinder, and afford the means of regulating the pressure of the one cylinder upon the other. The shaft *i*, which has also its plummer-blocks, carries at one end a pinion of 3¼ inches in diameter, which acts upon the wheel *f*, while, at the other end, it carries the fly-wheel *l* of 34 inches diameter and 60 lbs. weight. The winch-handle *m* is also attached to the shaft *i*, and serves to put the machine in motion.

(1359.) Fig 282 is a transverse section of the cutting-cylinder, showing the position of the cutters and their insertion into grooves which are planed out of the solid cast-iron forming the body of the cylinder; *a* is the axle, and *b* the body of the cylinder, which is 4 inches in diameter, and has 24 cutters inserted in its periphery. Fig. 283 is a longitudinal section of the same, for the purpose of exhibiting the manner in which the cutters are secured in their places. *a* is the axle, and *b* the body as before, *c c* being two opposite cutters. The body is 8 inches in length but is furnished with two caps *d d*, which make it up to 9 inches. The caps are cupped out, so that their edges *e e e e* embrace the ends of the body, and at the same time enter into notches cut in each end of the cutters, as seen in fig. 284, which is a cutter detached, and drawn to a larger scale exhibiting the notch *a a* into which the edges of the cupped ends enter. By this arrangement, the numerous cutters are all held firmly in their grooves: for so soon as the caps are applied, and fixed by the keys *f f*, fig. 283, being driven through the axle, the caps are pressed home upon the body and the cutters. On the other hand, when it is found requisite to remove a cutter, for sharpening or other purposes, it is only necessary to drive out one of the keys *f*, to withdraw the cap, and the cutters can be lifted out of their grooves without trouble.

(1360.) As this machine acts entirely by direct pressure, it will readily be observed that, in working it, the straw being laid in a trough *d*, fig. 281, and brought in contact with the cutting-

cylinder and its antagonist, the hay or straw will be continuously drawn forward by means of the two cylinders; and when it has reached the *line of centers* of the two, it will be cut through by the direct pressure of the cutting-edges of the one against the resisting surface of the other

Fig. 283.

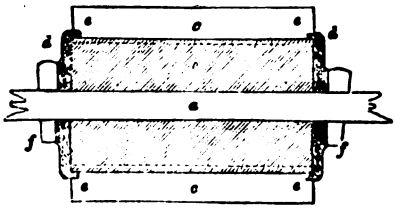


Fig. 282.

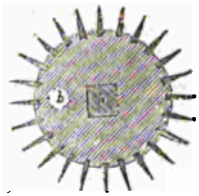

Fig. 284.

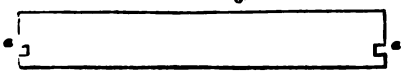
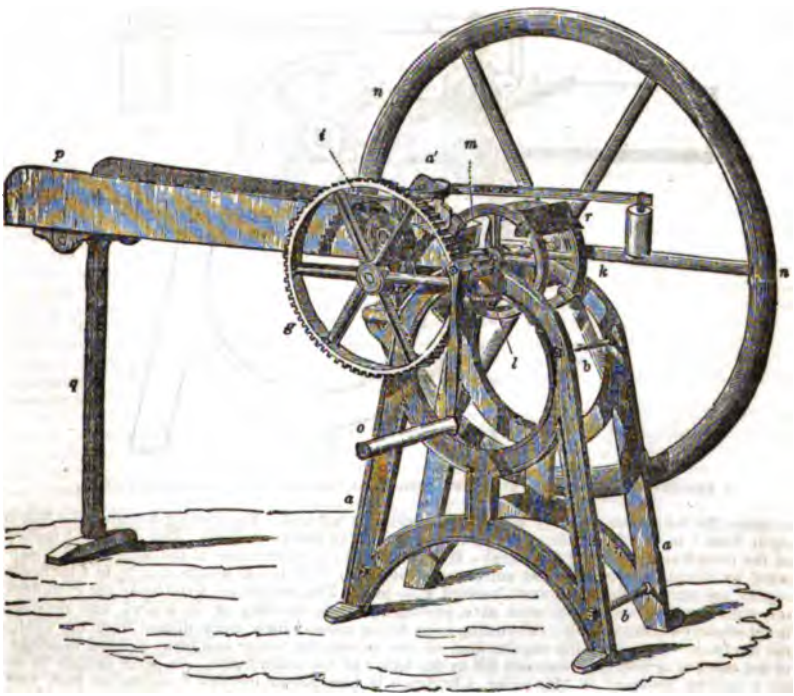


SECTIONS OF THE CUTTING-CYLINDER.

cylinder, and the process goes on with great rapidity. The straw is cut in lengths of about ¾ inch, and though it passes in a thin layer, yet the rapidity of its motion is such, that when driven by hand, at the ordinary rate of 44 turns of the handle per minute, the number of cuts made by the

Fig. 285.



THE CYLINDER STRAW-CUTTER WITH STRAIGHT KNIVES.

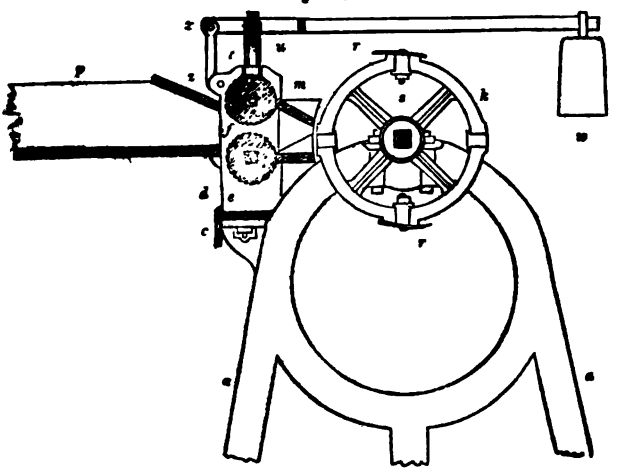
cutting-cylinder in that time is 360 : and the quantity, compared by weight, will be three times, nearly, what any other straw-cutter will produce, requiring the same force to work it, that is to say, a man's power. There is one objection to this machine, which is, the wearing out of the resisting cylinder but this balanced by the excess of work performed, and by the circumstance that the wearing cylinder can be removed at an expense not exceeding 2s., and it will last from 3 to 6 months. The price of the Canadian straw-cutter is £6 10s.

(1361.) *Cylinder Straw-cutter*, so named here from its having the knives or cutters (generally

two, but sometimes four) placed on the periphery of a skeleton cylinder, the knife lying nearly in the plane of revolution. Besides the cutting cylinder, they necessarily have a pair of feeding-rollers, which bring forward the substance to be cut, and also, from the velocity of their motion, regulate the length of the cut. Two forms of the machine exist, the essential difference of which is that, in the one, the cutters are placed upon the cylinder with a large angle of obliquity to the axis, generally about 35°, and are therefore bent and twisted until their edges form an oblique section of the cylinder, while the box, or the orifice through which the substance is protruded for being cut, lies parallel to the axis of the feeding-rollers. In the other variety, the knives are placed parallel to the axis of the cylinder, and therefore straight in the edge, while the cutting-box is elongated into a nozzle, and is twisted to an angle of 15° with the axis of the feeding-rollers. To this form of the machine I shall at present chiefly confine myself.

(1362.) The cylinder straw-cutter with straight knives, as constructed by James Slight and Co., Edinburgh, at prices from £7 10s. to £8 10s., is represented by fig. 285, being a view in perspective of the machine, while fig. 286 is a section of the principal parts; and in the two figures the same letters refer to the corresponding parts of each. The machine is made entirely of iron, chiefly cast-iron. The two side-frames *a a*, are connected together, at a width of from 12 to 15 inches, by the stretcher-bolts *b b*, two of which are seen in the right-hand side of the figure, and a third below on the left; a fourth is formed of the bed-plate *c*, which is bolted to a projecting bracket, and carries the cheeks or frame *d* of the feeding-rollers *e* and *f*. The lower roller *e* carries upon its axle the driving-wheel *g*, and also the feeding-wheel, indistinctly seen in the figure, but which works into its equal wheel *i*, fitted upon the axle of the upper roller *f*. In the machine, when adapted for hand power, the rollers vary from 5 to 8 inches in length, and are 3½ inches in diameter, and fluted. In the apex of the side-frames, bearings are formed for the axle of the cutter-wheels *k*, which form the skeleton cylinder, and whose axle carries also the driving-pinion *l*, acting upon the wheel *g*. The cutter-wheels are 11 inches diameter, and are set at from 10 to 13 inches wide. Intermediate between the feeding-rollers and the cutter-wheels is placed the cutting-box or nozzle *m*, bolted to the roller-frame in the position represented in fig. 286. On the farther end of the cutter-wheel axle the fly-wheel *n*, of 4 feet diameter, is fixed; and on the near end of

Fig. 286.



A TRANSVERSE SECTION, SHOWING THE RELATION OF THE PRINCIPAL PARTS.

the same, the winch-handle *o*, by which the machine is worked. The feeding-trough *p* is 4 feet in length, from 5 to 8 inches wide at the feeding end, and 18 inches behind. The depth is 6 inches, and the trough is formed of ¾ inch deal. It is hooked to the roller-frame at the mouth, and is supported by the jointed foot *q*. The cutters *r r*, from 10 to 13 inches in length, and 3½ to 4 inches in breadth, are made of the finest steel, backed with iron. The cutters are fixed upon the cylinders, each with two screw-bolts, as seen at *s*, passing through the ring of the wheel, and they are placed slightly eccentric to it; the cutting-edge being about ¼ inch more distant from the center than the back. To secure the regular feed of the rollers, the lower one turns in fixed bearings; but the other is at liberty to rise and fall in the fork *t* of the roller-frame. In order farther to secure a uniform pressure on this roller, a bridge *u* is inserted on the fork *t*, resting on both journals of the roller. A compensation lever *v*, has its forked fulcra in *x* through the strap *x x*, which is hooked on to pins in the roller-frame; and it thus bears upon the bridge *u* at both sides by means of the forked end, as seen at *a'* in fig. 285. A weight *w* is appended to the extremity of the lever, which, thus arranged, keeps a uniform pressure on the upper roller, while it is always at liberty to rise or fall according to the thickness of the feed which the rollers are receiving.

(1363.) Fig. 287 is a direct front view of the cutting-box detached, on a scale of 2 inches to a foot. *a a* are the ears by which it is bolted to the roller-frame; *b c* and *d e* are the upper and lower extreme edges of the nozzle, while *f g h i* is the base, as applied to the roller-frame. The

angle *b g f* or *e i h* is the obliquity which is given to the nozzle, and is about 15° with the horizontal axis. Fig. 288 is a plan of the same, in which the same letters of reference apply to the corresponding parts. *f g* is the base, lying on the same plane with the ears *a a*. The curve line *b c* is the contour of the upper edge of the nozzle, and the dotted line *b e* represents the lower edge *d e* of fig. 287.

Fig. 287.

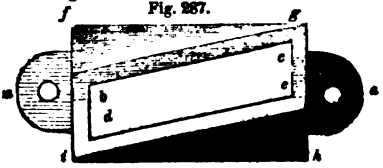


Fig. 288.

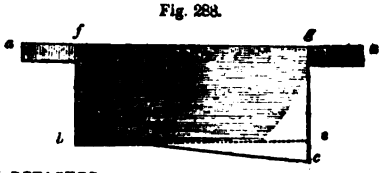


THE CUTTING-BOX DETACHED.

(1364.) The obliquity of the nozzle, as here represented, serves the purpose of causing the knife to make a progressive cut, approaching to the effect of clipping; thereby preventing the shock that would otherwise arise, were the nozzle and the edge of the knife parallel at the instant when the cut commences. The action of the machine would perhaps be improved by an increased obliquity of nozzle, as the stroke of the knives would thus be still less felt; but this could not easily be done unless the knife were placed oblique also in the opposite direction. But this involves a difficulty which the present machine was intended to obviate, namely, the preserving a straight-edged knife, which, in the hands of an unskilled workman, is much easier adjusted than a twisted one. And farther, a moderate degree of obliquity is preferable to an excess; in the former, the intervals of the cuts are so considerable as to allow the fly-wheel to exert its natural effect of storing, as it were, a quantity of momentum or force, which it freely gives out to meet the resistance of the next cut; when, on the contrary, the obliquity is very great, as is frequently the case in the machines with twisted knives, and more especially when there are four cutters applied to the cylinder, there may, in such cases, be no interval of action in the cutters for before one has completed its cut, the next has commenced, and the advantages of a fly-wheel are, in such cases, nearly, if not altogether, lost; hence we find that some of the machines with twisted knives are extremely heavy to work.

(1365.) There is, however, another cause of increased labor in the working of some straw-cutters, on the principle now before us. In many of the cylinder machines, the cutter wheels are of a diameter so large as to render the operation of cutting with them one of great labor. This arises from the circumstance of the action of the machine being a combination of the effects of the lever. The winch-handle is a lever, say of 12 inches radius, and the radius of the cutter-wheel, measured to the edge of the cutter, may be taken at 6 inches; here there is a mechanical advantage of two to one in favor of the power. Let the cutter-wheel be increased to 16 inches, or a radius of 8 inches, the proportion of the leverage is now materially changed, and the mechanical advantage in favor of the power is only 1½ to 1. The power, therefore, suppose it exerts in the first case a force of 30 lbs., it will require, in the second case, a force of 40 lbs., to overcome the same resistance, and so on in that proportion. But the fly-wheel, under the like circumstance, loses part of its effect, though not to the same amount; for, suppose its radius to the center of gyration to be 2 feet, the mechanical advantage of its momentum would be, in the first case, as 4 to 1, and in the second, as 3 to 1. In the construction of all cylinder straw-cutters, therefore, it is of importance to make the cutters of small diameter, that is to say, never to exceed 11 inches. It were, perhaps, better that they should be less than this, but on no account should they exceed it, especially for hand-machines. In the case of steam or water power, any small increase of resistance is less important, provided that a countervailing object is to be attained by it, such as a machine already made, or the like.

(1366.) While on the subject of *fly-wheels*, it may not be out of place to make a few remarks, pointing out where those auxiliaries to machinery may with propriety be applied, and where they ought not. In the first place, it may be asserted that in no case can a fly-wheel act as a *generator* of power; and under a false impression of this supposed function of fly-wheels, numerous instances occur of their misapplication, or at least a misconception of their effects; and, secondly, the only available function of fly-wheels is their capability of acting as *reservoirs* of that power or force that is communicated to them while in motion. Thus a comparatively small force applied to a heavy fly-wheel for a few seconds, will, on the principle of its absorbing and partially retaining that power and force, accumulate a momentum that may, through the agency of mechanical means, be discharged on a particular point, and produce an instantaneous effect that the first mover never could accomplish without such means. This is finely exemplified in the machine for punching and cutting thick iron plates and bars; and the principle applies in all cases where fly-wheels can be employed with advantage. The principle of action is this: Fly-wheels may be employed with advantage in every case where the intensity of either the *power* or the *resistance* is variable; and where both are variable, it becomes still more necessary. On the other hand, where both the power and the resistance are uniform, a fly-wheel may be held as an incumbrance, and can only act as a load upon the first mover. In the steam-engine, for example, of any form in which a crank is used to communicate motion to machinery, the fly-wheel is indispensably necessary; and such is the requisite governing power of fly to keep up steady motion, that its momentum is sufficient to compensate for considerable variation in the resistance of the machine or machinery upon which it operates. With water-wheels, however, the power is perfectly uniform, and is the resistance is also uniform, as in grist-mills and even threshing-mills, fly-wheels would be worse than useless; but where the resistance is intermitting, such as rolling and tilt-mills, and punching-machines, a heavy fly becomes necessary, in which the power of the first mover can be accumulated for a short period and which will be expended during the succeeding short period that the

driven machine is in action. In every case where manual labor is app not essential. This arises from the power itself being variable; for the winch varies according to the different positions which the winch occup tion, and has been ascertained to range in the proportion of 30 lbs. and is, that when he is in a position that restricts his exertion to 30 lbs., he mi the resistance unless at a very slow rate; but in the position where he ca can do more than overcome the resistance. And here it is that the fly- suppose the resistance requires an actual force of 45 lbs., while he is p a surplus of 15 lbs. This last quantity the ever-ready fly-wheel, whose he is not able greatly to increase; but it takes up, with a small increas force exerted by the hand, and this is stored up in the mass of the again at the next weak point in the revolution of the winch. Hence, produced to act upon the machine to which the power of the man is directed upon an intermitting machine, such as a straw-cutter, the de are very much increased; but as the point of the machine to which th at a much slower velocity than the center gyration in the fly, and as the ance are not likely to coincide exactly with the increments or decrem will be a mutual compensation going on among the forces to bring out is a possibility that a coincidence of the above circumstances may o times of consequence to observe the placing of the winch, so as to coun pensation.

(1367.) The power of horses to impel the machinery being of nearly u no regulator in itself; but it comes under the general law, if the resistanc in the threshing machine, which is slightly variable in resistance, it woul power, be considerably improved by the addition of a well proportioned f in another place. In various other machines worked with horse-power, frequently intermitting, such as blowing bellows, pumping, and the l ble; while in a malt or other mill, whose resistance is uniform, the fly we Steam power applied to a threshing-machine requires, as already obse wheel; but that of the steam engine for such purpose, should be above th ordinary purposes.

(1368.) The general theory of the application of fly-wheels may be re They are usefully employed in all cases of intermitting resistance and of in the first mover or in the resistance. Where the motion is uniform a first mover being also uniform, the fly-wheel is in almost every case unne an obstruction.

(1369.) The determination of the weight of a fly-wheel for any given pur very definite in its results; but approximations to it have been made Among these, we find Tredgold stating a rule for the fly wheels of stea practical purposes, is convenient, and comes near to the general practice taken with considerable latitude, seeing that the practice of engineers differ point; and the rule, though it applies to heavy fly wheels with tolerable ex with practice in the case of fly wheels for the hand, and other small machine approximation will be a tolerable guide in practice for the weight of small

(1370.) Taking the average force that a man will exert in turning a winch 23 lbs., when he turns it 45 times per minute, the rule will be:

RULE.—Multiply 20 times the force in pounds exerted on the winch by its divide this product by the cube of the radius of the fly-wheel in feet, mu ber of the revolutions per minute; the result will be the area of a section in square inches.

EXAMPLE.—The force applied to the winch being 23 lbs., its radius 1 foot per minute 45; required the section of the rim of a fly-wheel whose r feet diameter.

$$\frac{20 \times 23 \times 1}{1{\cdot}5^3 \times 45} = \frac{460}{151} = 3 \text{ inches, the area of section of the rim nearly.}$$

(1371.) Though this formula will serve for small fly-wheels, whose velociti 80 revolutions per minute, it becomes necessary, in order to make it agree with the constant. Thus, for velocities ranging from 80 to 150, the number 10 wi 20; and from 150 to 300, the number 5. In this last case, the fly-wheel c diameter; and in the former, it is restricted to 5 feet.

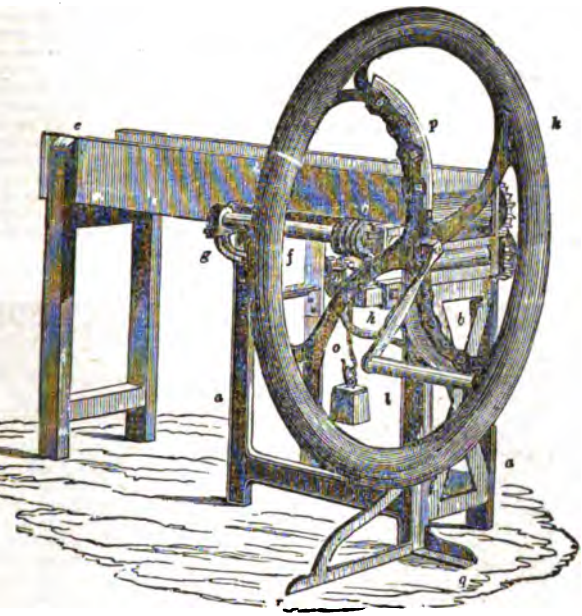
(1372.) *The Disk Straw-cutter.*—Of the disk straw-cutter the varieties are v they form a very important order of this machine; being that, also, which is fo ployed in England, it is the most numerous of the class. The principal feature fixed upon the fly-wheel, is invariable, except that it sometimes carries one, knives. The machinery or details are exceedingly varied. In some, it is ad rious lengths by means of ratchet-wheels and lever-catches applied to the moti rollers, and at the same time to move the substance forward only in the interval the knife; in others, the latter qualification only is attended to; in a third, tion of the substance is deemed sufficient; and these varieties of motion are p and various arrangements of spur, bevel, and screw geerings.

(1373.) The machine selected for illustration is one in which two knives ar which gives to the substance to be cut a continuous motion forward. The figur ing this, is taken from a machine manufactured by John Anderson and Son, found

[1] Tredgold on Steam-Engines.

0 10s. Fig. 289 is a view of this machine in perspective. The chief parts of the of cast-iron, consisting of a frame *a a* on each side of the machine, which are sup sely by the truss *b*. The front part of the side-frames extend upward and form

Fig 289.



THE DISK STRAW-CUTTER WITH CONVEX KNIVES.

er frame. The cutting-plate is attached in front of the latter portion of the frame- essed truly off for the passage of the knife over its face. The feeding-trough *e* is e fore-part to the roller-frame, and along its bottom to the upper edge of the side- ck end of the trough is supported in a light wooden-frame. The principal shaft *f* is o projecting brackets *g* and *h*, and upon it is mounted the single-thread screw *i*, and ; on the extreme end also of the shaft, the winch-handle *l* is attached. A bracket of a small shaft, on which the screw-wheel *n*, of 21 teeth, is mounted, and is turn- f the screw, when the fly-wheel is put in motion. On the opposite end of the spur-wheel is also placed, and acts upon another of equal diameter placed on the r feeding-roller. This last, as well as the upper roller, are furnished with the usual ions, for admitting of the rise and fall of the upper roller. The upper roller is ight frame that rises and falls in a slide of the roller-frame, and this is acted upon weight, of which the hook only is seen in the figure at *o*. The cutting-knife *p* is gth, and 4 inches in breadth. It is firmly bolted upon the arm of the fly-wheel, dge, which is convex, is so formed that every successive point, in passing the ing plate, forms equal angles with the edge of that plate. In many of the disk tting-edge of the knife is concave, formed on the same principle of equal angles, the better of the two.

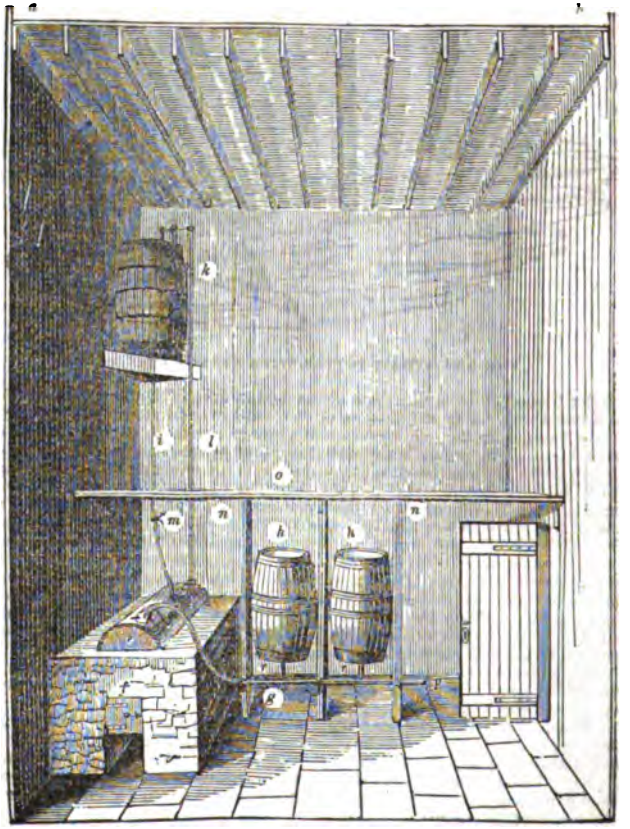
imensions of the principal parts of this machine are as follows Width of the frames th of cast-iron frames 30 inches, and hight 3 feet; length of feeding-rollers 12 in- diameter 4¼ inches; length of feeding-trough 5 feet, and width 12 inches. The et 3 inches diameter, and the hight to its center is 3 feet. From the entire weight being supported at one angle of the frame, the spreading brackets *q r* are attach- machine stability.

Steaming Apparatus.—The means employed for cooking food for horses and cattle, ng or steaming. In the first, an open vessel is of course employed, in which the bstances are placed, with a sufficient quantity of water. This method has been ient in many respects; and when the establishment is extensive, the vessel is re- ommodiously large, and is withal not economical.

ing in a separate vessel has been adopted in preference to the former method and ed in a variety of forms, but these may be ranked under two distinct kinds. The vessel, a boiler generally of cast-iron, having a channel or groove of 1 inch wide ep formed round its brim. The vessel is placed over a furnace properly construct-

ed, and is partly filled with water. The groove is also filled with water. A sheet-iron cylindrical pan, of 3 to 4 feet in depth, and of a diameter suited to pass into the groove of the water-vessel (which is generally about 3 feet diameter), is also provided. The pan has a perforated bottom to admit steam freely from the lower vessel. It is also furnished with an iron bow by which it can be suspended, and by which it can be conveniently tilted while suspended. This is the steaming-pan; and for the purpose of moving it to and from the boiler, a crane, mounted with wheel and pinion and a chain, completes the apparatus. To put this in operation, the pan is filled with the substances to be steamed, and covered over either with a deal-cover or with old canvas bags. It is then placed upon the boiler by means of the crane, and the fire being pretty strongly urged till the water in the boiler gives off its steam, which, passing up through the bottom of the pan, and acting upon the contents, produces in a few hours all the results of boiling. The water in the groove of the boiler serves as a sealing to prevent the escape of steam without passing through the pan. But notwithstanding this, it is evident that the steam can hardly ever reach the temperature of 212°; and hence, this apparatus is always found to be very tardy in its effects. When the contents of the pan have been found sufficiently done, the whole is removed from the boiler by means of the crane, and tilted into a large trough to be thoroughly mixed, and thence served out to the stock. A general complaint has been urged against this construction of apparatus, arising from the slowness of the process of cooking by it, and consequent expense of fuel. Boilers of the form here described are not well calculated to absorb the maximum of caloric that may be afforded by a given quantity of fuel, neither is the apparatus generally the best adaptation for the application of

Fig. 990.



THE CLOSED-BOILER STEAMING APPARATUS.

steam to the substances upon which the steam has to act. Such boilers, as already observed, can never produce steam of a higher temperature than 212°. If they did, the shallow water-luting, formed by the marginal groove, would be at once thrown out by the steam-pressure; for it is well known that the addition of 1° to the temperature of the steam increases its elasticity equal to the resistance of a column of water about 7 inches high. A groove, therefore, of 7 inches in depth

would be required to resist the pressure, which would even then be only 1-5 lb. of pressure on the square inch. Under such circumstances, the temperature in the steaming-pan will always be under 212°. Hence the tedious nature of the process by using this apparatus.

(1377.) The apparatus which deserves the precedence of the above mode is here represented in fig. 290. The principle of its construction is that of a closed boiler, in which the steam is produced under a small pressure of 3 to 4 lbs. on the inch. It is then delivered through a pipe to one or more separate vessels containing the substances that are to be cooked; and these vessels are so arranged as to be readily engaged or disengaged with the conducting steam-pipe. The outline *a b c d* of the figure represents a section of the steaming-house, with the apparatus in due order of arrangement, and of the extent that may be capable of supplying an establishment of from 10 to 16 horses. The boiler *e* is of a cylindrical form, 20 inches in diameter and 4 feet in length. It is set in brick-work *f*, over a furnace of 14 inches in width, with fire-grate and furnace-door. The brick building requires to be 6 feet 6 inches in length, 4 feet 6 inches in breadth, and the hight about 3 feet 6 inches. The furnace is built with a circulating flue, passing first to the farther end of the boiler, then, turning to right or left according as the chimney may be situated, returns to the front of the boiler, and terminates in the chimney on the side opposite to the first turning. The flues should be not less in width at the upper part than one-fourth the diameter of the boiler; and their hight will be about one-third the diameter. The steam-pipe is attached to the boiler at its crown, takes a swan-neck bend downward to within 12 inches of the floor at *g*, and terminates at *p*: it is furnished with as many branch nozzles as there are intended to be steaming-vessels. The steam-pipe may be either cast-iron or lead, and 2 inches diameter in the bore. The receptacles or steaming-vessels *h h* are usually casks of from 50 to 100 gallons contents. They are mounted with 2 iron gudgeons or pivots, placed a little above mid-hight; they are besides furnished with a *false* bottom, supported about 3 inches above the true bottom; the former being perforated with a plentiful number of holes, to pass the steam which is introduced between the two bottoms. The connection between the steam-pipe and the receptacle may be either by a stop-cock and coupling-screw—which is the most perfect connection—or it may be by the simple insertion of the one nozzle within the other, in the form of a spigot and faucet. In this latter case, the nozzle that leads from the steam-pipe is stopped with a wooden plug, when the receptacle is disengaged. Besides the steam-pipe, the boiler is furnished with a pipe *i*, placed in connection with a cistern of water *k*, the pipe entering into it by the bottom, and its orifice closed by a valve opening upward, the lower extremity of the pipe passing within the boiler to within 3 inches of its bottom. A slender rod *l* passes also into the boiler through a small stuffing-box; and to its lower end, within the boiler, is appended a float, which rests upon the surface of the water within the boiler. The upper end of this rod is jointed to a small lever which has its fulcrum supported on the edge of the cistern a little above *k*; the opposite end of the lever being jointed to a similar but shorter rod, rising from the valve in the bottom of the cistern. This forms the feeding apparatus of the boiler, and is so adjusted by weights that when the water in the boiler is at a proper hight, the float is buoyed up so as to shut the valve in the cistern, preventing any farther supply of water to pass into the boiler, until, by evaporation, the surface of the water has fallen so far as to leave the float unsupported, to such extent as to form a counterpoise to the valve, which will then open, and admit water to descend into the boiler, until it has again elevated the float to that extent that will shut the valve in the cistern. By this arrangement, it will be perceived that the water in the boiler will be kept nearly at a uniform hight; but to accomplish all this, the cistern must be placed at a certain fixed hight above the water in the boiler, and this hight is regulated by the laws which govern the expansive power of steam. This law, without going into its mathematical details at present, in so far as regards this point, may be stated in round numbers as follows: That the hight of the surface of the water in the cistern must be raised above the surface of that in the boiler, 3 feet for every pound-weight of pressure that the steam will exert on a square inch of surface in the boiler. Thus, if it is estimated to work with steam of 1 lb. on the inch, the cistern must be raised 3 feet; if 2 inches, 6 feet; 3 inches, 9 feet; and so on. If the steam is by any chance raised higher than the hight of the cistern provides for, the whole of the water in the boiler may be forced up through the pipe into the cistern, or until the lower orifice of the pipe, within the boiler, is exposed to the steam, which will then also be ejected through the pipe; and the boiler may be left dry. Such an accident, however, cannot occur to the extent here described, if the feeding-apparatus is in proper working order; and its occurrence to any extent is sufficiently guarded against by a safety-valve.

(1378.) The safety-valve of the steam-boiler is usually a conical metal valve, and always opening outward; it ought always to be of a diameter large in proportion to the size of the boiler and steam-pipe, so as to insure the free egress of any rapid generation of steam. For a boiler of the size under consideration it should be 2 inches in diameter on its under surface—that being the surface acted upon—this gives an area of fully 3 square inches; and if loaded directly, or without the intervention of a lever, for steam of a pressure of 1 lb. on the inch, it will require 3 lbs.; if 2 lbs. on the inch, 6 lbs.; if 3 lbs. on the inch, 9 lbs., and so on. With these adjustments, the steam, should it rise above the proposed pressure, will, instead of forcing the water through the feed-pipe, raise the safety-valve, and escape into the atmosphere until the pressure is reduced to the intended equilibrium.

(1379.) Another precautionary measure in the use of the steam-boiler is the guage-cock, of which there are usually two, but sometimes one, a two-way cock; they are the common stop-cock, with a lengthened tail passing downward, the one having its tail terminating about 1½ inches below the proper water level in the boiler, the other terminating 1½ inches above that level, which allows a range of 3 inches for the surface of the water to rise or fall. The first, or water-cock, then, when opened, will throw out water by the pressure of the steam upon its surface, until the surface has sunk 1½ inches below its *proper* level, when steam will be discharged, thus indicating the water in the boiler to be too low, and that measures should be taken to increase the supply. When the second or steam-cock is opened, it will always discharge steam alone, unless the water shall have risen so high as to come above its orifice, in which case the cock will discharge *water*, indi

eating a too large supply of water to the boiler, and that it should be reduced; for this purpose, the feed-pipe *i* is provided with a stop-cock *m*, whereby the admission of water can be entirely prevented at the pleasure of the attendant.

(1380.) The foregoing description refers to a steaming-apparatus of the best description, and implies that the water-cistern can be supplied either from a fountain-head, or that water can be pumped up to the cistern. But there may be cases where neither of these are easily attainable. Under such circumstances the feed-pipe may rise to the hight of 4 or 4½ feet, and be surmounted by a funnel, and under it a stop cock. In this case, also, a float with a wire stem, rising through a stuffing-box on the top of the boiler, must be employed—the stem may rise a few inches above the stuffing-box, in front of a graduated scale—having the zero in its middle point. When the water is at the proper hight in the boiler, the top of the stem should point at zero, and any rise or fall in the water will be indicated accordingly by the position of the stem. To supply a boiler mounted after this fashion, the first thing to be attended to, before setting the fire, is to fill up the boiler, through the funnel, to the proper level, which will be indicated by the float pointing to zero; but it should be raised, in this case, two or three inches higher. In this stage, the gauge-cocks are non-effective; but when the steam has been got up, they, as well as the float, must be consulted frequently; and should the water, by evaporation, fall so low as 3 inches below zero, a supply must be introduced through the funnel. To effect a supply, in these circumstances, the steam must be allowed to fall rather low, and the funnel being filled, and the stop-cock opened, the water in the former will sink down through the tube, provided the steam be sufficiently low to admit its entrance, but the first portion of water that can be thus thrown in will go far to effect this, by sinking the temperature. The sinking of the temperature by the addition of a large quantity of cold water, is the objection to this mode of feeding; but this is obviated to some extent from the circumstance, that unless the steaming receptacles are large or numerous, the first charge of water will generally serve to cook the mess, when a fresh charge can be put in for the next.

(1381.) In using this steaming-apparatus, it has been noticed that the casks are furnished with gudgeons, which play in the posts *n n*; these are kept in position by the collar-beam *o* to which they are attached; the casks being at liberty to be tilted upon these gudgeons. They are charged when in the upright position, and the connection being formed with the steam-pipe, as described, they are covered at top with a close lid or a thick cloth, and the process goes on. When the substances are sufficiently cooked, the couplings *r r* are disengaged, the upper part of the cask is swung forward, and their contents discharged into a trough which is brought in front of them for that purpose.

(1382.) The connections with the steam-pipe are sometimes, for cheapness, formed by a *sliding tube* of copper or brass, about 4 inches in length, which, after the nozzle of the cask and that projecting from the steam-pipe are brought directly opposite to each other, is slid over the junction, and as a moderate degree of tightness only is requisite in such joints, a strip of sacking wrapped round the ends of the slider is found sufficient. On breaking the connection, and opening the exit nozzles, the steam will of course flow out, but this is checked by a wooden plug, or even a potato or slice of turnip, thrust into the orifice, may be sufficient. It is advisable, however, that a main stop-cock should be placed in the steam-pipe anywhere between the boiler and the first receptacle.

(1383.) The most perfect connection between the steam-pipe and the receptacles is a *stop-cock and coupling-screw*. These should be of 1¼ inches bore, they are more certain in their effect, and more convenient in their application, though attended with more expense in the first cost of the apparatus. In this case no main-cock is required. The extremity of the steam-pipe should, in all cases, be closed by a small stop-cock, for the purpose of draining off any water that may collect in the pipe from condensation. A precaution to the same effect is requisite, in the bottom of each cask, to draw off the water that condenses abundantly in it; or a few small perforations in the bottom will effect the purpose.

(1384.) It must be remarked, in regard to steaming, that in those establishments where grain of any kind is given in food in a cooked state, dry grain cannot be cooked, or at least boiled to softness in dry steam, the only effect produced being a species of parching: and if steam of high temperature is employed, the parching is increased nearly to carbonization. If it is wished, therefore, to boil grain by steam, it must be done by one of the two following methods: The grain must either be soaked in water for a few hours, and then exposed to the direct action of the steam in the receptacle; or it may be put into the receptacle with as much water as will cover it, and then by attaching the receptacle to the steam pipe, by the coupling stop-cock, or in the absence of stop cocks, by passing a bent leaden pipe from the steam-pipe, over the upper edge of the receptacle and descending again inside, to the space between the false and the true bottoms; the steam discharged thus, by either method, will shortly raise the temperature of the water to the boiling point, and produced the desired effect.*

(1385.) The time required to prepare food in this way varies considerably, according to the state of the apparatus, and the principle of its construction. With the apparatus just described, potatoes can be steamed in casks of from 32 to 50 gallons contents, in 30 to 45 minutes. In casks extending to 80 gallons, an hour or more may be required. Turnips require considerably longer time to become fully ready, especially if subjected to the process in thick masses, the time may be stated at double that of potatoes. When the apparatus is ill constructed, the time, in some cases, required to cook turnips, extends to 5 hours. And, with reference to the apparatus first described (1376), the time is seldom under 5 hours.

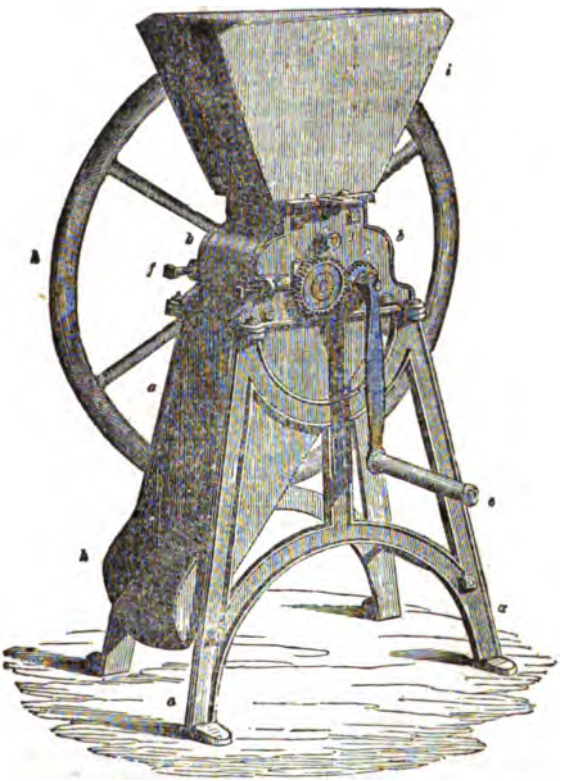
(1386.) The prices of steaming-apparatus vary accordingly to quality and extent; but, on an average, the open boiler and pan apparatus, including a power-crane, will range from £7 to £10; and the other, fig. 290, the price ranges from £8 to £16. The expense of building the furnace, and supplying mixing-troughs, will add about £2 10s. to each.

* See an article by me in the Quarterly Journal of Agriculture, vol. vi.

(1387.) *Corn-Bruisers.* In following up an economical system of feeding, the bruising of all grain so applied forms an important branch of the system, and, as might be expected, numerous are the varieties of machines applied to the purpose. These naturally arrange themselves under three distinct kinds. 1st. Machines which act on a principle that partakes of cutting and bruising, by means of grooved metal cylinders, and is applied to those chiefly driven by the hand. 2d. Machines adapted to bruise only by means of smooth cylinders; this is applied exclusively to those driven by steam, or other agency more powerful than the human hand. And, 3d, Breaking or grinding by the common grain millstones, and of course, only worked by power.

(1388.) That variety of the first division which I shall particularly notice, is represented in perspective in fig. 291. It is constructed almost entirely of cast-iron, except the hopper and discharging-spout; but its frame or standard may with propriety be formed of hard wood, when circumstances render the adoption of that material desirable. In the figure, *a a a* is the frame work, consisting of two separate sides, connected by two stretcher bolts, the screw-nuts of which are only seen near to *a* and *a* below. A case *b b*, formed of cast-iron plates, is bolted on the projecting ears at the top of the frame, and contains the bruising cylinders. The cylinders are 4 inches in diameter, and 6 inches in length, of cast-iron or of steel. They have an axle of malleable iron passing through them, having turned journals, which run in bearings formed on the cast-iron side-plates of the case, the bearings being accurately bored out to fit the journals. The spur-wheels *c* and *d* are fitted upon the axle of the cylinders, *c* having 14 teeth, and *d* 24 teeth. The cylinder corresponding to *d* is perfectly smooth, while that of *c* is grooved at a pitch of ¼ inch, and about 3-32 inch deep worked to sharp edges. The grooves lie obliquely on the face of the cylinder, being at an angle of 10° with the axle. The winch-handle *e* is attached to the axle of the roller *c*, whose bearings are permanent, while those of *d* are movable, being formed in separate plates, and fitted to slide to a small extent in a seat, for the adjustment of the cylinder to any desired grist.

Fig. 291.



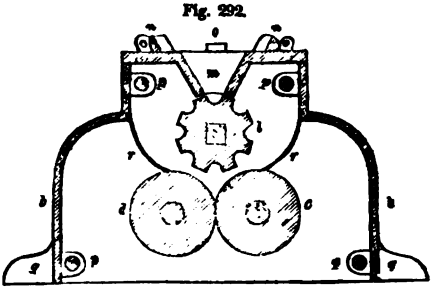
THE HAND CORN-BRUISER.

This adjustment is effected by means of the screws *f*, which act upon the sliding-plates of the bearings. *g* is one of the bearings of a feeding-roller, placed also within the case; it is turned by means of a toothed-wheel fitted upon the farther end of its axle, and which is driven by another wheel of 24 teeth on the axle of the cylinder *d*. The fly-wheel *h* is fitted upon the axle of

the cylinder *c*, and is 3¼ feet in diameter; *i* is the feeding-hopper, attached to the top of the case by two small hooks; and *k* is a wooden spout to convey the bruised grain from the case.

(1389.) Fig 292 is a section of the case, and the cylinders, detached from the frame. *b b* are the two ends of the case cut by the section; *c* is the grooved cylinder, *d* the smooth, and *l* is the feeding-roller, it is 3¼ inches diameter, and has cylindrical grooves formed on its surface to convey the grain; *o* is a cover of cast-iron fixed upon the top of the case; it has two rounds ears *n n*, with eye-holes which serve to steady the hopper, and to which it is screwed by the hooks already mentioned. A hopper-shaped opening *m* is formed in the cover; it is six inches long, 3 inches wide at top, and 1 inch at bottom, and the edges fit closely upon the feeding-rollers. Two plate-iron sliders are fitted upon the surface of this little hopper, which serve to enlarge or contract the opening longitudinally, and are fixed by screw-bolts in each plate; the head of one of the bolts is seen at *o*. *p p p p* are ears by which the case is bolted together, and *q q* are prolongations of the side-plate of the case; *r r* are additional plates of sheet-iron, to prevent the grain from being thrown over the cylinders unbruised.

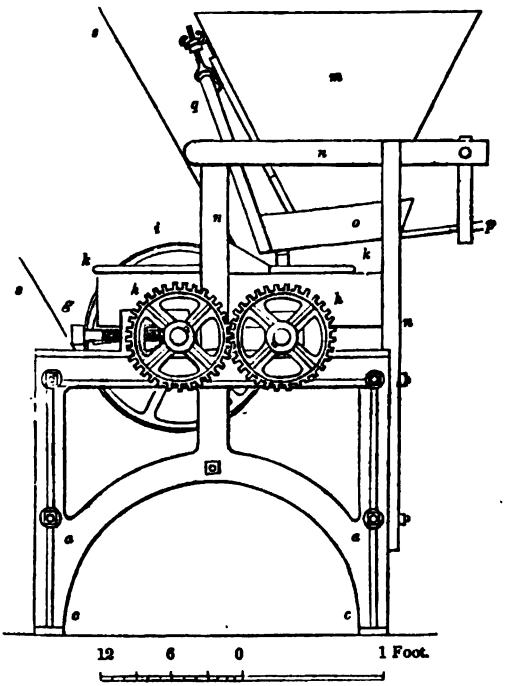
Fig. 292.



TRANSVERSE SECTION, SHOWING THE RELATION OF THE PRINCIPAL PARTS.

(1390.) This is a very efficient machine for bruising either oats or beans: the adjustment of the plain cylinder to the requisite distance being easily accomplished by the adjusting-screws; and

Fig. 293.



THE ELEVATION OF THE POWER CORN-BRUISER.

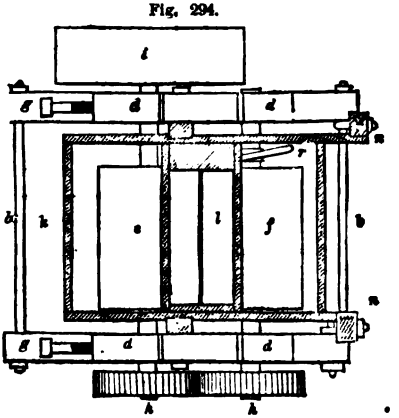
to prevent the abrasion of the grooved cylinder, by coming in too close contact with the other, a stopper is applied on each side, to keep the slides from overreaching the due safety distance. From the different velocities of the two cylinders, the grooved one being the fastest, it produces a cutting as well as a bruising action, which renders its effects on the grain more perfect than simple pressure. It can be worked by one man, who will bruise 4 bushels of oats in an hour. The price of the machine is £6 10s.

(1391.) Various other forms of this machine are in use, some with both cylinders grooved, others with only one grooved cylinder acting against a grooved plate; in this last state it is much used for bruising beans.

(1392.) Among the varieties of the bruising-machine of the 2d division, I may just notice one that is found very efficient. It consists of two plain-edged wheels or pulleys, as they may be termed, usually about 6 inches broad on the rim or sole; the one ranges from 2½ feet to 4 feet in diameter, and its fellow only half the diameter of the larger. They require to be truly turned on the rim, and work in contact. The smaller one is always driven by the power, and the larger usually by contact with the smaller. The smaller wheel makes, according to its diameter, from 150 to 200 revolutions per minute. Where plain cylinders are employed for bruising, and their surfaces moving with equal velocity, the effect is to press each grain into a flat, hard cake: but when one of the surfaces is left at liberty to move by simple contact, it is found that the effect is different from the above, for the grain passes, bruised indeed, though not into a hard cake, but has apparently undergone a species of tearing, leaving it in a more open and friable state than as described above. This machine, however, does not answer well for bruising beans, for here, again, they come through in the form of a flat cake. If beans, therefore, are used in an establishment where this bruiser is adopted, a separate one, on the principle of fig. 291, is required for the beans alone; that machine though serviceable for a small establishment, being incapable, even with power, to produce the quantity in a reasonable time that would be required in a large one.

(1393.) *Plain Roller Corn-bruisers, for power.*—A very efficient corn bruiser, adapted for power, is shown in figs. 293, 294, 295. The first being an elevation, the second a plan, and the third a section of the machine; the same letters apply to such corresponding parts as are seen in all the three figures. In fig. 293 *a a* is one of the side-frames, of cast-iron, which are connected together by stretcher-bolts *b*, and the frame so formed is bolted to a floor through the palms at *c c*. On the top bar of the frames there are two strong snugs *d d* cast, sufficient to resist the pressure of the rollers, and are formed also to receive the brass bushes in which the journals of the two rollers are made to run. The two rollers *e* and *f* are respectively 8 and 9½ inches diameter, and are 18 inches in length, fitted with malleable iron shafts 1¾ inches diameter; the roller *f* runs in permanent bearings, but *e* has its bushes movable, for adjustment to the degree of bruising required, and this adjustment is effected by the adjusting-screws *g*. The shaft of each roller carries a wheel *h*, equal in diameter, which is nine inches. The roller *e* has also upon its shaft the driving pulley *i*, which by means of a belt *s s* from any shaft of a threshing-machine or other power having a proper velocity, puts the rollers in motion. The rollers are inclosed in a square wooden case *k k*, in the cover of which a narrow hopper-shaped opening *l* is formed to direct the grain between the rollers. A hopper *m* for receiving the grain is supported on the light wooden frame-work *n n*, which also supports the feeding-shoe *o*, jointed to the frame at *p*, and suspended by the straps *q*, which last is adjustable by a screw at *q* to regulate the quantity of feed. A smooth-edged oblique wheel *r*, fig. 294, is mounted on the shaft of the roller *f*, and by its oscillating revolutions, acting upon a forked arm which descends from the shoe, a vibratory motion is given to the latter, by which a regular and continued supply of the grain is delivered from the hopper to the rollers. After passing the rollers the grain is received into a spout, which either delivers it on the same floor, or through a close spout in the floor below. The velocity of the rollers, which are driven by the belt *s s*, may be 250 revolutions per minute. The dimensions of the frame *a* are 30 inches in length and 24 inches in hight; the width over all being also 24 inches. The price of this machine, as manufactured by James Slight and Co., is £10.—J. S.

Fig. 294.



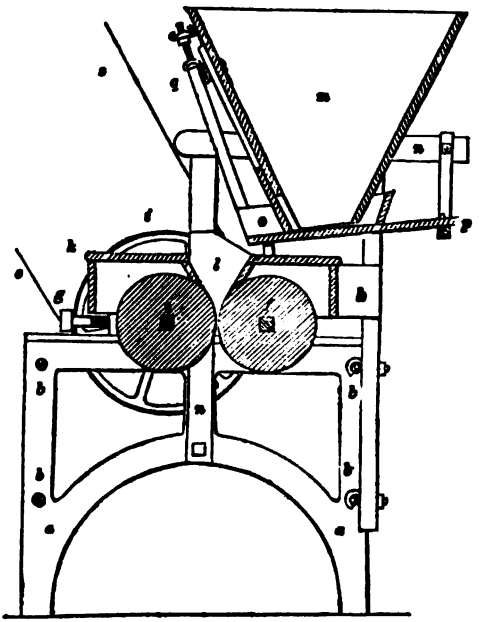
THE PLAN OF THE POWER CORN-BRUISER.

(1394.) The horse is an intelligent animal, and seems to delight in the society of man. It is remarked by those who have much to do with blood-horses, that, when at liberty, and seeing two or more people standing conversing together, they will approach, and seem, as it were, to wish to listen to the conversation. The farm-horse will not do this; but he is quite obedient to call, and distinguishes his name readily from that of his companion, and will not stir when desired to stand until *his own name* is pronounced. He distinguishes the various sorts of work he is put to, and will apply his strength and skill in the best way to effect his purpose, whether in the threshing-mill, the cart, or the plow. He soon acquires a perfect sense of work. I have seen a horse walk very steadily toward a feering-pole, and halt when his head had reached it. He seems also to have a sense of time. I have heard another neigh almost daily about 10 minutes before the time of loosening in the evening, whether in summer or winter. He is capable of distinguishing the tones of the voice, whether spoken in anger or otherwise; and can even distinguish between musical notes. There was a work horse of my own, which, even at his corn, would desist eating and listen attentively, with pricked and moving ears, and steady eyes, the instant he heard the note of low G sounded, and would continue to listen as long as it was sustained: and another, that was similarly affected by a particular high note. The recognition of the sound of the bugle by a trooper, and the excitement occasioned in the hunter when the pack give tongue, are familiar instances of the extraordinary effects of particular sounds on horses.

(1395.) When alluding to the names of horses, I may mention that they should be *short and emphatic*, not exceeding two syllables in length, for longer words are difficult of pronunciation; and inconvenient to utter when quick or sharp action is required of the horse; and a long name is almost always corrupted into a short one. For geldings, Tom, Brisk, Jolly, Tinker, Dragon,

Dobbin, seem very good names; for mares, Peg, Rose, Jess, Molly, Beauty, Mettle, seem as good and as to the name of stallions, they should be somewhat high-sounding, as indicative of greater importance of character, as Lofty, Farmer, Plowboy, Matchem, Diamond, Blaze, Samson, Champion, are names which have all distinguished first rate draught horses.

Fig. 295.



THE SECTION OF THE POWER CORN-BRUISER.

(1396.) This seems a befitting place to say a few words on the farmer's *riding* and *harness* horses. Usually a young lad, or groom, is hired to take charge of these, to go errands and to the post-office, and otherwise make himself serviceable in the house. Sometimes the hedger or shepherd acts the part of groom. My shepherd acted as groom, and his art in grooming is so skillful that many friends remarked to me that they would be glad to see their *professed* grooms turn out a saddle-horse or gig in so good a style as he did. Besides being useful in carrying the farmer to market, or other short distances, a roadster is required to carry him over the farm when it is of large extent, and when the work-people necessarily receive pretty constant attention in the important operations of seed-time and harvest. The harness-horse is useful to a family at all times, as well as to the farmer himself, when he visits his friends; and many farmers now prefer riding to market in a gig or drosky, to horseback; and it must be owned to be the pleasanter mode of the two.

(1397.) I have said that the agricultural pupil should have no horse of his own at first, to tempt him to leave home and neglect his own training. But to know how a riding-horse ought to be kept by a groom, and to be able to correct him when he neglects his duty or performs it in an unsatisfactory manner, I would advise him to undertake the charge of one himself for some time; not merely to superintend its keeping, but to clean it himself, to water and corn it at stated times at morning, noon, and night, and to keep the saddle and bridle in proper order. I groomed a new-broke-in blood filly for four months one winter, and got more insight into its form, temper, and management, and wants, than I could have obtained by observation alone in a much longer time. On coming home at night from visiting a friend, I made it a point with myself to make my charge comfortable for the night before thinking of my own rest.

(1398.) A saddle-horse is treated somewhat differently in the stable from a work-horse. The first thing to be done early in the morning is to shake up the litter nearest the strand with a fork, removing the dung and soiled straw to a court-yard, and sweeping the floor clean. Then give the horse a drink out of the pail which is constantly kept full of water in the stable. The usual practice is to offer the water *immediately* before giving the corn; but I conceive it more conducive to the health of the horse to slake his thirst a while before giving him corn, the water by that time having reached its destined place, and acquired the temperature of the body. Should the horse have to undertake a longer journey than walking about the farm, a stinted allowance of water before starting on the journey is requisite, say to 10 gluts; but if he is to be at home, then he may drink as much as he pleases. He is then groomed by being, in the first place, gently gone over the whole body with the carry-comb, to loosen the mud that may possibly have been left adhering upon the hair from the former night's grooming, and also to raise the scurf from the skin

The whole body should be then wisped down with straw, to clear off all the dust and dirt that the curry-comb may have raised to the surface. The brush follows, to clear the hair of its dust and scurf, the curry-comb being used to clean the brush. Of wisping and brushing, wisping is the more beneficial to the legs, where the hair is short and the tendons and bones are but little covered, because it excites in them warmth, and cleans them sufficiently. Both wisping and brushing should be begun at the head and terminated at the other end of the body, along the lie of the hair, whichsoever way that may be, and which, notwithstanding its different swirls, all tends from the upper to the lower part of the body. Many a groom rests content with the brushing just mentioned; but it does not entirely remove the dust raised to the surface, and therefore a wisping is required to do it. The wisp for this purpose is best made of Russia mat, first wetted, and then beaten to softness, and rolled up somewhat firmly into the form of a wisp sufficient to fill the hand. A wisp of hair-cloth makes the skin clean, but in dry weather it is apt to excite such a degree of electricity in the hair of the horse as to cause it to attract much dust toward it. On the horse being turned round in the stall, his head, neck, counter, and fore-legs, should be well rubbed down with this wisp, and this done, he should again be turned to his former position, and the body, quarters, and hind-legs, then rubbed down; and when all this has been accomplished, the horse may be considered clean. All this grooming implies the bestowal of much more labor than most farmers' riding-horses receive. They are usually scuffled over in the morning with the curry-comb, and then skimmed down with the brush, and with a hasty combing of the mane and tail, the job is considered finished. The mane and tail ought to be carefully combed out, and wetted over at the time of combing with a half-dry water-brush. The sheet should then be thrown over the horse, and fastened (not too tightly) with the roller. On putting on the sheet, it should be thrown more toward the head of the horse than where it is intended to remain, and thence drawn gently *down the hair* with both hands, to its proper position, while standing behind the horse. The litter is then neatly shaken up with a fork, taking care to raise the straw so far up the travis on each side as to form a cushion for the side of the horse to rest against when he lies down. The feed of corn is then given him, and a little hay thrown into the rack; and on the stable-door being shut, he is permitted to enjoy his meal in peace. At mid-day, he should have another drink of water from the pail, the dung removed, the litter shaken up, and another portion of oats given him. At 8 o'clock at night, the sheet should again be taken off, the curry-comb and brush used, and the entire dressing finished again with a wisping of the Russia mat. The sheet is thrown over him as in the morning, the litter shaken up and augmented, water given, and the supper of oats, or a mash, finishes the day's treatment of the saddle-horse."*

(1399.) The treatment just described is most strictly applicable to the horse remaining all day in the stable; but when he is ridden out, a somewhat different procedure is required. When he comes home from a long and dirty ride, the first thing is to get clear of the mud on the belly and legs. A very common practice is to wade the horse through the pond, as the farm-horses are, but such should not be the course pursued with a saddle-horse, because wading through a pond cannot thoroughly clear his legs of mud *to the skin*, he being clean-shanked and smooth-haired, and there still remains the belly to be cleaned by other means than wading. The plan is, being that adapted for winter, to bring the horse into the stable upon the pavement, and, on taking off the saddle and bridle and putting on a halter, scrape all the mud as clean off the belly and legs as can be done with a knife—a blunt table-knife answers the purpose well. Then, with a pailfull of lukewarm water, wash down *the legs*, outside and inside, with a water-brush, and then each foot separately, picking out the mud with the foot picker; then wash the mud clean from the belly. A scrape with the back of the knife, after the washing, will bring out all the superfluous water from among the hair. On going into the stall the horse should be wisped firmly with straw, rubbing the belly first, and then both sides of each leg until they are all thoroughly dry. It is scarcely possible to get the belly dry at once; it should, therefore, get another good wisping with dry clean straw after the legs are dry. On combing out the mane and tail, putting on the sheet, and bedding plentifully with dry straw, the horse will be out of danger, and feel pretty comfortable even for the night; but should he have arrived some time before the evening time for grooming,

---

*In giving these details, and all which follow, we are aware that many of them are too minute, and otherwise ill adapted to American life and management generally; but then the reader must reflect that there are also many patrons of The Farmers' Library who are wealthy men, living in cities, who keep their carriage horses and pet nags for the saddle, with their superfluous grooms and all necessary appliances, to follow out all these directions. And besides, a sensible man never objects to knowing how any department of industry or of pleasure is managed in the country, where such departments have been carried on, as those have in England, to the highest pitch of perfection and refinement. And here we may relate an anecdote of a shrewd Massachusetts man of the world, who was some years since on a tour in England, and on a visit to the Duke of Buccleuch. After showing him many displays of the splendor and luxury of aristocratic living, His Grace took him to his stables, where genius and wealth had combined, to see how much money could be expended, and how much elegance displayed, on such an object. Our Yankee friend perhaps supposing he was expected to be confounded and overcome with astonishment at all he saw, instead of lifting up his eyes and exclaiming as did the Queen of Sheba when she visited Solomon in all his glory, went peering under and about the troughs and stalls; and, on being asked by the Duke if there was anything deficient in his stable appointment; answered "There is but one thing, your Grace, that is wanting to their completeness. I was looking for a *silver pot de chambre*, for each of your Grace's hunters." [*Ed. Farm. Lib.*

the curry-comb and wisp then applied will remove any moisture or dust that may have been over looked before.

(1400.) Considerable apprehension is felt in regard to wetting the abdomen of horses, and especially at night, and the apprehension is not ill founded, for if the wet is allowed to remain, even to a small degree, quick evaporation ensues from the excited state of the body consequent on exercise, and rapidly reduces the temperature of the skin. The consequence of this coldness is irritation of the skin, and likely grease on the legs, and this is the danger of wetting the bellies of farm-horses, and of any sort of horse, with *cold* water: for *warm* water cleans the hair and makes it dry sooner, even that on the abdomen, which is generally much longer than that of the legs; but, on the other hand, unless as much labor is bestowed as will dry the skin, and which is usually more than can be expected to be given by ordinary country grooms, it is safer for the horse to remain in a somewhat dirty state, than to run the risk of any inflammation by neglected wet limbs and abdomen. At the same time, if the requisite labor *shall* be bestowed to render the skin completely dry, there is even less risk in wetting the belly than the legs, inasmuch as the legs, in proportion to their magnitude, expose a much larger surface for evaporation, and are not so near the source of animal heat as the body.

(1401.) Saddle-horses receive oats in proportion to the work they have to perform, but the least quantity that is supposed will keep them in such condition as to enable them to do a good day's work at any time, is three half-feeds a day, one in the morning, another at mid-day, and the third at night. When subjected to *daily* exercise, riding-horses require 3 feeds a-day, and an extra allowance for extra work, such as a long journey. A mash once a-week, even when on work daily, is requisite; but when comparatively idle, a part of the mash, whenever prepared for the work-horses, may be administered with much advantage. I am no advocate of a bran-mash to a horse in good health, as it serves only to loosen the bowels without bestowing any nourishment. Boiled barley is far better. A riding-horse should have hay, and not straw, in winter; and he will eat from ½ to ¾ of a stone of 22 lbs. every day.

(1402.) On *cleaning harness* there should be two pairs of girths in use with the saddle, when the horse has much work to do, to allow each pair to be thoroughly cleaned and dried before being again used. The best way to clean girths is first to scrape off the mud with a knife, and then to wash them in *cold* water, and hang them up so as to dry *quickly*. *Warm* water makes them shrink rapidly, and so does long exposure to wet. If there is time, they should be washed in the same day they have been dirtied; but if not, on being scraped at night, they should be washed in the following morning, and hung up in the air to dry, and if the air is damp, let them be hung before the kitchen fire. Girths allowed to dry with the mud on soon become rotten and unsafe. The stirrup leathers should be taken off and sponged clean of the mud, and dried with a cloth. The stirrup-irons and bit should be first washed in water, and then rubbed dry with a cloth immediately after being used. *Fine* sand and water, on a thick woolen rag, clean these irons well, and a dry rub afterward with a cloth makes them bright. Some smear them with oil on setting them past to prevent rust, but oil, on evaporation, leaves a resinous residuum to which dust readily adheres, and is not easily taken off afterward. The curb-chain is best cleaned by washing in clean water, and then rubbed dry and bright by friction between the palms of both hands. The saddle-flaps should be sponged clean of mud, and the seat sponged with a wrung sponge, and rubbed dry with a cloth. Carriage-harness should be sponged clean of mud, kept soft and pliable with fine oil, and, when not japanned, blackened with the best shoe black. There should be no plating or brass on a farmer's harness; plain iron japanned, or iron covered with leather, forming the neatest, most easily kept, and serviceable mounting. Bright metallic mountings of every kind soon assume the garb of the shabby genteel in the hands of an ordinary rustic groom.

(1403.) In regard to the *diseases* of the horse, if we were to regard in a serious light the list of frightful maladies incident to that animal, which every work on veterinary science contains, we would never purchase a horse; but fortunately for the farmer, his horses are exempt from a large proportion of those maladies, as almost every one relating to the foot, and their consequences, are unknown to them. Nevertheless, many serious and fatal disorders do overtake farm horses in their usual work, with the symptoms of which you should be so far acquainted as to recognize the nature of the disease; and as you should be able to perform some of the simpler operations to assist the animal in serious cases until the arrival of the veterinary surgeon, a short account of these operations may prove useful. One or more of them, when timely exercised, may have the effect of soon removing the symptoms of less serious complaints. They consist of bleeding, giving physic and drenches, applying fomentations, poultices, injections, and the like.

(1404.) *Bleeding.*—"In the horse and cattle, sheep and dog, bleeding, from its greater facility and rapidity," says Professor Dick, "is best performed in the jugular or neck-vein, though it may also be satisfactorily performed in the *plate* and *saphena* veins, the former coming from the inside of the arm, and running up directly in front of it to the jugular; the latter, or thigh-vein, running across the inside of that limb. Either the fleam or lancet may be used. When blood is to be drawn, the animal is blindfolded on the side to be operated upon, and the head held to the other side; the hair is smoothed along the course of the vein by the moistened finger, the point selected being about 2 inches below the angle of the jaw. The progress of the blood toward the heart is to be obstructed, and the vein thus made sufficiently permanent and tense. A large-bladed fleam and a good-sized lancet are preferable, as the benefit of the operation is much increased by the rapidity with which the blood is drawn. From 8 to 10 pints imperial is a moderate bleeding for the horse and ox, regulated in some degree by the size. From 12 to 16 or even 20 pints is a large one: and sometimes in skillful hands, it is expedient to bleed till fainting is induced, and the animal drops down under the operation. The vessel in which the blood is received should be such that the quantity can be readily ascertained. When this is sufficient, the edges of the wound are to be brought *accurately together*, and kept so by a *small sharp pin* being passed through them, and retained by a little tow. It is of importance, in closing the wound, to see it *quite close*, and that *no hairs or other foreign bodies* interpose. For a time the head should be tied up, and care taken that the horse does not injure the part."

(1405.) The dangers arising from carelessness in blood-letting are not numerous; and "the first of which, though it may alarm the inexperienced, is very trifling. It is a globular swelling, *thrombus*, sometimes as large as the fist, arising immediately around the new-made incision. The filtrating of the blood from the vein into the cellular membrane, which is the cause of the disease, is rarely very copious. Gentle pressure may be used at first, and should be maintained with a well-applied sponge and bandage, kept cool with cold lotion. Occasionally there is *inflammation of the jugular* from bleeding. . . . The cause is usually referred to the use of a foul fleam, or from allowing hairs to interfere with the accurate adjustment of the edges of the wound. The first appearance indicative of the disease is a separation of the cut edges of the integuments, which become red and somewhat inverted. Suppuration soon follows, and the surrounding skin appears tumefied, tight and hard, and the vein itself, above the orifice, feels like a hard cord. After this the swelling of the neck increases, accompanied with extreme tenderness, and now there is constitutional irritation, with tendency to inflammatory fever. . . . In the first stage we must try to relieve by evaporating lotions or by fomentation. If these fail, and as soon as the disease begins to spread in the vein, the appropriate remedy is to touch the spot with the actual cautery, simply to sear the lips of the wound, and apply a blister over it, which may be repeated. Purgatives in full doses must be administered, and the neck, as much as possible, kept steady and upright."

(1406.) *Blistering.*—"Blistering plasters are never applied to horses. An ointment is always used, of which rather more than half is well rubbed into the part to be blistered, while the remainder is thinly and equally spread over the part that has been rubbed. When there is any danger of the ointment running and acting upon places that should not be blistered, they must be covered with a stiff ointment made of hog's lard and beeswax, or kept wet with a little water. . . . The horse's head must be secured in such a way that he cannot reach the blister with his teeth. . . . When the blister has become quite dry the head may be freed. Sometimes it remains itchy and the horse rubs it; in that case he must be tied up again. . . . When the blister is quite dry put some sweet-oil on it, and repeat it every second day. Give time and no work, otherwise the horse may be blemished by the process."

(1407.) *Physicing.*—"Physicing, which, in stable language, is the term used for purging, is employed for improving the condition when in indifferent health, and as a remedy for disease. The medicines chiefly used are—for *horses*, Barbadoes aloes, dose from 3 to 9 drachms; croton *bean*, from 1 scruple to ½ drachm, or *cake*, from ½ drachm to 1 drachm, to which may occasionally be added calomel, from 1 to 1½ drachms. For *cattle*, aloes in doses somewhat larger than for the horse; Epsom salts, or common salt, dose from 1 lb. to 1½ lbs., with some stimulus, as ginger, anise or carraway-seed; also linseed-oil, dose 1 lb., and croton-oil, 15 to 20 drops, or the bean or cake, the same as in the horse. For *dogs*, jalap, dose 1 drachm, combined with 2 grains of calomel; croton oil, dose 2 drops; bean, 5 grains; and syrup of buckthorn, dose 1 oz. These, it will be observed, are average doses for full-grown animals; in the young and small they may be less, in the large they may require to be greater; but much injury has often been done by too large doses too frequently repeated. To the *horse* physic is usually administered in the form of a bolus or *ball*; to *cattle* by drinking or *drenching*, though for both either way may be employed. A ball is conveniently made of linseed-meal, molasses and the active ingredient, whether purgative, diuretic or cordial; it should be softish, and about the size of a pullet's egg. In administering it the operator stands before the horse, which is unbound and turned with its head out of the stall, with a halter on it. An assistant stands on the left side to steady the horse's head and keep it from rising too high; sometimes he holds the mouth, and grooms generally need such aid. The operator seizes the horse's tongue in his left hand, draws it a little out and to one side, and places his little finger fast upon the under jaw,; with his right hand he carries the ball smartly along the roof of the mouth, and leaves it at the root of the tongue; the mouth is closed and the head is held till the ball is seen descending the gullet on the left side. When loth to swallow, a little water may be offered, and it will carry the ball before it. A hot, troublesome horse should be sent at once to a veterinary surgeon. Instruments should, if possible, be avoided, and adding croton farina to the mash often answers the purpose." *Drenches* should be given with caution to either horse or ox; "that no unnecessary force be used, that they be never given by the nostrils, and especially that, if the slightest irritation is occasioned in the windpipe, the animal shall immediately be set at liberty, that by coughing, he may free himself of the offending matter." "The horse must undergo *preparation for physic*, which is done by gently relaxing the bowels. During the day his food should be restricted to bran-mashes, a ¼ peck being sufficient for a feed, and this, with his drink, should be given warm; corn should be withheld and hay restricted. He may have walking and trotting exercise morning and evening. The physic is given on an empty stomach early in the morning; immediately after, a bran-mash is given; that over, the horse goes to exercise for perhaps an hour, and is watered when he returns. The water should be as warm as he will take it; and he should have as much as he pleases throughout the day; bran-mash should be given as often as corn usually is, and better warm than cold; if both are refused bran may be tried, but no corn, and but little hay. Sometimes gentle exercise may be given in the afternoon, and also next day. The physic usually begins to operate next morning, though it rarely takes effect in 12 hours, frequently not for 30. When the physic begins to operate, the horse should stand in the stable till it *sets*, which may be in 12 hours."* The stable should be well littered behind the stall to receive the discharge. "Many practitioners and horse-proprietors," says Mr. Youatt, "have a great objection to the administration of medicines in the form of drinks. . . . There are some medicines, however, which must be given in the form of drink, as in colic. . . . An ox-horn, the larger end being cut slantingly, is the usual and best instrument for administering drinks. The noose of a halter is introduced into the mouth, and then, by means of a stable-fork, the head is elevated by an assistant considerably higher than for the delivery of a ball The surgeon stands on a pail on the off-side of the horse and draws out the tongue

* Dick's Manual of Veterinary Science.

with the left hand. He then with the right hand introduces the horn gently into the mouth and over the tongue, and, by a dexterous turn of the horn, empties the whole of the drink—not more than about 6 oz.—into the back part of the mouth. The horn is now quickly withdrawn and the tongue loosened, and the greater portion of the fluid will be swallowed. A portion of it, however, will often be obstinately held in the mouth for a long time, and the head must be kept up until the whole is got rid of, which a quick but violent slap on the muzzle will generally compel the horse to do. The art of giving a drink consists in not putting too much in the horn at once, introducing the horn far enough into the mouth, and quickly turning and withdrawing it without bruising or wounding the mouth, the tongue being loosened at the same moment. A bottle is a disgraceful instrument to use, except it be a flat pint bottle with a long and thick neck."* The near-side horn has the most handy twist for administering a drink with the right hand.

(1408.) *Fomentations.*—"Clean water is the best fomentation. It should be as hot as the hand can bear it, yet not hot enough to pain the animal. In fomenting the horse the groom has rarely enough water, and he does not continue the bathing long enough to do any good. If the leg is to be fomented get a pailfull of water as hot as the hand can bear it; put the horse's foot into it, and, with a large sponge, lave the water well above the affected part, and keep it constantly running down the whole limb. Foment for half an hour, and keep the water hot by adding more."

(1409.) *Poultices.*—"Poultices should be formed of those materials which best maintain heat and moisture, and they should be applied as warm as possible and can be safely borne. They are usually made of bran-mash, turnips or oat-meal porridge. Linseed-meal alone makes the best of poultices, and some of it should always be added to the other ingredients. Wet bandages act as poultices."

(1410.) *Lotions.*—"Of *cooling* lotions cold water is the menstruum. It may be made colder by the introduction of a little salt or ice. Sal-ammoniac and vinegar may be added for the same purpose. The object is to reduce heat and promote evaporation. The addition of a little spirits is made with the same object."

(1411.) *The Pulse.*—"Of the *horse* the natural pulse is from 35 to 45 beats in the minute; under fever it rises to 80, 90 and 100. The most convenient spot to examine it is at the edge of the lower jaw, a little before the angle, where the maxillary comes from the neck to be distributed over the face. The pulse is one of the most important indications in all serious disorders."

(1412.) *Injections.*—"Injections, though easily administered by means of the old ox-bladder and pipe, are still more conveniently given with the syringe. For laxative clysters for the horse or cow, from 1 gallon to 12 pints imperial of warm water or gruel, at the temperature of 96° Fahr., with a couple of handfulls of salt or 2 oz. of soft soap, prove useful. Stronger ones may be obtained by adding a few ounces of aloes to the mixture. In cases of diarrhœa or over-purging, the injection should consist of a few pints of warm gruel, to which is added 1 oz. of catechu electuary, or from ½ drachm to 1 drachm of powdered opium. The only art in administering a clyster—where, however, there is often bungling, and even injury by wounding the rectum—is *to avoid frightening the animal*, anointing the pipe well, and *gently* insinuating it *before the fluid is forced up.*"

(1413.) "In general, bran-mashes, carrots, green meat and hay form the sick horse's diet, gruel and tepid water his drink."† Of the diseases themselves, I shall only notice those at present which usually affect *farm*-horses in winter.

(1414.) *Horse-Louse (Trichodectes equi).*—The horse is infested by a louse as well as the ox, and which is represented in fig. 296. Color of the head and thorax bright chesnut, the former very large and somewhat square, the surface with a longitudinal black line toward each side, forming an angle near the middle; antennæ with the third joint longest; abdomen pale, tawny yellow, with fine pubescence, the first eight segments having a dusky transverse band on the upper half, the lateral margins also with a dusky band; legs pale chesnut; length 1 line. Common in the tail-head and neck of the horse, especially when fresh from pasture in autumn. Found also on the ass. A little oil will destroy this animal when first established; but if allowed to remain on for some time, mercurial ointment will be necessary, but in small quantities at a time. The ass, however, has a louse peculiar to itself, the *Hematopinus asini*; of a rusty red; abdomen whitish, tinged with yellow, with a row of dark horny excrescences on each side; head long, with a deep sinuosity behind the antennæ; length 1 to 1¾ lines. It frequents the mane and neck, and is common.‡

Fig. 296.

THE HORSE-LOUSE, TRICHODECTES EQUI.

(1415.) *Batts.*—One of the most common complaints among farm-horses is the flatulent colic, gripes or batts. It arises from indigestion, which again is occasioned by various causes, such as hard work immediately after feeding, drinking water largely after a feed of corn, bad state of the food, fast eating, and, in consequence, a paucity of saliva, an overloaded stomach, a sudden change of food from soft to hard and dry, and more likely to occur after eating turnips, potatoes, carrots and grass, than hay and oats, and after peas than barley. The indigestion arises in two forms; the food either undergoing no change, or running rapidly to fermentation. In the former case *acute foot founder* is apt to arise, and its treatment is purgatives, drenches and injections. In the latter case, the symptoms are most alarming. The horse falls down, rolls over, starts up, paws the ground with his fore-foot, strikes his belly with the hind foot, perspiration runs down and agony appears extreme. Relief may be obtained from this dose: Linseed-oil, raw, 1 lb.; oil of turpentine from 2 to 3 oz.; laudanum from 1 to 2 oz., or hartshorn from ½ oz. to 1 oz. The following tincture may be kept in readiness: In 2 lbs. of whisky, digest for 8 days, 3

* Youatt on the Horse, edition of 1842.

† Dick's Manual of Veterinary Science.

‡ Denny's Monographia Anoplurorum Britanniæ.

oz. of ginger, 3 oz. of cloves, and then add 4 oz. of sweet spirits of nitre. Half a pint imperial of this tincture is a dose in a quart of warm water. The abdomen should be rubbed, the horse walked slowly about and supplied with a good bed, and with room to roll about. If there is no relief in half an hour a second dose may be given, and ere long, if still required, a third. Farm-horses that have keen appetites and devour their food greedily, and when they have been long in the yoke, are most apt to take this disease.

(1416.) *Inflammation of the Bowels.*—The symptoms of the batts are very similar, at first, to those of inflammation of the bowels, and, if mistaken, serious mistakes may arise, as the treatment of the two complaints is very different. The symptoms may be distinguished thus: In batts, the pulse remains nearly unaltered, whereas in inflammation it is quickened; all the extremities, the ears and feet, feel cold in batts, hot in inflammation. Whenever inflammation is apprehended, blood may be taken; in batts this is not necessary; but under such an apprehension, the assistance of the veterinary surgeon should be obtained as speedily as possible. I have cured many horses of the batts by administering stimulating drinks with a handy cow's horn. I remember of one horse being seized with inflammation of the bowels, on its arrival home from delivering corn at the market-town; and though the usual remedies of bleeding and blistering were resorted to, they proved ineffectual, no doubt from being disproportioned to the exigencies of the case, and the horse sunk in five days in excruciating agony. There was no veterinary surgeon in the district at that time, which was many years ago. Now, however, thanks to the Veterinary College of Edinburgh, through the really practically useful tuition of its indefatigable Principal, Professor Dick, there is not a populous district of the country in which a skillful veterinarian is not settled. To the surgeon, therefore, in a serious case such as this—and, indeed, in all cases of extensive *inflammation*, and especially in the interior of the body—recourse should immediately be had. I say *immediately*, for it is but fair to give the surgeon a *chance* of treating the case correctly from its commencement, and not to impose upon him the task of amending your previous bungling. Inflammation of the *lungs*, as well as inflammation of the *kidneys*, both of which the farm-horse is subject to, should always be treated by the veterinarian; but fortunately, these formidable maladies may, almost with certainty, be evaded with well-timed working, discrimination of work according to the state of the weather, and by good food, supplied with regularity and in due quantity.

(1417.) *Common colds* frequently occur among farm-horses at the commencement of winter, and when not entirely unheeded, but treated with due care, seldom leave serious effects. "A cold requires nothing more but confinement in a moderately warm stable for a few days, with clothing, bran-mashes instead of corn, and a little laxative and diuretic medicine." The evil lies not so much in the complaint itself, as in its ordinary treatment; it is seldom thought seriously of by farmers—"it is *only* a cold," is the usual remark—and, in consequence, the horse goes out every day, feels fatigued, gets wet, becomes worse, and then the lungs not unfrequently become affected, or a chronic discharge is established from one of the nostrils. One season 9 horses out of 12 in one stable were affected, one after another, by a *catarrhal epidemic*, which required bleeding, poulticing, or blistering under the jaw, besides the medical remedies mentioned above. These I was obliged to take charge of myself, there being no veterinarian in the district, and all fortunately recovered. The remaining 3 were slightly affected afterward, and easily brought through; but had the cases been unheeded from the first, very serious loss might have been incurred by death.

(1418.) *Grease.*—"The well-known and unsightly disease called grease," says Professor Dick, "is a morbid secretion from the cutaneous pores of the heels and neighboring parts, of a peculiar greasy, offensive matter, attended with irritation and increased vascular action. It is most frequently seen in coach and cart-horses, but often also in young colts which are badly cared for; and it is most common in the hind-feet, but occurs in all. Its main cause seems to be sudden changes in the condition of the foot from dry to wet, and from heat to cold, greatly augmented, of course, by evaporation." Hence the evil effects of washing the legs at night, without thoroughly drying them afterward. "The first appearance of grease," continues the Professor, "is a dry state of the heels, with heat and itchiness. Swelling succeeds, with a tendency to lameness; the discharge augments in quantity, the hair begins to fall off. . . . . In the early stage the parts should be washed with soap and water, and a solution of sugar of lead and sulphate of zinc applied; this may not be chemically scientific, but we have found it superior to anything else. Even in old and aggravated cases it is very efficacious. . . . . If the horse be strong and full of flesh, laxatives should be given, followed by diuretics; if weak, tonics may be added to these last. The feeding, too, must be varied with the condition: green-meat and carrots should be given, and mashes frequently, as a substitute for corn. During convalescence, exercise should be given, and bandages and pressure hasten the cure." I have no hesitation in saying that it is a disgrace for any steward, and in the want of such a functionary, it is so in the farmer himself, to allow his horses to become greasy. There is a complaint called a *shot of grease*, arising from a different cause from the common grease. "In the horse, plethora," says Professor Dick, "creates a strong disposition to inflammation of the eyes, feet and lungs, and sometimes to an eruption which is called *surfeit*, or the *nettle-rash*. The hair falls off in patches, and the skin is raw and pimpled. There is also a tendency to *grease*, and to what has been designated a *weed* or *shot of grease* in the heavy draught-horse. One of the legs, generally a hind one, suddenly swells, the animal becomes lame; there is pain in the inside of the thigh—increased upon pressure; and fever supervenes. . . . . We have seen it occur chiefly during continued rest after hard work and exposure to weather, in animals which were highly fed. The best treatment is large bloodletting, scarifying the limb, fomenting, and applying hay, straw, or flannel bandages, with purgatives and diuretics. The pressure of a bandage will expedite the reduction of the part to its natural dimensions."

(1419.) *Stomach-staggers.*—"The most prominent symptoms of this disease are the horse's hanging his head, or resting it on the manger, appearing drowsy, and refusing food; the mouth and eyes being tinged with a yellowish color; there is twitching of the muscles of the chest, and

the fore-legs appear suddenly to give way, though the horse seldom falls. Inflammation of lungs or bowels, or lockjaw, may supervene. Its cause is long fasting and overwork; but the quality of the food acts as a cause. Its treatment is relieving the stomach and bowels with searching laxatives, such as croton, aloes and calomel, with ginger. Clysters should also be given, and afterward cordials. Blood-letting from the jugular vein will be attended with advantage. Finally, steady exercise and careful feeding will prevent a recurrence of the disorder."* I had a year-old draught-colt that was affected with this disease. He was a foul-feeding animal, delighting to eat the moistened litter from the stable and byre. He was bled and physiced by a veterinarian, who had established himself in the neighborhood, and the front of his head blistered. He quite recovered, and having been removed from the temptation of foul feeding, he was never again similarly affected. The practice of keeping *he-goats* in the stables of inns, and of those persons who have extensive studs, is supposed, by the common people, to act as a *charm* against the mad staggers; but, as Marshall judiciously observes, the practice may be explained on physiological principles. "The staggers are a nervous disorder," he says, "and as odors, in many cases, operate beneficially on the human nerves, so may the strong scent of the goat have a similar effect on those of the horse. The subject," he adds, "is worthy of inquiry."† And he gives a striking instance of the good effects of the practice.

(1420.) *Thrush and Corns.*—I have said that the feet of the farm-horse are not liable to so many diseases as those of horses subjected to high speed on hard roads. Farm-horses, however, are liable to *thrush* and *corns* in the feet. The former is situate at the hind part of the cleft of the frog, originating principally from continued application of moisture and dirt, and hence it may be most expected to be seen in dirty stables, of which there are not a few in the country. After being thoroughly cleaned out, the hollow may be filled with calomel, which generally cures; or with pledgets of tow dipped in warm tar, or spirit of tar, applied at night, and retained during the day. The general health of the horse should be attended to. *Corns* are usually the consequence of the irregular pressure of the shoe on peculiarly formed hoofs; and are mere bruises, generally produced by the heel of the shoe, and which, from the extravasated blood, assume a reddish or dark color. They usually occur only in the fore-feet; and their site is almost invariably in the inner quarter between the bar and crust, at the heel. The obvious cure is removal of the pressure of the shoe.

(1421.) *Broken wind.*—Besides natural complaints, farm-horses are liable, in the execution of their work, to accidents which may produce serious complaints. Thus overwork, in a peculiar state of condition, may produce *broken wind*, which is the common phrase given to all disorganized affections of the lungs, though the term is defined by veterinarians to be "the rupture of some of the air-cells of the lungs, whereby air-vesicles are produced on the surface, and the expulsion of the air is rendered less direct and easy. It is usually produced by animals being urged to over-exertion when in bad condition, though a horse may become broken-winded in a straw-yard." There are many degrees of broken wind, which receive appellations according to the noise emitted by the horse; and on this account, he is called a piper, trumpeter, whistler, wheezer, roarer, highblower, grunter, and with thick wind, and with broken wind. I had two uncommonly good horses affected in the wind by working much in the *traces* of a four-horse plow, which were employed to rip up old turf dykes intermixed with large stones, and to break up rough ground. These serious effects of such work gave me the hint to relinquish it, and take to the spade, which I soon found did the work much better, and in the end cheaper. The horses got gradually worse under the disease, and at length being unable to maintain their step with the rest, were disposed of as broken-winded horses.

(1422.) *Sprains.*—"A sprain, or strain, is violence inflicted, with extension, often rupture and displacement, upon the soft parts of a joint, including cellular membane, tendons, ligaments, and all other parts forming the articulation. The dislocation or disruption may be complete, or it may be a mere bruise or stress; and innumerable are the shades of differences between these extremes. Effusion of the fluids is an attendant consequence. Parts of vital importance, as in the neck or back, may be implicated, and the accident be immediately fatal, or wholly irremediable; on the contrary, they may be to that extent only, that, with time and ease, restoration may be accomplished. They constitute a serious class of cases. The marked symptoms are, pain in the injured parts, and inability of motion, sometimes complete. The treatment is at first rest, a regulation of the local action and constitutional disturbance, according to circumstances, by venesection, general and local, the antiphlogistic regimen, fomentation, bandages, and other soothing remedies; and when the sprain is of an older date, counter-irritation, friction, and gentle exercise." Farm-horses are not unfrequently subject to strains, especially in doing work connected with building, draining, and other heavy work; and they are most apt to occur in autumn, when geldings are generally in a weak state. For rough work of this kind, old seasoned horses are best adapted, and such may often be procured for little money at sales of stock.

(1423.) *Saddle-galls.*—When young horses are first put to work, the parts covered by the saddle and collar are apt to become tender, heated, and then inflamed, and if the inflammation is neglected, the parts may break out into sores. Washing with a strong solution of salt in water with tincture of myrrh is a good lotion, while attention should be paid to the packing of both saddle and collar, until they assume the form of the horse intended to wear them. "Tumors, which sometimes result from the pressure of the saddle, go by the name of *warbles*, to which when they alcerate the name of *sitfasts* is applied, from the callous skin which adheres to the center. Goulard water may be used to disperse the swelling; a digestive ointment will remove the sitfast; and the *sore* should be healed with a solution of sulphate of zinc."

(1424.) *Crib-biting* and *wind-sucking.*—These practices are said to increase the tendency to indigestion and colic, and to lower condition, rendering the horses which practice them unsound. "A crib-biter derives his name from seizing the manger, or some other fixture, with his teeth, arching his neck, and sucking in a quantity of air with a peculiar noise. . . . . Wind-sucking

* Dick's Manual of Veterinary Science. † Marshall's Rural Economy of Gloucestershire, vol. ii.

consists in swallowing air, without fixing the mouth. The horse presses his lip against some hard body, arching his neck, and gathering together his feet." Both vices are said to be prevented by fastening a strap round the neck, studded with one or more sharp points or prickles opposite the lower jaw; but this means will not avail in all cases, for I had a year-old colt, which first began crib-biting in the field, by seizing the gate or any other object he could find. Being prevented using the gate by a few thorns, he pressed his mouth against any object that would resist him, even against the sides or rumps of his companions, and he then began to be a wind-sucker. A strap of the above form was put on, recommended to me by an artillery officer; but though it remained upon the colt for more than a twelvemonth, night and day, and as tight as even to affect his appearance, he continued to crib-bite or wind-suck in spite of it, even to the laceration of his skin by the iron studs. Growing largely to the bone, though very thin, he was taken up to work at the early age of two years, solely with the view of seeing if the yoke would drive him from the practice, but it had no such effect. Whenever he came into the stable he set to with earnestness to bite and suck with the strap on, until he would become puffed up as if to bursting, and preferred sucking wind to eating his corn. At length I was so disgusted with the brute that I sold him to a carrier, to draw a heavy single cart, and got a fair price for him, though sold as a crib-biter.

(1425.) *Dust-ball.*—Millers' horses are most liable to be affected with this disease. It is composed of corn and barley dust, saved in grinding meal, and used as food, and occurs sometimes in the stomach, but more frequently in the intestinal canal. "In an advanced stage no doubt can remain as to the nature of the disorder. The countenance is haggard, the eye distressed, the back up, the belly distended, the respiration becomes hurried, bowels habitually costive, and sometimes the horse will sit like a dog on his haunches. Relief may frequently be afforded. Strong purgatives and large injections must be given, and under their continued action the offending body is sometimes removed." On using barley-dust as food for horses, it would be well to mix it thoroughly with the other prepared ingredients, instead of using it in the dry state."

(1426.) *Worms.*—Farm-horses are sometimes affected with worms. These are of 3 kinds: the round worm, *teres*; the thread-worm, *ascaris*; and the tape-worm, *tænia*. "In the horse the tenia is very rare; in the dog exceedingly common. When the horse is underfed his bowels are full of teres and ascaris; and the appearance of his staring coat, want of flesh and voracious appetite betoken it. They occasion gripes and diarrhœa, but the mischief they produce is not great. The principal habitat of the ascaris is the cœcum, although they are sometimes found in countless multitudes in the colon and rectum. Turpentine is a deadly poison to all these worms; but this medicine, so harmless in man, acts more disagreeably in the lower animals. Hence it must not be given to them pure or in large quantities, but mixed in small proportion with other oils, as linseed, or in a pill; and, with these precautions, it may be found at once safe and efficacious."

(1427.) *Nebulæ or Specks in the Eye.*—Farm-horses are not subject to the more violent diseases of the eye; but, being liable to accidents, the effects of inflammation—nebulæ or specks—do sometimes appear. "The former are superficial, the latter dip more deeply into the substance of the part. Directly in the sphere of vision these, of course, impede it, and cause obscurity of vision. Even here we must proceed gently. These blemishes are the pure consequences of inflammation, and this subdued, their tendency is to disappear. Time and nature will do much, and the duty of the practitioner consists in helping forward the salutary process where necessary, by gently stimulating washes, while irritating powders should be avoided."* With these sensible remarks of Professor Dick I shall conclude what I have to say of the diseases of the farm-horse at this time.

(1428.) The offals of the horse are not of great value. His *hide* is of most value when free of blemishes. It tans well and forms a good leather, which, on being japanned, is chiefly used for covering carriages. I was informed by a friend who settled in Buenos Ayres as a merchant, that he once bought a lot of horses, containing no fewer than 20,000, for the sake of their hides alone, and that some of them would have fetched good prices in England. They were all captured with the *lasso*.

(1429.) *Horse-hair* is used in the manufacture of damask-cloth for sofas and chair-bottoms. The dyeing of it of various beautiful colors and the manufacture of the damask figures have been much improved of late. Horse-hair is also used for making fish-lines, horse-tails for cavalry caps and stuffing for matresses, for which last purpose it is prepared by being wound up hard and baked in an oven.

(1430.) "Hair, of all animal products, is the least liable to spontaneous change. It can be dissolved in water only at a temperature somewhat above 230° Fahr. in Papin's digester, but it appears to be partially decomposed by this heat, since some sulphureted hydrogen is disengaged By dry distillation hair gives off several sulphureted gases, while the residuum contains sulphate of lime, common salt, much silica, and some oxides of iron and manganese. It is a remarkable fact that fair hair affords magnesia instead of these latter two oxides. Horse-hair yields about 12 per cent. of the phosphate of lime. Hair also yields a bituminous oil, which is black when the hair is black, and yellowish when the hair is red."†

(1431.) "Button-moulds are made of the bones of the horse, ox and sheep. The shavings, saw dust and more minute fragments in making these moulds, are used by the manufacturers of cutlery and iron toys in the operation of case-hardening, so that not the smallest waste takes place."‡ The bones of all these animals, when reduced small, make the valuable manure—bone-dust—now well known to every farmer.

BOOK OF THE FARM.

1. FATTENING, DRIVING AND SLAUGHTERING SWINE.*

"Where oft the swine, from ambush warm and dry,
Bolt out, and scamper headlong to their sty."
BLOOMFIELD.

(1432.) That the youngest pigs may receive better treatment, the court and shed at *b*, fig. 3, Plate III., the same as in the plan at *b*, in fig. 4, Plate IV., and described in (68), are made purposely for them. These pigs consist, probably, of the last litters of the season of as many brood sows as are kept. Here they should be provided daily with turnips as their staple food, of the sort given for the time to the cattle, and sliced as small as for sheep; and they should, besides, have a portion of the warm

[* There are few subjects in regard to which we are in less need of being enlightened by the experience of other countries than in the breeding and management of swine. If, as assuredly it must be admitted, we are, over a large portion of the country, neglectful both as to improvement of the breed and treatment of them in all stages of their growth and existence, it is not that there is any great difficulty in understanding both the one and the other; but mismanagement in this, as in too many other cases, results from sheer listlessness and want of thought. The hog may quickly be brought to the shape that we desire, and which best adapts him to the food at command and the uses designed by the farmer; and common sense tells every one that as the sole purpose of rearing him is for meat, he should be kept *always* in thriving condition by attention to the necessary warmth and sufficiency of food, so that he may be kept always growing apace, until finally to be fattened. The region of which Indian corn is the staple, and where there is most of it, is the natural habitat of the hog in our country; nor could he be reared in the Eastern States with that economy which our countrymen there know so well how to practice, were it not for the essential object which they keep constantly in view, and to which the hog is there made largely subservient, to-wit: the *manufacture of manure*.

But conversant as we are with swine husbandry, there may yet be found in this chapter some interesting remarks on the preparation and value of different kinds of food—a subject of importance to every agriculturist who desires, as all should desire, to economize labor and materials in the process of fattening. Useful, too, should be the lesson it teaches, to keep for fattening hogs a constant supply of pure clean water, and to study cleanliness throughout, as far as practicable, in a department where the general impression and practice agree that dirt without stint is tolerable, if, indeed, it be not medicinal and useful! The manner of fattening hogs, where Indian corn is used for the purpose, as in the South and West, is to "put them up" in large open pens on the ground, without litter and without shelter. Here they are left to burrow and sleep in mud and mire, exposed to all weathers, consuming, probably, before they get "ripe fat," one-third if not one-half more than would be necessary were they sheltered in a warm pen, with clean litter and with clean water and rich food in abundance at pleasure, free alike from exposure and excitement. Experiment has abundantly proved the truth of Johnson's declaration, that "the 'greater the difference between the temperature of the body and that of the atmosphere in which 'they live, the more food they require to 'feed the lamp of life.'" All this, however, is philosophically and plainly described in our Monthly Journal of Agriculture. *Ed. Farm. Lib.*]

mash made for the horses, with such other pickings from the farm-house which the kitchen affords. They should also be provided with a trough of clean water and plenty of litter under the shed every day. The court-yard should be cleaned out every day. Pigs are accused of dirty habits, but the fact is otherwise, and the accusation applies more truly to their owners who keep them dirty, than to the natural habits of the animals themselves. When constrained to lie among dirt and eat food fit only for the dunghill, and even that dealt out with a grudging hand, how can they exhibit other than dirty propensities? But let them have room, choice of clean litter and plenty of food, and it will soon be observed that they keep their litter clean, place their droppings in one corner of the court and preserve their bodies free from dirt.

(1433.) The sties *c*, figs. 3 and 4, Plates III. and IV., are intended for sows about to litter. Whenever the period of their confinement approaches each sow should be put into one of these and supplied with food; but the treatment of sows will better fall to be described in spring. The form of door best suited for securing pigs in their sties may be seen in fig. 23.

(1434.) By direct experiment, which will be found related below, it has been ascertained that pigs fatten much better on cooked than on raw food. This being the case it is only waste of time and materials, and also loss of flesh, to attempt to *fatten* pigs on raw food of whatever kind; for although some sorts of food fatten better than others in the same state, yet the same sort when cooked fattens much faster and better than in a raw state. The question, however, simply is, what is the best sort of food to *cook* for the purpose of *fattening* pigs? Roots and grains of all kinds, when cooked, will fatten pigs. Potatoes, turnips, carrots, parsnips, as roots; and barley, oats, peas, beans, rice, Indian corn, as grain, will all fatten them when prepared. Which, then, of all these ingredients should be selected as the most nourishing and, at the same time, most economical? Carrots and parsnips, among roots, are not easily attainable in this country, and therefore cannot be considered as economical food; and as to the other two sorts of roots, when cooked, potatoes doubtless contain much more nourishment than turnips, even in proportion to their price, for it is as easy to obtain 10s. for a ton of Swedish turnips as 8s. for a boll of 40 stones of potatoes; and yet potatoes contain 4 times the nutritive matter of Swedes, and 6 times of common turnips.* Steamed potatoes, then, may form the staple ingredient of pig-feeding. As to grains, I have never heard of wheat or wheat-flour being given to pigs; it would certainly not be economical; barley or oat-meal being usually employed. Peas and beans, whether raw or cooked, are proverbially excellent food for pigs. And as to rice and Indian corn, they will both fatten well, if cooked. Amid all these ingredients for choice, regarding the question of economy alone, it may be assumed that entire feeding on grain, of whatever kind, would be too expensive, so that, as steamed potatoes are of themselves nourishing food, a proportion, with any of the grains, should form a moderately-priced food which will insure fatness. It has been ascertained in England that upon 2 pecks of steamed potatoes mixed with 9 lbs. of barley-meal and a little salt, given every day to a pig weighing from 24 to 28 stones, will make it *ripe* fat in 9 weeks. Taking this proportion of food to weight of flesh as a basis of calculation, and assuming that 2 months will *fatten* a pig sufficiently well, provided it has all along received its food regularly and amply, I have no doubt that feeding with

* The Farmers' Almanac and Calendar for 1842.

steamed potatoes and barley-meal, for the first month, and, in the second, with steamed potatoes and peas-meal (both seasoned with a little salt), and lukewarm water, with a little oat-meal stirred in it, given by itself twice a day as a *drink*, will make any pig, from 15 to 30 stones, *ripe fat for hams*. The food should be given *at stated hours*, 3 times a day, namely: in the morning, at noon and at nightfall. One boiling of potatoes in the day, at any of the feeding-hours that is found most convenient, will suffice; and at the other hours the boiled potatoes should be heated with a gruel made of barley or peas-meal and boiling water; the mess being allowed to stand awhile to incorporate and cool to blood-heat. It should not be made so thin as to spill over the feeding-trough, or so thick as to choke the animals; but of that consistence which a little time will soon let the feeder know the pigs relish best. Washing fattening pigs with warm water and soap rapidly promotes their fattening; and, after the first trial, they delight in the scrubbing. A convenient form of trough for fattening pigs is described below in fig. 297. The swing-door, on being fastened on the side nearest the pigs, serve the purpose of warding them off until the trough is cleaned out or replenished with food. The trough should be thoroughly cleaned every day, and being subdivided into three parts, more than one pig may be fattened in the same sty. But when only one occupies a sty—which is the least troublesome arrangement—one division may be filled with one of the meals daily, thus giving a clean trough every meal; and all the divisions should be cleaned in the morning before supplying the first meal. After every meal is supplied the swing-door is fastened nearest the outside, thus giving the pigs access to their food, as well as preventing them being disturbed at their meals. The quantity of food given at any time should be apportioned to the appetite of the animals fed, which should be ascertained by the person who feeds them; and it will be found that less food, in proportion to the weight of the animal, will be required as it becomes fatter. When pigs are fattening they lie and rest and sleep a great deal, no other creature showing "love of ease" so strongly in all their motions; and, in truth, it is this indolence which is the best sign of their thriving condition. The opposite effects of activity and indolence on the condition of animals is thus contrasted by Liebig: "Excess of carbon," says he, "in the form of fat, is never seen in the Bedouin or in the Arab of the Desert, who exhibits with pride, to the traveler, his lean, muscular, sinewy limbs, altogether free from fat. But in prisons and jails it appears as a puffiness in the inmates, fed as they are on a poor and scanty diet; it appears in the sedentary females of Oriental countries; and, finally, it is produced under the well known conditions of the fattening of domestic animals;"* and among these last the pig may be instanced as the most remarkable.

(1435.) The denominations received by pigs are the following: When new-born, they are called *sucking pigs*, or simply *pigs;* and the male is called *boar pig*, the female *sow pig*. A castrated male, after it is weaned, is named a [barrow] *shot* or *hog*. Hog is the name mostly used by naturalists, and very frequently by writers on Agriculture; but as it sounds so like the name given to young sheep, I shall always use the term pig and swine, for the sake of distinction. A spayed female is a *cut sow pig*. As long as both sorts of cut pigs are small and young, they get the name of *porkers* or *porklings*. A female that has not been cut, and before it bears young, gets the name of an *open sow;* and an entire male receives, and retains ever after, the name of *boar* or *brawn*. A cut boar is a *brawner* [barrow],

* Liebig's Animal Chemistry.

and the flesh of both boar and brawner is *brawn*. A female that has taken the boar is said to be *lined;* when bearing young she is called a *brood sow;* and when she has brought forth pigs, she is said to have *littered* or *farrowed*, and her family of pigs at one birth are called a *litter* or *farrow* of pigs.

(1436.) Of *judging* of a fat pig, the back should be nearly straight; and though arched *a little* from head to tail, it is no fault. The back should be uniformly broad and rounded across along the whole body. The touch all along the back should be firm but springy, the thinnest skin springing most. The shoulder, side, and hams should be deep up and down, and in a straight line from shoulder to ham.* The closing behind should be filled up; the legs short, and bone small; the neck short, and thick, and deep; the cheeks rounded and well filled out; the face straight, nose fine, eyes bright, ears pricked, and the head small in proportion to the body. A curled tail is a favorite, because indicative of a strong back [and healthy, thriving condition]. All these characters may be observed in the figure of the brood-sow in one of the Plates; though, of course, the sow is not in the fattened state. A black colored pig is always black of skin, and a white one white, and which latter color gives to the pig a cleaner appearance than the black. A *fat* pig ought never to be driven, but carried in a cart when desired to be transported from one place to another.

(1437.) As to the breed which shows the greatest disposition to fatten, together with a due proportion of lean, I never saw one to equal that which was originated by Lord Western, in Essex. I received a present of a young boar and sow of that breed from Lord Panmure, and had the breed for 10 years; and such was the high condition constantly maintained by the pigs on what they could pick up at the steading, besides the feed of turnips supplied them daily, that one could be killed at any time for the table as a porkling. They were exceedingly gentle, indisposed to travel far, not very prolific, however, but could attain, if kept on, to a great weight; and so compact in form, and small of bone and offal, that they invariably yielded a greater weight of pork than was judged of before being slaughtered. Though the less valuable offal was small, the proportion of loose seam was always great, and more delicious ham was never cured in Westphalia than they afforded.†

[*In the United States, where so large a proportion of the hogs slaughtered is made and cured for *bacon*, and where the ham is much the most valuable part—length from the tail to the hips, or as they are called in cattle the pins, so as to throw their points well forward toward the shoulder is a matter of importance in the formation of the hog; as it insures a greater proportionate weight in that part of the animal. The best bacon in the world, some would except the Westphalia, is to be found in our Middle States, where corn is one of our chief staples, and where the hog is left to run at large, and scuffle for his living, from the time he is weaned until put up finally to be fattened on corn, which is too generally thrown in upon the ground and on the cob. True, where there is a "gang" of turkeys, they are usually fattened on the wasting and leaving of the hog, as the hog is the scavenger to clean up and fatten on the leavings of bullocks fed with corn, on the cob, in open field.

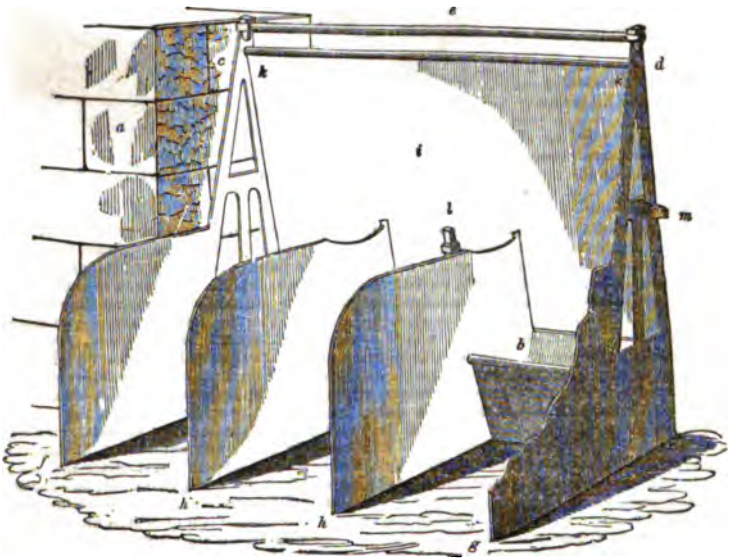
However careless in other things, the salting and smoking of their pork generally commands the close attention of the husbandman, and not unfrequently of the good housewife. The standard for the best hams, in the region to which we have referred, is where the whole hog weighs from 130 to 160 or 175 at most. Without subjecting them to the best of all tests, no one who never compared them, can realize the difference between a Maryland ham of about twelve pounds, properly smoked with hickory wood, and such as one sometimes meets with elsewhere, half smoked and from a great fat beast of 300 pounds weight.

[† We should prefer the Mackey breed—if to be had under the sanction of Col. Jaques of Charles town, Mass.—as to its genuineness. Mr. Webster took great pains to procure, and had at Marsh-

(6*

(1438.) [*Pigs'-Troughs.*—A very convenient trough for a piggery has been long manufactured by the Shots Iron Company, of which fig. 297 is a view in perspective from the interior of the court. It is nearly all made of cast-iron, and possesses the great convenience of allowing the troughs to be filled with food from the outside of the building, the feeder being at the same time free from any annoyance from the inmates. Troughs of this kind are placed in proper sized openings in the external wall of the piggery court, in the manner shown in the figure, where *a* marks the wall on one side of the opening, that on the hither side being left out of the figure, in order to exhibit the form of the trough. The trough, part of which is seen at *b*, is 4 feet in length, 16 inches wide at top, and 8 inches at bottom, and is 9 inches deep. The two ends *c* and *d* rise in a triangular form to the hight of 3½ feet, and are connected at the top by the stretcher bolt *e*. The lower part of each end extends inward to *f g*, making a breadth of 3 feet 4 inches when complete, but this part of the end *g* in the figure is broken off, to show part of the trough *b*. Two intermediate divisions *h h* divide the trough into three compartments; these divisions extend to the same length as the ends *f g*, and are all 21 inches in hight. By means of these divisions, each animal, when there are more than one together, has its own stall, and can take its food undisturbed by its neighbors. A swing-door *i* is jointed on the pivots *k k*, to complete the form by filling up the opening of the wall. In the figure this door is thrown to the full extent outward, where it always

Fig. 297.



THE PIGS'-TROUGH, WITH SUBDIVISIONS, TO STAND IN AN OPENING OF THE OUTER WALL OF THE STY.

stands during the time the animals are feeding, and is fixed there by a slide-bolt on the outside. When food is to be introduced the bolt is withdrawn, and the door moved from that position to *l*, and there bolted until the compartments of the trough are cleaned and filled, when the door is again swung back to its original position, and the food is placed before the animals. The door has slits formed in it corresponding to the divisions *h h*, to allow of its swinging freely, and yet have depth sufficient to close the entire opening down to the outward edge of the trough. A dowel or stud *m* is let into the wall at each end, to secure the upper part of the trough. On a late visit to the Duke of Buccleuch's home-farm at Dalkeith Park, which is conducted by Mr Black, I was much interested with the piggery, where the stock is of the finest quality, and,

---

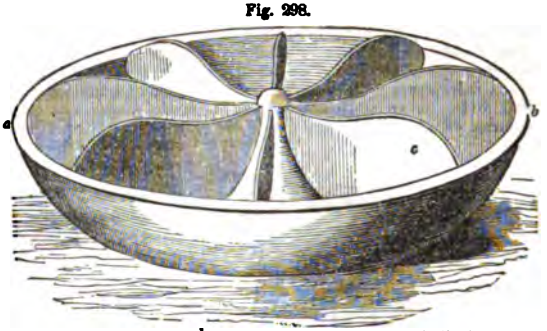
field, some time since, the real Simon Pure of that race. But the best breed of hogs that we have ever seen, according to our judgment, were sent into Maryland from England, in 1823, by Mr. Wright, a brother-in-law of the late Mr. Champion, as a present to the then Editor of the American Farmer. They were black hogs, of which an account may be seen, with a portrait of the sow, in the old American Farmer, vol. 6. They got the name of "Skinner's breed," and some traces of them may yet be found in Virginia. If they could be bred back to the form and qualities of the original stock, they would deserve to be very highly prized. Any farmer, however, of common sagacity and attention, may soon modify and shape a breed to suit his own locality and views. From those who have not the spirit and true love of business to do even that, you will be sure to hear the common remark, "say what you will about breeds, but give me the *corn house breed.*" Men without energy or proper ambition are rarely without some such easy resort, in the way of self-excuse.]

(9)

among other things of interest, saw what is very probably the original of the trough here described. The troughs in this piggery are composed of wood, but precisely on the same principle, as here figured and described, and their introduction there dates as far back as the time of the late Duke Henry of Buccleuch, whose invention they are supposed to be, and which must be at least of forty or more years' standing.

(1439.) *The Ring Pigs'-Trough.*—I have seen in England a very handsome pigs'-trough adapted for standing in the middle of a court. It is formed also of cast-iron, but in one entire piece, and is here represented in fig. 298. Its external appearance when viewed as it stands on the ground, approaches to that of a hollow hemisphere; but interiorly the bottom parts rise up in the center, forming a central pillar, thus converting the hemisphere into an annular trough, whose transverse section is a semicircle, and the entire section of the two troughs forms two semicircles conjoined. The diameter *a b* of this trough is 30 inches, the edge is finished with a round baton, serving both for strength and for comfort to the animals which eat out of it; the depth is about 9 inches, and it is divided into eight compartments by the divisions *c*, which are formed with a convexity on the upper edge to prevent the food being thrown from the one compartment into another.—J. S.]

Fig. 298.



THE RING PIGS'-TROUGH, TO STAND IN A COURT.

(1440.) In regard to the *slaughtering* of pigs, they should be made to fast for nearly a day, to clear their bowels of as much food as possible. The season best adapted for the purpose is in the cool months of the year; the flesh in the warm months not becoming sufficiently firm, and is then liable to be fly-blown before it should be cured. For using fresh pork, the season of course does not signify. When you wish to make hams for your own use, Christmas is a good time for slaughtering pigs, and, in doing it, great care should be taken that the animals receive no injury by bruises before being killed, as the flesh, where bruised, will become blood-burned, and will not take with the salt. When the time for slaughtering arrives, the animals should be taken out of their sties gently one by one as slaughtered, and placed on their back on a considerable quantity of straw, and held in that position by assistants, while a long knife is introduced with a firm hand through the counter near the bottom of the neck, through the opening between the ribs at the sternum into the heart, care being taken that the point of the knife does not miss the opening, and go between the shoulder-blade and the ribs. This error is frequently committed in slaughtering pigs; it is called *shouldering*, and has the effect of collecting a mass of blood under the shoulder-blade, where it coagulates, and prevents the whole shoulder from being cured. Before the slaughtering commences, a large quantity of boiling water should be provided, with which to scald off the hair. This is effected either by putting the carcass into a large tub of water, or, should there not be a tub of sufficient size, the hot water can be poured on the carcass on the straw, and scraped clean of the hair from every part of the body. The hoofs are taken off at this time. The net fat and entrails are separated, and the carcass is dressed in the most simple manner, without flourishes, and with only a single stretcher to keep apart the flaps of the belly.

(1141.) The carcass hangs in the slaughter-house until next day, when it is sawn up the back bone into two sides. If it is intended for pickled pork, the sides are cut up in Scotland in the same way as the Scotch mode of cutting up mutton (fig. 255), namely, *a*, fig. 299, is the leg, and *b* the loin, in the hind-quarter; *c* the ribs, and *d* the breast, in the fore-quarter. The leg *a* makes an excellent leg of pickled pork, served with pea-pudding; and the loin *b* a juicy fresh roast. The back-ribs of *c* are a fine roasting piece, and also for pork-chops, one of the most delicate dishes of the hasty modes of dressing meat. The fore-end of *c*, and the whole of the breast *d*, are fit for pickling. The head, split in two, is also pickled, and considered a delicacy, as the fat upon the cheeks is gristly.

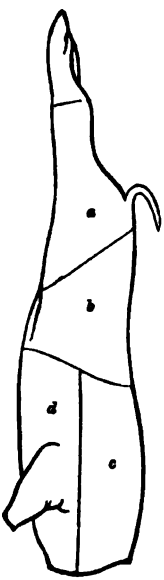
(1442.) The English mode of cutting up pork is different from what has just been described, and, upon the whole, perhaps better adapted for family use. Fig. 300 gives a representation of it, where, in the fore-quarter, *a* is the spare-rib, so called because the flesh and fat are taken off the ribs for salting; and the ribs are then roasted, and make a savory dish; *b* is the hand or shoulder, fit for pickling; *c* the belly or spring, also fit for pickling, or for rolling up, when well seasoned and stuffed, for brawn, and eaten as a relish. In the hind-quarter are *d* the fore and *e* the hind loin, both best when roasted, the fore one *d* also making excellent chops; and *f* the leg, which is cut short for pickling. The *neck* is called a *crop* of pork, and, when divided into its vertebræ, are cut for chops, and called *griskins*. The head, when divided in two, is again divided at the jaw into an upper part called the *face* or *cheek*, and the lower part named the *chap*. Some times the two chaps are not divided.

(1443.) According to Mr. Donovan, a hand of salt pork, weighing 4 lbs. 5 oz., lost in boiling 11 oz. The bone weighed 9 oz.; the meat was 3 lbs. 1 oz. If the first cost of the pork was 7½d. per lb., the meat alone, when duly boiled, cost 10¼d., and with the bone nearly 9d. per lb. The loss in boiling salt pork is consequently 15½ per cent.*

* Donovan's Domestic Economy, vol. ii.

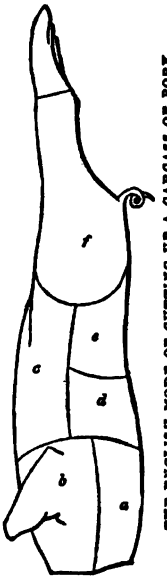
(1444.) Of the time required for digesting pork dressed in various ways, pigs' feet soused and boiled take 1 hour; sucking-pig roasted, 2½ hours; pork recently salted, raw or stewed, 3 hours; pork-steak, and recently salted pork, broiled, 3¼ hours; pork recently salted, fried, 4½ hours; pork recently salted, boiled, 4¼ hours; and pork, fat and lean, roasted, 5¼ hours.*

Fig. 299.



THE SCOTCH MODE OF CUTTING UP A CARCASS OF PORK.

Fig. 300.



THE ENGLISH MODE OF CUTTING UP A CARCASS OF PORK.

(1445.) *Pickled* pork derives its name from the mode in which pork is cured in a strong brine or pickle of salt and water. The flesh is first rubbed with salt, then subjected to pressure, then rubbed again, and packed in barrels, and strong brine poured over it. Immense quantities of pork are pickled, for home and foreign consumption, by the pieces being simply placed in brine, but is, of course, inferior to what is cured as above described. The largest establishment for the curing of pork I ever saw was in Belfast. A carcass is cut up in a few seconds in this manner: One man stands at the end of a large hacking-block of wood, provided with a long-faced hatchet, and two others stand on each side of the block. A carcass, of whatever size, is placed on the block, on its back, with its head toward the hatchet; a man then seizes each of the limbs, and keeps the carcass open. With three or four strokes of the hatchet, the carcass is divided into two from snout to tail. One chop cuts off each of the half heads, and one each of the legs. The heads are thrown into one heap, and the legs into another. The two men at the hind-quarter then take their knives and cut off the hams, which are put by themselves, and taken away and rubbed with salt, and placed in rows on the ground, with the fleshy side uppermost, covered with dry salt. The remainder of the carcass gets two or three chops across the ribs, according to its size, and the pieces are thrown into a large tub of brine. The whole thing is done in far less time than I have taken to describe it. For family use, no pickle should be used in curing pork, as it extracts the natural juices of the meat; the pieces, cut of a convenient size, should be rubbed with good dry, Liverpool salt, both on the skinny and fleshy parts, and packed in a jar covered with a lid or cloth; and from eight days to a fortnight, according to the size or thickness of the pieces, the pork will be ready for use. The navy tierce of pork consists each of 80 pieces of 4 lbs.

(1446.) When the carcasses are meant for *ham* for family use, they are treated in this manner: After being sawn asunder, the sides should be carefully handled, that the back-bone be not broken, and placed on a table, when all the loose seam or tallow is taken out, and the kidneys extracted out of it. The muscle lying along the back-bone under the loin is taken out, and, when used fresh, makes an excellent collop for sausages; and the diaphragm or skirt is also cut off. The tongue is cut out, the brains scooped out, the ears extracted by their sockets, the tail cut away, and the four feet disjointed at the knees. Every loose and useless shred of fat, sinew, nerve, flesh, and skin, should be carefully removed.

(1447.) The next process is the *salting*. Let the sides be placed with the skin side uppermost, and all where there is *skin* let it be rubbed hard with the palm of the hands, by two persons, for fully half an hour, in a warm place, with good dry salt, taken in indefinite quantity. Thin-skinned uniformly fat pork will feel warm under the rubbing, and the skin become somewhat loose and sweaty, which are the best signs that the flesh is taking in the salt. A hard-skinned side will not exhibit these symptoms, nevertheless it will take in the salt too, though not so kindly. The ends of the shanks should be well rubbed with salt. After this rubbing, the side is turned over, and 4 oz. of saltpetre, finely pounded, are strewed over the inside, and especially over all the fleshy parts that have been cut with the knife, such as along the line of the back-bone, and the inside of the ham. The use of the saltpetre is to give a uniformity to, and highten the color of, the flesh, which, in pork, becomes red on being converted into ham. A layer of salt of about ¼ of an inch thick is then laid on the side over the saltpetre. In this state the side is carried carefully, and laid upon a board or wooden floor. Other sides are treated exactly in the same manner, one after the other, and laid upon one another, with the skinny sides downmost; but perhaps 4 sides are enough to form one heap, laid alternately, head and tail, to lie compactly. A board is then laid above them, supporting a number of weights; the whole being covered with a woolen cloth, to keep out the frost, should it arrive. In the course of a day or two, brine will run from the heaps, which should be wiped up from the floor. In a fortnight the sides should again be laid on the table, and the brine that may have collected on the ribs poured out, the loose wet salt removed, and the skinny side again rubbed with dry salt for about a quarter of an hour. The loose salt should then be all brushed off by the hand, and the skin wiped dry. To prevent flies blowing the end of the shanks at the joints, a brown-paper bag makes a close enough covering for them; and a wooden skewer being thrust through both shank and bag, and both tied firmly to the leg with twine, the remainder of the twine is formed into a stout loop by which the side is

* Combe on Digestion and Dietetics.

suspended from hooks. The inside is then covered with a uniform coating of barley or peas-meal, pushing it well into every crevice with the finger. The dampness of the flesh will make the meal stick on, but there is none put on the skinny side. The side is then hung up from the roof of a warm, dry room, the kitchen being the most appropriate place; and the kitchen roof thus garnished conveys an idea of plenty and good cheer. I sent this recipe, through a friend, to a lady whom I understood was at the time engaged on a work on the culinary art, and it may be found substantially in the above shape in her valuable pages.

(1448.) From experiment, it was ascertained by Mr. Donovan that if the first cost of ham be 10d. per lb., the meat, duly boiled, skinned and browned, will cost 1s. 1½d. per lb.; the loss there by being consequently 33 per cent.

(1449.) Hog's lard is rendered in exactly the same manner as mutton suet (1513); but as lard is liable to become rancid, yellow-colored, and acquire a strong smell when exposed to the air, it is usually tied up in bladders. For this purpose it is allowed to cool a while, after it is melted, and the bladder (a pig's or calf's) being made ready by being thoroughly cleaned and turned outside in, is filled with the lard by a funnel, and tied up. Lard "melts completely at 99° Fahr., and then has the appearance of a transparent and nearly colorless fixed oil. A thermometer placed in it sinks gradually to 80°. The lard then begins to congeal, and the thermometer remains at 80° all the time of congealing, which occupies several minutes. It is clear from this that 80° is the melting point of hog's lard. Its specific gravity at 102° is 0·9028; at 60°, it is 0·9302. . . . . It consists of elain 62 parts and of stearine 38 parts out of the 100 parts. . . . . When subjected to pressure between folds of blotting-paper, the elain is absorbed, while the stearine remains."* For domestic purposes, hog's lard is better than even butter for frying fish; but is quite unfit for pastry, though much used in that way on the score of economy.

(1450.) Hog's skin is usually thick, and, when tanned, its great toughness renders it valuable for the seats of riding-saddles. Hog's bristles are formed into brushes for painters and artists, and for numerous domestic uses. Some of the offals of the pig make excellent domestic dishes, such as blood, mealy and sweet puddings; and pork sausages, made of the tender muscle under the lumbar vertebræ, are sweeter, higher flavored, and more delicious than those of beef. If it were not for taking up too much room, I could give excellent recipes for making these puddings and sausages; because I do not think such matter foreign to the pages of a work which professes to make you acquainted with what can be made available on a farm.

(1451.) An experiment on the comparative advantages of feeding pigs on raw and boiled food was made in 1833 by Mr. John Dudgeon, Spylaw, Roxburghshire. He put up 6 *he* pigs in one lot, and 5 *she* ones in another, and they were all carefully *cut*, and 9 weeks old. The he pigs were put on *boiled* food, namely, potatoes and hashed beans; the she ones on raw of the same sort. The 6 he pigs increased in live-weight, from 2d July to 12th October, 38 stones 6 lbs. 4 oz., or 6 stones 5 lbs. 11 oz. each; whereas the 5 she ones only increased, in the same time, 17 stones 11 lbs. 8 oz., or 3 stones 7 lbs. 14 oz. each. Other 3 pigs were fed at the same time on boiled and raw food indiscriminately, as it happened to be left over after serving the other two lots. The facts brought out in this experiment are, that the pigs "fed exclusively upon boiled meat did thrive in a superior manner to the others, and even to those which had an occasional mixture of raw and boiled meat; thus showing that boiled meat is at all times more nutritive than raw." The "pigs were repeatedly washed with soap and water, which refreshed them greatly, and caused them to relish their food." Those "which got a mixture of food both prepared and raw, approached nearer to those which were fed on boiled to their feeding properties; but they appeared occasionally shy at having their meat so mixed. It is therefore better, in general, to continue for some time only one description of food; as, whatever the animals become accustomed to, they begin to relish, and thrive upon it accordingly."†

(1452.) Mr. Robert Walker, Ferrygate, East-Lothian, also made an experiment on the same subject in the same year. He put 5 pigs on steamed potatoes and prepared broken barley, and other 5 on raw potatoes and raw broken barley. The pigs were 2½ months old. On the 4th March, 1833, the live weight of the 5 pigs fed on raw food was 7 sts. 10 lbs.; on the 1st June following, it was 16 sts. 13 lbs., showing an increase of 8 sts. 3 lbs., or an increase in each pig of 1 st. 9 lb. On the 4th of March, the live weight of those fed on steamed food was 7 sts. 8 lbs., and on the 1st June it was 19 sts. 13 lbs., showing an increase over the whole of 12 sts. 5 lbs., or an increase on each pig of 2 sts. 6½ lbs. The increase in the time was 67 lbs. more than double the original live weight of the pigs fed on steamed food; whereas, in those fed on raw, the increase was only 7 lbs. more than the double; "so that there can be very little doubt," as Mr. Walker concludes, "that steamed food is more profitable for feeding pigs than raw food. In fact, I do not think it possible to make pigs *fat* on raw potatoes, without other food, when confined to them alone."‡

(1453.) Dairy farms are well suited for rearing pigs on the dairy refuse in summer, but in winter the most that can be done is to keep the brood-sows in pig in fair condition for littering in spring. On corse and pastoral farms, no more pigs can conveniently be reared than to serve the farmer's family. On mixed farms, pigs constitute a portion of the regular stock.

(1454.) With regard to the *diseases* of swine, they are fortunately not numerous, as it is no easy matter to administer medicine to them. The safest plan, in most cases, I believe, is to slaughter them whenever any symptoms of internal disease show themselves. Swine are infested with a louse *(Hæmatopinus suis)*, like all domesticated animals. It is represented in fig. 301. Head and thorax of a dull, rusty color, the former pear-shaped and narrow, with an angular black line at the apex, and one on each side before the eyes; abdomen large, flat, and oval, of a bluish or yellowish ash gray color, most of the segments with a black horny prominence at each side, surrounding a white breathing-hole; legs pale ochre-yellow, the thigh marked with dusky bands,

* Thomson's Animal Chemistry.
† Prize Essays of the Highland and Agricultural Society, vol. x. ‡ Ibid., vol. x.

length 1¼ to 1¾ lines. This species is generally very plentiful on swine, more particularly on those fresh imported from Ireland. It appears to abound most on lean animals. "In walking," says Mr. Denny, "it uses the claw and tibial tooth with great facility (which act as a finger and thumb), in taking hold of a single hair; the male is much smaller, sub-orbicular, and the segments lobate. The egg or nit is ¼ of a line in length, of a cream color, and elegantly shagreened, oblong, and slightly acuminated, surrounded by a lid which, when the young insect is ready to emerge, splits circularly—or, as a botanist would say, has a circumcisile dehiscence."* Oil in the first stage, and mercurial ointment in after stages, will destroy this insect.†

Fig 301

THE SOW-LOUSE (HÆMATOPINUS SUIS).

(1455.) *Consumption* is a disease which affects pigs. It is brought on by "neglect and exposure to cold and damp. The animal becomes thin, the coat staring, the skin appearing as if glued to the ribs; obstinate cough supervenes; discharge is frequent from the nose, and glandular swellings appear about the neck. On dissection, the lungs are studded with tubercles." "It is in the early stage alone of the complaint," says Professor Dick, "that anything can be done, and the prospect of cure is but faint.‡ In alluding to the lungs, I may mention a remarkable instance of their state I once observed in a sow of my own. She had borne several litters, and became asthmatic, which increasing so as to appear distressing to the animal, she was killed; and one lobe of the lungs was found to be so completely ossified that its surface was converted into a shell nearly as hard as the crust of a crab, and it was filled with a thick yellow fluid. Having understood afterward that this was a remarkable case, I regret that the lobe was not examined by a veterinarian. I take this opportunity of suggesting to every farmer, who may happen to meet with any instance of structural disorganization in any part of any animal he owns, to have it examined by a competent veterinarian.

(1456.) Pigs are subject to a cutaneous disease called *measles*, which is supposed to render the flesh unwholesome. "The measles," says a writer, "are very prevalent, though seldom fatal; and if not checked, affect the grain of the meat, which may be commonly seen in the shops of a faded color, and the flesh punctured, as it were, with small holes, or distensions of the fibre. The commencement of the disease appears in languor and decline of appetite, followed by small pustules in the throat, together with red and purple eruptions, more distinct after death than during the life of the animal; but may, it is said, be removed in this stage by giving small quantities of levigated crude antimony in the food. Generally speaking, even if the animals be in health, a small quantity of nitre and sulphur, occasionally mixed up with their food, besides stimulating their appetite, will frequently prevent disease; neither can we too much insist on cleanliness, nor upon the punctual regularity of feeding at stated times."‖ The injunction contained in the last words, if followed, will do more for the preservation of health in pigs, than the administration of any specific after disease has once shown itself. I can safely say that, with the simple means here enjoined, I never had a pig that was in the least affected in the skin by either disease or vermin.

---

2. TREATMENT OF FOWLS.

"Thither the household feathery tribe crowd,
The crested cock, with all his female train,
Pensive and dripping;———"

THOMSON.

(1457.) Of all the animals reared on a farm, there are none so much neglected by the farmer, both in regard to the selection of their kind, and their qualifications to fatten, as all the sorts of domesticated fowls found in the farm-yard. Indeed, the very supposition that *he* would devote any of *his* time to the consideration of poultry, is regarded as a positive affront on his manhood. Women, in his estimation, may be fit enough for such a charge, and doubtless they would do it well, provided they were not begrudged every particle of food bestowed upon those useful creatures. The consequence is what might be expected in the circumstances, that go to most farmsteads and the surprise will be to meet a single fowl of any description in *good* condition, that is to say, in such condition that it may be

* Denny's Monographia Anopluorum Britanniæ.
† I find that the ox-louse (*Hæmatopinus eurysternus*), fig. 268, has been erroneously printed on page 151.
‡ Dick's Manual of Veterinary Science. ‖ British Husbandry, vol. ii.

killed at the instant in a fit state for the table, which it might be if it had been treated as a fattening animal from its birth. The usual objection urged against feeding fowls is that it does not pay, and no doubt the usual price received for lean, stringy-fleshed, sinewy-legged fowls is far from remunerative; but whose fault is it but the rearer of them, that fowls are sent to market in such a state, and why should purchasers give a high price for any animal, be it fowl or beast, that is in under condition? There would be some excuse for the existence of lean fowls at a farmstead were there any difficulty of fattening poultry of every kind at no great expense; but the idea of expense is a perfect bugbear; and this is one, like all others that seize us through our fears, would vanish were a plan adopted for rearing fowls more consonant to common sense than the one usually pursued. To judge from common practice, the prevalent sentiment seems to be, that fowls cannot be ill off when they get leave to shift for themselves. Such a principle is a grievous error in the rearing of any kind of live stock. Better a man keep no stock at all than allow such a sentiment to influence his conduct to them. Fowls may be considered worthless stock, and so they generally *are*, but are you sure that it is not your mode of managing them that renders them so? But apart from every consideration of profit to be derived from sales in market-towns, there is the superior one of the farmer having it *at all times* in his power to eat a well-fed fowl at his own table; and there is no good reason why he should not be able to enjoy such a luxury at any time he choses. There would be economy in it too, in the long run, inasmuch as *good* poultry, at command, will keep him out of the butcher market, into which he cannot go without cash in hand, and *cash* he cannot command except by realizing the money value of some commodity or other from the farm. Few farmers kill their own mutton, that is to say, keep fine fat sheep for their own use; lamb, they may kill in the season; but as to beef, it must be purchased; so that, situate as the farmer usually is, the produce of the poultry-yard and pig-sty constitute the principal items of his board. And why should he not have these in the highest perfection?

(1458.) Winter is a season in which no fowls are brought forth in Great Britain. The climate is too severe for them; the cold would either kill chickens outright or prevent their growth so as to render it unprofitable to bestow the great attention which their rearing would require. None of the fowls usually lay eggs in winter. But notwithstanding this natural barrier to the propagation of fowls in winter, both chickens and eggs may, by good management, be obtained in that season.

(1459.) The ordinary fowls on a farm are the cock *(Phasianus gallus)*, the turkey *(Meleagris gallopavo)*, the goose *(Anas anser)*, the duck *(Anas domestica)*, and the pigeon *(Columba livia)*, the white-backed or rock dove, which was long ago confounded with the blue-backed dove *(Columba œnas)*. In regard to all these I shall first state the condition in which they are found on a farm in winter, and then describe the mode in which food should be daily supplied them; and as they may all be fed with nearly the same ingredients, the mode of feeding to be described will apply to all.

(1460.) And first, in regard to the condition of the *hen*. As hatchings of chickens are brought out from April to September, there will be broods of chickens of different ages in winter; some as old as to be capable of laying their first eggs, and others only mere chickens. The portion of those breeds which should be taken for domestic use are the young cocks and the older hens, there being a feeling of reluctance to kill young hens, which will supply eggs largely in the following season. At all events,

should any hen-chickens be used for the table, the most likely to become good layers next season should be preserved. The marks of a chicken likely to become a good hen are a small head, bright eyes, tapering neck, full breast, straight back, plump ovoidal-shaped body, and moderate-lengthed gray-colored legs. All the yellow-legged chickens should be used, whether male or female, as their flesh never has so fine an appearance as the others. As to the color of the feathers, that is not a matter of much importance, some preferring to have them all white, others all black; but I believe there is none better for every useful purpose than the mottled gray. Young fowls may either be roasted or boiled, the male making the best roast and the female the neatest boil. The older birds may be boiled by themselves and eaten with bacon, or assist in making broth, or that once favorite winter-soup in Scotland—*cockieleekie*. A chicken never eats more tenderly than when killed a short time before being dressed; but if not so soon used, it should hang in the larder for 3 or 4 days in winter. An old fowl will become the more tender on being kept for a week before being used. The criterion of a *fat* hen is a plump breast, and the rump feeling thick, fat, firm, on being handled laterally between the finger and thumb. A corroborative criterion is thickness and fatness of the skin of the abdomen, and the existence of fat under the wings. White flesh is always preferable, though poulterers insist that a yellow-*skinned* chicken makes the most delicate *roast*.

(1461.) *Turkeys* being hatched in May, will be full grown in stature by winter, and, if they have been well fed in the interval, will be ready for use. Indeed, the Christmas season never fails to create a large demand for turkeys, and it must be owned there are few more delicate and beautiful dishes presented at table, or a more acceptable present given to a friend, than a fine turkey. Young cocks are selected for roasting, and young hens for boiling, and both are most relished with a slice of ham or of pickled ox-tongue. The varieties in common use are white, black and mottled gray; and of these the white yields the fairest and most tender flesh. The criterion of a good turkey is fullness of the muscles covering the breast-bone, thickness of the rump and existence of fat under the wings; but the turkey does not yield much fat, its greatest property being plenty of white flesh. Young turkeys attain to great weights. I have had yearly young cocks weighing, at Christmas, 18 lbs. each in their feathers. Norfolk has long been noted for its turkeys, where they are fed on buckwheat, and large droves are annually sent to the London market. A turkey is deprived of life by cutting its throat, when it becomes completely bled. The barbarous practice of cutting out their tongues and hanging them up by the feet to bleed slowly to death, for the alleged purpose of securing whiteness of flesh, ought to be severely reprobated.

(1462.) *Geese*, having been hatched in the early part of summer, will also be full grown and fit for use in winter. I believe there is very little difference in flavor or appearance, as a dish, between the young male and young female goose, though there may be some difference of size. The criterion of a fat goose is plumpness of muscle over the breast, and thickness of rump when alive; and, when dead and plucked, the additional one of a uniform covering of *white* fat over the whole breast. It is a very good young goose that weighs in its feathers 12 lbs. at Christmas. The goose is as favorite a dish at Christmas as the turkey, but people tire of it sooner, and in consequence it is not so frequently served at table. A green goose at Michaelmas is, however, considered a greater delicacy in England than a turkey-poult. Geese are always roasted; and their flesh is much hightened in flavor by a seasoning of onions as a stuffing, and

by being served up with apple-sauce. A goose should be kept a few days before being used. It is bled to death by an incision across the back of the head, which completely bleeds it. Large flocks of geese are reared in Lincolnshire, and thence driven to the London market. It is rare to see a *gray* gander, and as rare to meet a *white* goose. I remember seeing large flocks of geese on the islands in the Elbe near Hamburg, which were reared chiefly for their quills, their carcasses being salted and sent to Holland. The invention of the steel-pen, however, has much injured the quill-dressing trade, and, in consequence, *good* quills are now not easily obtained; and their deterioration still farther encourages the use of the steel-pen. Geese have long been proverbially good watchers. I have seen a gander announce the approach of beggars toward the kitchen-door as lustily as any watch-dog.

(1463.) *Ducks*, being also early hatched, are in fine condition in winter if they have been properly fed. Ducklings soon became fit for use, and are much relished with green peas in summer. I believe there is no difference in flavor and delicacy between a young male and young female duck. They are most frequently roasted and stuffed with sage and onions; though often stewed, and if smothered among onions, when stewed, there are few more savory dishes that can be presented at a farmer's table. A duck never eats better than when killed immediately before being dressed. It is deprived of life by chopping off the head with a cleaver, which completely bleeds it.

(1464.) Hens and turkeys are most easily caught on their roosts at night with a light, which seems to stupefy them; and geese and ducks may be caught in any outhouse at any time they are driven into it.

(1465.) As young pigeons alone are made use of, and as the pigeon does not hatch in winter, they require no other notice at present than what regards their feeding; and to give you an idea of their gastronomic powers, of three rock-doves which were sent to Professor MacGillivray, "The number of oat-seeds in the crop of the second amounted to 1,000 and odds, and the barley-seeds in that of another were 510. Now, supposing," says he, "there may be 5,000 wild pigeons in Shetland, or in Fetlar, which fed on grain 6 months every year, and fill their crops once a day, half of them with barley and half with oats, the number of seeds picked up by them would be 229,500,000 grains of barley, and 450,000,000 grains of oats—a quantity which would gladden many poor families in a season of scarcity. I am unable," he adds, "to estimate the number of bushels, and must leave the task to the curious."* And the task I have undertaken, and find the result to be 422 bushels of barley and 786 of oats.†

(1466.) The prices of poultry in towns are pretty high. In Edinburgh, for instance, in winter, a couple of chickens are 2s. 6d.; hens from 1s. to 1s. 9d. each; ducks 3s. per couple; turkeys 3s. 6d. to 8s. apiece; geese 3s. 6d. to 5s. each; and eggs are from 1s. 2d. to 1s. 8d. per dozen. In the country towns the prices are fully one-third below these; but the highest prices in London are not more. In Russia fat turkeys are 1s. 10d., geese 2s., and fowls and ducks 1s. 3d. *per couple!*‡ In Ireland poultry of all kinds are cheap; but not so much so as in Russia.

(1467.) Farmers usually sell poultry alive, excepting in some parts of

* MacGillivray's History of British Birds, vol. i.

† I ascertained the result by weight; and as the facts may be worth recording, I may mention that in an average of 3 drachms, there were 75 grains of chevalier barley in each drachm of a sample weighing 56½ lbs. per bushel; and 97 grains of Siberian early oat in 1 drachm of a sample weighing 46 lbs. per bushel. Of Chidham white wheat, weighing 65 lbs. per bushel, there were 86 grains in the drachm.

‡ Venables' Tour in Russia, Appendix.

the country, such as the Borders, where geese are killed and plucked for the sake of their feathers before being sent to market. Poulterers in towns, on the other hand, kill and pluck every sort of fowl for sale, so that the purchaser has it in his power to judge of the carcass; and if he buys an inferior article at a high price it must be his own fault. It is easy to judge of a plucked fowl, whether old or young, by the state of the *legs*. If a hen's spur is hard, and the scales on the legs rough, she is old, whether you see her head or no; but the head will corroborate your observation, if the under-bill is so stiff that you cannot bend it down, and the comb thick and rough. A young hen has only the rudiments of spurs, the scales on the legs smooth, glossy and fresh colored, whatever the color may be, the claws tender and short, the under-bill soft, and the comb thin and smooth. An old hen-turkey has rough scales on the legs, callosities on the soles of the feet, and long, strong claws; a young one the reverse of all these marks. When the feathers are on, an old turkey-cock has a long beard, a young one but a sprouting one; and when they are off the smooth scales on the legs decide the point, beside difference of size in the wattles of the neck, and in the elastic snot upon the nose. An old goose, when alive, is known by the roughness of the legs, the strength of the wings, particularly at the pinions, the thickness and strength of the bill, and the firmness and thickness of the feathers; and when plucked, by the legs, pinions and bill, and the coarseness of the skin. Ducks are distinguished by the same means, but there is this difference, that a duckling's bill is much longer in proportion to the breadth of its head than that of an old duck. A young pigeon is easily discovered by its pale-colored, smooth-scaled, tender, collapsed feet, and the yellow, long down interspersed among the feathers. A pigeon that can fly has always red-colored legs and no down, and is then too old for use.

(1468.) The hen-houses are placed at *d* on the plan and view, figs. 3 and 4, Plates III. and IV. They are divided into 3 apartments, each having a giblet-check door to open outward, and all included within a court-yard provided with an outer door and lock. The use of 3 apartments is to devote one of them to the hens and turkeys, which roost high; another to the geese and ducks, which rest on the floor; and the third to a hatching-house to accommodate both. When geese are obliged to rest below hens they are made uncomfortable and dirty by the droppings of those which roost above them. The innermost apartment, being the largest, should be occupied by the most numerous body of fowls, namely: the hens and turkeys; the right-hand one by the geese and ducks; and the left-hand one in hatching, to which access is given by a trap-ladder and opening through the wall at the road, to admit the laying hens. There should be an opening with a sliding-shut in the outer door, as well as one in the doors of the geese-house and hatching-house, to give admittance to the birds when disposed to go to rest in the afternoon; and these shuts should be fastened every night. In the accommodation thus appropriated to every class of fowls, each apartment will be taken up by its own class. The usual practice is to put all kinds of fowls into the same apartment; and the small space occupied by even this single room seems to be grudged, as if any sort of accommodation, however hampered or incommodious, were good enough for poultry. How breeders and feeders of stock can reconcile their minds to such indifference toward any class of their live-stock, while possessing the desire of having a good fowl at their table, is more than I can imagine, unless they believe that quite opposite modes of treatment will produce similar results! In very cold weather the inner apartment, occupied by the hens and turkeys, could be kept sufficiently warm by

neaping the horse-dung from the work-stable under and upon the feeding-trough in the court K, immediately behind the back wall of the hen-house, as high up against it as is thought desirable; and a quantity of straw could be put on the slated roofs of all the apartments during a continued storm. Snow forms a warm covering on a roof, but the heat from fowls roosting under soon melts it; so that it is better to remove the snow and put on straw, and allow the snow to fall upon the straw. Fowls thrive best where there is a mild temperature, but not a great heat; and such expedients will supply them with a sufficiency of heat during the severity of a winter storm.

(1469.) The pigeon-house is placed in the gable of the boiling-house U, fig. 8, Plate III., to receive warmth in winter from the fire usually kept in that apartment. When pigeons are thus artificially supplied with heat, they not only continue to hatch longer in autumn, but will recommence in spring sooner than they would otherwise do. Indeed, by a little management in this way, and taking care to keep the house always pretty full of pigeons to retain heat among themselves, they might be encouraged to hatch all the year, with the exception, perhaps, of two months in the depth of winter, in December and January. Pigeons, like other birds, are most prolific when not too old; and as old cocks are exceedingly tyrannical to the young ones, they should be destroyed as well as the oldest hens. It is no easy matter to get hold of flying pigeons to kill them, as they are always on the alert and make their escape; but there are various ways of destroying them, and a favorite one is shooting, but it is not the best in this case, as young ones may be wounded while aiming at the older birds. The safest plan is to mark the birds you wish to destroy daily for some time, in order to recognize them readily, and the old cocks are easily discernible by their forward manner, and the interruption they give at the pigeon-holes to the entrance of others. These remarks apply specially to the recognition of old cocks, but are inapplicable to old hens, as they never conduct themselves so. Other means must, therefore, be taken to recognize them, and the same may be applied to the cocks; and these are those given above for the detection of dead old and young pigeons. The marks are rough, scaly legs, callous soles of the feet, high red color of the scales, strong bill, strong wings, thick covering of feathers, and brightness of the play of colors upon the neck. All these marks are most conspicuous in winter, the very season when the process of *cocking* a pigeon-house, as it is termed, should be performed, as then there are no young to be unknowingly deprived of their parents. The safest way of doing it is to enter the pigeon-house gently, late of a dark night, with a light. On entering with the light, and shutting the door, it will bewilder the pigeons, and the first movements should be to stop up the holes to prevent them escaping, which the old cocks will be the first to attempt; and should the holes be beyond the reach of the floor, a ladder should be taken in to assist in effecting the purpose. Two persons are required to capture the pigeons, as they will endeavor to elude every attempt; and one to take special charge of the light, which, if taken out of the lantern—and it should be so if the lantern is not of glass—to afford plenty of light, is apt to be blown out by the wind occasioned by the pigeons flying about. Should this be the case, a lucifer match should be in readiness to rekindle it. A light landing net used by anglers is a convenient instrument for entrapping a pigeon, whether sitting or flying. Every bird that is caught should be examined and recognized, and every one exhibiting signs of old age should be destroyed, by pushing the point of the thumb with force into the back of the head, and severing the cervical vertebræ, or applying

the teeth for that purpose; but should these modes be disliked or impracticable, rather than torture the poor devoted animals by abortive attempts, let their heads be cut off at once by a sharp table-knife. When this process of *weeding* is performing, it should be done effectually at once, and not repeated in the same season, as a nocturnal visitation such as this cannot fail to intimidate the whole flock. Nor should it be done in the season of hatching, though done without fail every year, and the consequence will be that your pigeon-house will be stored with prolific birds, and receive no annoyance from birds which have become barren. Perhaps a dozen of birds, male and female, so destroyed, may suffice at a time. On removing the stopping from the holes, and the slain birds, and closing the door, the creatures will be left in quietness.

(1470.) The daily treatment of fowls may be conducted in this manner: Some person should have special charge of them, and the dairy-maid is perhaps the best qualified for it. As fowls are very early risers, she should go to the hen-house in the morning, on her way to the byre, and let out all the fowls, giving the hens and turkeys a feed of light corn and cold boiled potatoes, strewed along at some convenient and established place out of the way of the general passage of horses and carts; such as between the hammels N, and the byre-court *l*, fig. 3, Plate III. The ducks should get the same food either near the horse-pond, or where there is a pond or trough of water, as they cannot swallow dry food without the assistance of water. Geese thrive well upon sliced turnips, a little of which, sliced small, should be left by the cattle-man for the dairy-maid at any of the stores, and given at a place apart from the hens. When stated places are thus established for feeding fowls at fixed hours, they will resort to them at those hours; at least the well-known call will bring the hour to their recollection, and collect them together on the spot in a few seconds, and the regular administration of food being as essential for their welfare as that of other stock. Ducks pick up a good deal of what falls about the stable, and near the corn-barn door, as well as in the straw-barn; and geese will help themselves to the turnips that may chance to fall from the troughs of the cattle; and they are also fond of raw potatoes. After her own dinner, say 1 o'clock P. M., the dairy-maid takes a part of the potatoes that have been boiled at that time, and while a little warm, gives them crumbled down, from their skins, with some light corn, to the turkeys and hens. At this time of the day, the spaces below the stathels of the stacks in the stack-yard form excellent dry sheltered places for laying down food, and the stack-yard is a very probable place for their resort after their morning meal, especially when it rains or snows. In laying down food for the fowls, the pigeons should be remembered, as they will feed with the hens, and on the same sort of food. Before sunset the fowls are all collected together by a call, and put into the house, and which they will readily enter; and many will have taken up their abode in it already, especially the turkeys, which go very soon to roost. The ducks are the latest idlers. The floors of the different apartments should be littered with a little fresh straw every day, sufficient to cover the dung, and the whole cleaned out every week. Sawdust or sand, where they are easily obtained, form an excellent covering for the floor of hen-houses. Troughs of water should be placed in the court-yard, and supplied fresh and clean every day.

(1471.) This mode of daily treatment will maintain fowls in a condition for using at any time, and it cannot be said to involve much expense, for the riddlings of potatoes boiled and light corn may be considered as the offal of the farm; but the truth is, food administered to these creatures at

irregular intervals, though it be of the finest quality, will be comparatively thrown away, when compared to the good effects of food of even inferior nutriment given them at *stated hours*. This plan contrasts favorably with that which gives them large quantities of food at long intervals, and in an unpleasant state; and also with that which permits fowls to shift for their meat at the farmstead. Either of these ways will never fatten fowls; for food given in overabundance at one time and restricted at another, can never *fatten* any animal; nor will they obtain sufficient food at all times when made to shift for themselves, because fowls are like all other animals, some can forage about most perseveringly, while others are indolent, and some careless of food when it is not placed before them. A regular plan is recommended, which is, always supply them with a certain quantity of food, ascertained by experience, and dependent on the nature of the flock; when this is repeated daily at stated times, their condition must increase, because it cannot decrease, the minimum quantity of food being always sufficient to appease hunger; and this want they can never feel keenly when supplied with food at appointed times. Thus, in the long run, more nutriment will be derived from inferior food regularly administered, than from richer given irregularly. Should it be desired, however, to be particularly indulgent to fowls intended for immediate use, the following materials will render the respective sorts of fowls perfectly *ripe* in a short time. Boiled potatoes, warm, and light wheat, for hens; boiled potatoes, warm, and firm oatmeal porridge, warm, for turkeys; boiled potatoes, warm, and oats, for geese; and boiled potatoes, warm, and boiled barley, warm, for ducks. The potatoes and porridge should be crumbled down in small pieces. But *immediate* effects, even from superior food, can only be expected on fowls that have been regularly fed as recommended above, up to the time the superior food is indulged in. Let starved fowls receive the same ingredients, and a long time will elapse ere they exhibit symptoms of improved condition, besides the risk they run, in the mean time, of receiving injury from surfeit and indigestion. No doubt, superior feeding would incur cost, if persevered in throughout the season; but I am not disposed to deny that, were proper breeds of fowls only cultivated, and the shortness of time taken into consideration in which a pure breed will *ripen* upon it, that profit would be derived from its use. The experiment has never been satisfactorily attempted by the farmer, and all the accounts we know of superior feeding, apart from experiments by men of science, are only derived from the establishments of noblemen, whose object is not to obtain profit, but the possession of a superiorly fed animal.

(1472.) Other ingredients may be and are used for the feeding of fowls, among which may be mentioned brank or buckwheat, rice, and Indian corn. Buckwheat is successfully grown in England; not so in Scotland. It is said to fatten poultry well, though not so well as grain. Rice may be given either raw or boiled; in the former state fowls will pick it as readily as grain after feeding on boiled potatoes, and, when boiled, it will fatten without the aid of potatoes, but, of course, it is more expensive, as even *good* damaged rice can seldom be obtained under 16s. or 18s. per cwt., which is nearly 2d. per lb., without the expense of cooking. Fine barley, weighing 56 lbs. per bushel, selling, as it is at present, at 3s. 6d. per bushel, is only $\frac{3}{4}$ of a penny per lb. Indian corn is employed in America, in the southern parts of Germany, and in Lombardy, for feeding poultry, and they become very fat upon it. It is too large to be swallowed raw, like the horse-bean of this country, but when steeped in water, or boiled, it is easily eaten. If sold at even 8s. per bushel, its cost would be

under 2d. per lb. "From a desire to save expense," says Boswell, "the bran of wheat, and sometimes pollard, or middlings, are given to fowls; but these bruised skins, where little if any of the farina of wheat remains, appear to contain a very small portion of nourishment in proportion to the cost price. M. Reamur found by experiment that it is little or no saving to substitute bran for good grain in feeding poultry. Bran is not given dry, but mixed with water to the consistence of paste. Some people boil this; but it does not increase the bulk, except in a very trifling degree, and is, therefore, of small advantage. He found that 2 measures of dry bran, mixed with water, were consumed by fowls in the same time that they would have eaten a single measure of boiled barley, equivalent to ⅗ of a measure of barley."* Bran of itself, therefore, it appears, is of no use to fowls as food; but it may be made the means of conveying nourishing food to them, in the shape of fat, broth, and other rich liquids from the kitchen, which they could not otherwise avail themselves of but through such an absorbent. Fowls are very fond of bread, and even of butcher-meat, cooked or raw; and they will pick a rough bone very neatly. They sometimes also display carnivorous propensities. Many a time have I observed them watching for a mouse at the casting down of a stack in the stack-yard; and the moment one was seen to escape, away they would run, cocks and hens together, in full chase after it; and on mobbing it, peck it not only to death, but to pieces, and then swallow it.

(1473.) I have said that *eggs*, and chickens too, may be obtained in winter by good management. The young hens of the first broods in April will be old enough to lay eggs in winter. A few of these should be selected for the purpose; and when the period of laying approaches—which may be ascertained by their chaunting a song and an increased redness of the comb—they should be encouraged by better feeding and warmer housing at night. The feeding consists of warm potato and firm oatmeal porridge twice a day—at morning when they are let out, and in the afternoon at 1 o'clock. To give them peace in feeding upon their more tempting fare, they may be fed by themselves in the court-yard of the hen-houses, and the door shut upon them after the rest of the fowls have left their night's quarters. And their more comfortable housing consists in directing them into the hatching-house betimes every afternoon, and therein making for them a number of comfortable nests of clean oat-straw, to choose among; and when they have taken to the one each selects for her own, leaving an old egg in it for a nest-egg. These three or four young hens will lay as many eggs every day; and though they are not so large as those of more matured fowls, being only pullets' eggs, still they will be fresh; and it is no small luxury to enjoy a new-laid egg at breakfast every winter morning—a luxury which I enjoyed for as many years as I lived in the country.

(1474.) With regard to *young broods in winter*, I believe few people will impose upon themselves the trouble of setting hens on eggs so late in the season for the purpose of rearing chickens in winter; and yet it may be done without difficulty; but sometimes the task is imposed involuntarily upon one, inasmuch as some hens will secrete their nests in the fields, among corn, or at a hedge-root, or other safe place, and bring out strong broods of chickens on the eve of winter. In such an event, the little innocents, brought into a cold world, cannot be allowed to perish merely for want of care. When such a brood makes its appearance, or is purposely brought forth, it should be kept apart from the rest of the flock, in a warm and

* Boswell's Poultry Yard.

sheltered place; and where no better place presents itself, it may be comfortably housed in a corner of the boiling-house, (U, fig. 4, Plate IV.,) where a hamper or basket, placed over mother and chickens, or a fence of some kind, erected across a corner near the fire, will protect them from external danger. Thence they should be let out in the forenoon, to enjoy the air and bask in the sun, and be returned to their shelter long before sunset. In rainy weather they should be conducted to a shed; and in hard frost they may be kept in the house altogether, as frost soon benumbs their legs, and if they lose the power of which, they will soon droop and die. A nest of straw, elevated some inches above the floor, to keep them above the draft of air that sweeps along the floor, and having a broad base to afford the chickens an easy access to their nest, should be formed, for the hen to brood them on at night; and when fresh litter is given them every evening, a little of the cleanest and warmest to be found under a cow in the adjoining byre, where she has lain, will be most acceptable to the tiny limbs of the active brood. Food should be given them from morning to evening every three hours. It may consist of warm boiled mealy potatoes crumbled down small, picks of oatmeal porridge, mealy boiled potatoes warm, mixed with oatmeal, and a flat dish of clean water. With a little variety of food, daily attention, and temperate housing, they will get on well, and by spring be as plump as partridges and as valuable as ortolans. I am surprised to observe Mr. Mowbray say that "to *attempt* to rear winter chickens in this climate, even in a carpeted room, and with a constant fire, would in all probability be found abortive. I have repeatedly made the experiment," he adds, "with scores, without being able to preserve an individual through the winter."* The difficulty I consider small, though the trouble may be unnecessary, but neither a "carpeted room," nor a "constant fire," will assist much in the rearing of chickens, the whole secret of the art consisting of suitable food, moderate degree of temperature, fresh air and constant attention.

(1475.) Such is the way I would recommend the feeding of poultry on a farm. It is not an expensive mode in a pecuniary point of view, consisting entirely of ordinary fare and regular attention; and therein consists the entire value of the plan. That the plan is valuable and worthy of imitation has been proved beyond doubt, by its supplying fowls of every kind in their respective seasons, in high condition—at any period of the season they were required—and without any previous formal preparation. Thus, a chicken, a young cock, a hen, were at command throughout the year; a duckling throughout the autumn; and a goose or a turkey from Michaelmas to March; and this not for one year, or only in a favorable season, but year after year for fifteen years, as long as I had opportunity to practice it. In short, a *young* fat fowl and a fresh egg were never wanting, from January to December; and there is a great deal of truth in Cobbett's remark, where he says, "one thing about fowls ought always to be borne in mind. They are never good for anything after they have attained their full growth, unless they be capons or poullards."†

(1476.) In regard to the undue means used for pampering fowls to fatness, I quite agree with Cobbett that "crammed fowls are very nasty things;" and when we reflect on the worse than imprisonment practiced for the purpose, by cooping up fowls in the dark, and tying their feet together, the means used to obtain the end become reprehensible. Liebig explains the rationale of this latter practice. "Experience," he says, "teaches us that in poultry the maximum of fat is obtained by tying the feet and by a

* Mowbray's Practical Treatise on Domestic Poultry. † Cobbett's Cottage Economy.

medium temperature. These animals, in such circumstances, may be compared to a plant possessing in the highest degree the power of converting all food into parts of its own structure. The excess of the constituents of blood form flesh and other organized tissues, while that of starch, sugar, &c., is converted into fat. When animals are fed on food destitute of nitrogen, only parts of their structure increase in size. Thus, in a goose, fattened in the method above alluded to, the liver becomes three or four times larger than in the same animal when well fed with free motion, while we cannot say that the organized structure of the liver is thereby increased. The liver of a goose fed in the ordinary way is *firm and elastic;* that of the imprisoned animal *soft and spongy*. The difference consists in a greater or less expansion of its cells, which are filled with fat."* This practice appears to me the more reprehensible, in that its principal effect is to increase the bulk of offal only.

(1477.) *Peacocks* may be treated in the same manner as turkeys; and as to guinea-fowls, notwithstanding the deliciousness of their eggs, they should never be tolerated in a farm-yard, both on account of the horrid noise they make, and of the strong propensity they always evince to annoy other fowls.

(1478.) The *feathers* of the various sorts of fowls used are either disposed of or converted into domestic use. The following directions on sweetening and managing feathers are given by a notable housewife of my acquaintance; and as they very nearly accord with my own experience, I shall transcribe them in her own intelligent words. "Every one is aware that the feathers of cocks and hens are very inferior to those of geese and ducks for the purpose of filling beds and pillows; and, consequently, it is scarcely necessary to mention that the former should be kept separate from those of the latter two fowls. As the birds are plucked, the large feathers should be selected and placed asunder. Paper-bags are the best recipients. The pinion feathers should be stripped from the quill, and added to the other feathers; and, if great caution have not been used in plucking the birds, they should be carefully looked over, that no part of the skin has been torn and adhering to the base of the quills. The bags of feathers should be placed in the bread-oven on the day after it has been heated, and, after some hours, removed to a dry, airy place; and this ought to be done every week." On this part of the subject, I may mention a less troublesome plan than the oven, where the adjoining apartment behind the kitchen fire is not in constant use, which is that in such a situation feathers may be hung up in bags against the wall behind the fire, and there they will soon win. "Notwithstanding," continues our instructress, "every apparent caution shall have been used, the feathers are frequently found to be tainted, either from carelessness in plucking, or by neglecting to attend to them afterward; and no *subsequent baking or picking* will be found available to restore them. In this case, the only method to render them sweet is to boil them, which is to be effected in the following manner: One or two large canvas or calico bags must be made, into which the feathers from the small paper-bags must be emptied and tied up; a washing-copper must be nearly filled with rain-water, and made to boil. The calico bags then, one at a time, are to be dipped, and, by means of a stick, pushed about, and squeezed and kneaded for the space of four or five minutes, then lifted out and taken out of doors, and being tied together and the openings kept secure, that no feathers may escape, they must be hung over a line and left to drain and dry. Several times a day the bags are to be shaken up and turned over; and as soon as the feathers appear to be

* Liebig's Animal Chemistry.

light and drying, which will not be the case for nearly a week, the bags must be hung up during dry weather only, and taken in every night. In about a fortnight the feathers will become perfectly sweet and ready for use; and the water in which they were boiled will sufficiently indicate that this plan was not only necessary, but efficacious, in cleansing them from impurities which would else have rendered them useless." As an attestation of the practical efficacy of the plan, the lady adds, "having tried the method ourselves, we can assure our readers of its eligibility."*

(1479.) In regard to the *diseases* of fowls, I can safely say that if fowls are attended to in a systematic manner, with wholesome food prepared for them every day, and their roosting place kept clean and airy, very few diseases will affect them at any age.

[The reader will please remember that only *Notes* are promised to this "Book of the Farm," not dissertations. They are better placed in another part of this journal.

On the subject of *Poultry*, when a country lad, not unobservant of all such things, our experience covered the whole ground; and who that was thus reared does not retain in his memory, through life, lively associations as connected with this department of his juvenile sports and speculations? We have somewhere seen it said that Mr. WEBSTER'S first investment was in a Dominica cock, which he carried under his arm in a smart journey on foot, stopping to fight him against every cock that dared crow along the roadside; and this, be it said *en passant*, is not the only point in which the "Great Expounder" has evinced Southern propensities. On the subject of poultry management generally, our observation agrees, in the main, as to want of care and system, with what is here said.

In this case, as in many others badly conducted, common sense dictates all that is necessary to be borne in mind. In the first place, if the barn-yard, dung-hill and proper range of the poultry do not afford sufficient food to keep them in good, healthy and thriving condition, the deficiency should be supplied with regularity; for in this, as in all other instances, it should be a cardinal maxim with every farmer, that whatever is worthy of being kept at all is worthy of being *well kept*. Be it a rule in regard to everything that engages your time and consumes your substance, that it be either *cared for or killed!* Then, again, as to poultry, vermin and exposure to heat and cold are great obstacles to success in rearing them; and of course too much attention cannot be paid to cleanliness and equable temperature. Farthermore, not one in twenty of husbandmen and housewives keep in their head, or otherwise, a *register of the age* of their breeding-fowls. Having allowed them to commence breeding, they are usually left to die of age and disease, which must more or less infect the health of the whole flock. With poultry, as with sheep, to keep them in sound condition, none should be allowed to survive a fixed age. When they have passed the period of the highest capacity as breeding-stock, they should be fatted for sale or consumption; instead of which, everything is left to chance, and thus some poultry-yards that we have seen, instead of presenting a lively, beautiful scene of varied and splendid plumage, rosy gills, sparkling eyes, and all animate with health, gallantry and courage, are more like *hospitals des invalides*, a drooping hen in one corner, and a sniffling cock in another. But, as we before said, this is no place for a treatise on Rearing Poultry. There is one, however, on *Rearing Ducks*, published in the June, 1846, number of this journal, written by a very learned clergyman of Charleston, S. C., which every good housewife ought to have at her *fingers' ends*. In the matter of different breeds of fowls, there is much room for indulging the imagination. It may be ranked among the "fancy stocks." We have ourselves been fool enough to give $5 for a hen of the Ostrich breed that would weigh 5 pounds as she sat on her roost; but we agree in one thing with MOWBRAY, the author of a very cockney sort of a book on "Pigs and Poultry," that

"Small-boned, well-proportioned poultry greatly excel the large-boned, long-legged kind, in color and fineness of flesh and delicacy of flavor; for it is held good that, of all animals of the domestic kind, those which have the smallest, cleanest, finest bones, are in general the best proportioned, and are covered with the best and finest grained meat, besides being, in the opinion of good judges, the most inclined to feed, and fatted with the smallest proportionable quantity of food to the greatest comparative weight and size."

It is said that the Poland fowl, which is rather under size, jet black with top-knots, are the best layers; but we should be disposed to rely on the true old "game breed." Mr. Colt has this top-

* Quarterly Journal of Agriculture, vol. x. There is a curious fact given, in Head's Home Tour, of the modes of plucking feathers off fowls of various kinds in a large poulterer's establishment in Lincoln.

knot breed milk-white. We have no doubt of the truth of what the Author asserts, that "chickens never eat more tenderly than when killed a *short time* before being dressed; but if not so soon used, they should hang in the larder for three or four days in winter"—or in the ice-house in summer, say we.

This suggestion of cooking *immediately* on being killed, is probably against the general impression, but is nevertheless correct, as we happen to know by experience; and we are confident the same may be said of butchers' meat. Cook immediately, or keep for some days. After the animal gets dead cold, the first tendency of the fibre seems to be to get stringy and tough; the next to relax and break up. The best fried chickens to be met with—what in the Eastern States they call, and esteem a great delicacy, "spring chickens"—are to be had at the old-fashioned, ordinary-looking, but clean, well-kept turnpike-road tavern, 9 miles from Alexandria, D. C., on the road to Fairfax Court-House, kept by Mr. GOODING; and there the process is, when the stage drives up to breakfast, the scullion counts noses, and away he runs to wring off chickens' heads in a given proportion. They are then instantly scalded, picked and washed out clean in *warm* water; then quartered and thrown into a pan of *ready boiling, clean lard*; and being in a minute or two "done brown," are served up to the sharp-set passenger, hot and *dry*, not swimming again, as in most taverns, in dirty grease. In this way the fowl never gets cold, and is truly "as tender as a chicken." The traveler gets his penny-worth, rubs down his abdominals, and in half an hour goes his way, rejoicing that we live in a land of democratic liberty and abundance, surveying as he goes one of the most glorious and the most abused and neglected regions that the sun shines upon.

Mr. Gooding, by the way, is esteemed a trump-card in his line, but in the majority of such cases we have observed that though it be the landlord who is ever foremost to receive the traveler and run away with all the "credit" as well as the *change*, the good *housewife* is usually more than "half the battle." *Ed. Farm. Lib.*]

---

3. WHEAT AND FLOUR.*

(1480.) Systematic writers on Agriculture, and most others, when treating of the various plants usually cultivated on a farm, always describe their characteristics in botanical phraseology; and though this way of describing them seems a proper one, when different genera of plants have to be distinguished from each other; yet when more varieties of the same species, and especially when those varieties are numerous, have to be treated of, a more natural method of describing or classifying them seems desirable, so as they may easily be distinguished by other people than botanists. Thus, Professor Low, when treating of wheat, enumerates 11 different subdivisions† which are cultivated, all which doubtless, possess distinct botanical characteristics; but the distinctions betwixt these are not likely to be apprehended, far less applied, by the majority of farmers; and much less likely still are they to discriminate, with botanical accuracy, betwixt the very numerous varieties that are now cultivated in different parts of the empire. Mr. Lawson has described 83 varieties of wheat,‡ and Colonel Le Couteur mentions having in his possession, in 1836, no fewer than 150 varieties;‖ and the Museum of the Highland and Agricultural Society in Edinburgh possesses 141 varieties.§ To distinguish between all these, with botanical exactness, would puzzle any farmer.

(1481.) For this reason, it has occurred to me that some method should be established of recognizing the different kinds of grain in use, by their external characters in the ear and in the grain. Colonel Le Couteur has given a classification of wheat involving the principle I have

---

[* It may be of some satisfaction to the reader as he proceeds in the perusal of what is here said in reference to grains which constitute important staples of our own country, to have at hand a memorandum of the amount of each produced in the United States.

Thus, according to the Census of 1839, a very fallacious authority it is true, but the only one we have, the crop of Wheat in all the United States was 84,823,272 bushels. The largest crop in any State was that of Ohio, being put down at 16,571,661 bushels. The second—Pennsylvania, 13,213,077, and the third on the list is that of New-York, to wit: 12,286,418.

By a Census of the State of New-York, probably taken with more accuracy, under an Act of Assembly passed 7th May, 1845, it appears that the whole number of bushels harvested in the State that year was 13,391,757 bushels, from 595,013 acres, or something less than 14 bushels to the acre. *Ed. Farm. Lib.*]

† Low's Elements of Practical Agriculture. ‡ Lawson's Agriculturist's Manual.
‖ Le Couteur on Wheat. Dedication. § Catalogue of the Museum.

mentioned, and he gives a similar reason for attempting it, when he says— "No one has done so as a branch of Agriculture, in those plain terms which may be intelligible, not to the botanist or scientific reader only, but to the great mass of farmers." And the principal object he considers to be held in view, in attempting such a classification, is, that the nature and real qualities of each variety may be ascertained as to their properties for making bread.*

(1482.) In prosecuting his ideas of a classification, Colonel Le Couteur divides all the varieties of wheat into two classes, namely, *beardless* and *bearded*. In so far he imitates the modern botanists, who divide the cultivated varieties of wheat into the two divisions of *barbatum* and *imberbe*, signifying the above characteristics; but, unfortunately for the stability of this division, the distinction is immutable, for some bearded wheats lose their beards on cultivation, and some beardless ones are apt to become bearded, when cultivated on poor soils and exposed situations. Some of the other grains indicate a tendency to this sort of degeneracy, for even the potato-oat assumes a beard when sown a long time on the same ground in a poor state. He then subdivides beardless wheat into white, red, yellow and liver-colored, smooth chaffed and velvet chaffed; and the bearded he divides under the same colors. Some varieties of wheat are, no doubt, decidedly downy on the chaff, but others, again, are so little so that it is difficult to distinguish them from some of the roughest varieties of smooth chaffed: and it is well known that the same wheat will be differently affected, in that respect, by the soil upon which it has been grown; for a sharp soil has a tendency to render the chaff and straw smoother and harder than a deaf soil, which has a tendency to produce soft and downy chaff and straw. This downiness, therefore, is not so fixed and important a character as to be adopted to rank one great division of wheat under its denomination. The associating together the characters of wheat in grain and in the ear, is also, in my opinion, injudicious, inasmuch as neither character separately can positively indicate the state of the other, as I shall soon show, and both are not required to indicate the flouring properties of any variety of wheat, in respect to its superiority in making bread. A baker will at once distinguish the grain which will afford the flour best suited for bread, but he could indicate nothing of its properties by an ear of wheat. Colonel Le Couteur puts down a liver-colored wheat, as a distinctive color, along with others. I confess I cannot distinguish this color; for I never remember to have seen wheat of a liver-brown color. I think all the colors of wheat may be classed under two of the primary colors, *yellow* and *red*, for even the whitest wheat has a tinge of yellow in it, and the brownest wheat is deeply tinged with red; but as *white* and *red* are the terms by which the colors of wheat have been longest known, these should be retained. The variety of wheat which should form the standard of each color has never yet been settled; but judging from the collection of wheat in the Highland and Agricultural Society's Museum, I should say that the Hungarian white wheat, *a*, fig. 358, indicates the purest white, and the blood-red wheat the purest red.

Fig. 302.

CLASSIFICATION OF WHEAT BY THE EAR. EAR OF RYE.

* Le Couteur on Wheat.

(1483.) Were I to attempt to classify wheat by *natural marks*, I would make two classifications, one by the ear and the other by the grain, so that each could be described by its own characteristics, and, if desirable, either could be illustrated by the characteristics of the other. In this way confusion would be avoided between the characters of the ear and of the grain. The farmer who grows the wheat in the ear and sells it in the grain should be acquainted with both; but the baker, who is only acquainted with grain, knows nothing by the ear. Were he, however, to receive an ear of each variety of grain he purchased, he would be able to describe at once to the farmer what particular variety afforded him the flour best suited for his purpose.

(1484.) *Wheat.*—On examining the *ears* of wheat that have come under my notice, I think they may be divided into the 3 classes as represented in fig. 302, and which may be distinguished thus: *a* is a *close* or *compact* eared wheat, which is occasioned by the spikelets being set near each other on the ruchis or jointed stem, and this their position has a tendency to make *the chaff short and broad*, and the spikelets are so also. This figure, as well as the others, shows the ear half the natural size. This specimen of the close eared wheat is Hickling's Prolific. The second class of ears is seen at *b*, the spikelets being of *medium* length and breadth, and placed just so close upon the rachis as to screen it from view. The ear is not so broad, but longer than *a*. The *chaff* is of *medium length and breadth*. This specimen is the well known Hunter's white wheat. The third class is seen at *c*, the spikelets of which are set *open*, or so far asunder as to permit the rachis to be easily seen between them. The ear is about the same length as the last specimen, but is much narrower. *The chaff is long and narrow*. This is a specimen of Le Couteur's Bellevue Talavera white wheat. These three classes of varieties constitute the *Triticum sativum imberbe* of botanists, that is, all the varieties of the beardless cultivated wheat. Formerly they were divided by botanists into *Triticum hybernum* or winter wheat, and *Triticum æstivum* or summer wheat; but experience has proved that the summer wheat, so called, may be sown in winter, and the winter wheat sown in summer, and both thrive. Paxton says that Triticum is derived from "*tritum*, rubbed; in allusion to its being originally rubbed down to make it eatable."* It is of the natural order *Gramineæ*, and of the third class *Triandria*, and second order *Digynia*, of the Linnæan system.

(1485.) In *d*, fig. 302, is represented a bearded wheat, to show the difference of appearance which the beard gives to the ear. The bearded wheats are generally distinguished by the *long shape* of the *chaff* and the open position of the spikelets, and therefore fall under the third class. But cultivation has not only the effect of decreasing the strength of the beard, but of setting the spikelets closer together, as in the specimen of the white Tuscany wheat, shown at *d* in the cut, which is considered the most compact eared and improved variety of bearded wheat. Bearded wheat constitutes the second division of cultivated wheat of the botanists, under the title of *Triticum sativum barbatum*. The term bearded wheat is used synonymously with spring wheat, but erroneously, as some beardless wheat is as fit for sowing in spring as bearded, and some bearded may be sown in winter. Figure *e* is a specimen of *rye*.

(1486.) In regard to classifying wheat by the *grain*, on observing a great variety of forms, I think they, as well as the ears, may all be classed under 3 heads. The first class is shown at *a*, fig. 303, where all the grains are *short, round*, and *plump*, with the bosom distinctly enough marked, and well filled up. In the cut, the grain to the left is seen with the median line along its bosom; another, below it, with the round or opposite side lying undermost: and the third and fourth show the germ and radical ends respectively. All fine *white* wheats belong to this class, and they are enclosed in *short, round*, and generally *white chaff*, which, when ripe, become so expanded as to endanger the falling out of the grain. Very few *red* wheats belong to this class. In reference to the ear, this class is found in *short-chaffed* and broad spikelets, which are generally compact. The specimen here is Hungarian white wheat. The second class is represented by *b*, where the grains are *long and of medium size*, that is, longer and larger than the grains of the first class. The *chaff* is *also medium sized*. In reference to the ear, it is of the *medium* standard, in respect to breadth and closeness of spikelets, though *medium sized grain* is *not* confined to this sort of ear; for it is found in the *compact* ear, as in Hickling's Prolific white and red wheat, as well as in the *open* ear, such as the red Dantzic creeping wheat. Most of the *red* wheats belong to this class of grain, though many of the *white medium sized*—such as Hunter's white—also belong to it. This specimen is the Caucasian red wheat, whose ear is bearded, and belongs to the open-spiked class *c*, fig. 302. The figure at *c*, fig. 303, represents the third form of grain, which is *large and long* to a greater degree than the last class. Its *chaff* is *long*, and in reference to the ear, the spikelets are generally open, though, in the case of this specimen, the Odessa long white wheat, the ear is medium-sized, though the chaff is long as well as the grain. The three sorts of wheat in the cut are all placed in similar positions, and are of the natural size.

Fig. 303.

CLASSIFICATION OF WHEAT BY THE GRAIN.

(1487.) It will be seen from what has been stated, that no direct relation exists between the *ear* and the *grain*; that the compact ear does not always produce the round grain nor the white wheat; that in the medium ear is not always found the medium-sized grain: and that the open ear does not always produce the large, long grain. But still, there exist coincidents which

* Paxton's Botanical Dictionary, *Triticum*. See also Hooker's British Flora, Edition of 1831.

connect the *chaff* and the *grain*. For example, the *length* of the *chaff* indicates the *length* of the *grain*, upon whatever sort of ear it may be found: and, generally, the *color* of the chaff determines *that* of the grain. As also, the opening spikelet bears grain of coarser quality than the compact. On wishing, therefore, to determine the sort of *grain* which any number of *ears* of different kinds of wheat may contain, it is the *form* and *color* of the *chaff* that determines the point, and not whether the ear carries compact, medium, or open spikelets, or whether it be bearded or beardless, or whether it be woolly or smooth.

(1488.) But a more important consideration than its classification, in regard to wheat, is the mode of *judging* it, to ascertain the purposes to which it may be best employed, in the particular condition in which it may be seen. These purposes are, for seed and and for the making of flour; whether the flour is to be employed in the manufacture of bread or of confections, or in some of the arts, such as starch-making. In its *best* condition, all wheat, whether red or white, small or large, long or round, should appear plump within its skin, not in the least shriveled or shrunk. The skin should be fine and smooth, not in the least scaly or uneven in its surface. The color, be what tint it may, should be bright and lively and uniform, not in the least dull, bleached, or party-colored. The grains should all be of the same size and form, not short and long, round and long, small and large. The grains should be quite perfect: there should be no bruises, or holes, or dried rootlets hanging from the dimpled end, or woolly appendage from the other end. If perfect in all these respects, wheat is fitted for any purpose, and may be purchased by the general merchant. For particular purposes additional properties may be regarded.

(1489.) When wheat is quite opaque, indicating not the least translucency, it is in the best state for yielding the finest flour, such flour as confectioners use for pastry; and in this state it will be eagerly purchased by them at a large price. Wheat in this state contains the largest proportion of fecula or starch, and is therefore best suited to the starch-maker, as well as the confectioner. On the other hand, when wheat is translucent, [partially transparent,] seemingly hard and flinty, it is best suited to the common baker, as affording what is called *strong* flour; that is, flour that rises boldly with yeast into a spongy dough; or in other words, the wheat then contains the largest proportion of gluten. Bakers will, therefore, give more for good wheat in this state than in the opaque; but for bread of first quality the flour should be fine as well as strong, and therefore a mixture of the two conditions of wheat is best suited for making the best quality of bread. Bakers, when they purchase their own wheat, are in the habit of mixing wheats that respectively possess those qualities; and millers who are in the habit of supplying bakers with flour, mix such wheats and grind them together for the special purpose. Some sorts of wheat, however carefully they may have been preserved pure, naturally possess *both* these properties, and on that account are great favorites with bakers, though not so with confectioners; and I presume, to this mixed property is to be ascribed the great popularity which Hunter's white wheat has so long enjoyed. We hear of "*high mixed*" Dantzic wheat, which has been so mixed for the purpose, and is in high repute among bakers. Generally speaking, the lightest-colored white wheats indicate most opacity, and of course yield the finest flour, and red wheats are most flinty, and therefore yield the strongest flour; for a translucent red wheat will yield stronger flour than a translucent white wheat, and yet a red wheat never realizes so high a price in the market as white, because it contains a larger proportion of refuse in grinding.

(1490.) For *seed*, the dimpled end of the grain should be distinctly marked, and the site from which the rootlets issue should be rather prominent; and the end from which the blade springs should be covered with a slight degree of wooliness or hairiness. The protuberances of the rootlets and woolly ends should not have been rubbed off by any process, such as sheeling, as the grain is thereby rendered unfit for seed by being deprived of its vitality. Nor should the grain have been kiln-dried, because that process may also deprive it of vitality, and its effects may partly be detected in the undue hardness of the grain, and partly also from the smoky flavor which the grain has acquired. But hardness alone is not a sufficient criterion, as some wheats become much harder in ordinary drying than others; and in some parts of the Continent, such as on the shores of the Mediterranean, some wheats are naturally so hard as to induce that in the ordinary state to be called soft. If no smokiness can be detected in the flavor, the surest test of existing vitality, when time is allowed to apply it, is to germinate the wheat near the fire, in a glass, among as much water as will swell the grains.

(1491.) *Damaged* wheat may be detected in various ways. If it has been in sea-water, although it may not be enlarged by moisture, it can never lose the saline taste; and although it may have been washed in fresh water and dried in a kiln, still the washing gives it a bleached appearance, and the subsequent drying may be detected by either the smell or the taste. Wheat that has been sheeled, to make it look round and plump, may be detected by the appearance of the ends being rubbed down. Wheat that has been heated in the stack, though not affected in color, will taste bitter on being chewed. Wheat that has been long in the granary appears dull and dirty, though it may have been passed through the fanners; and although it may not have been injured, it always contracts a musty smell. Wheat is liable to the attacks of insects in the granary, which breed within its shell and eat the kernel. This mode of destruction, occasioned by the weevil, is easily detected by the grain feeling light in hand, and the holes may easily be seen from which the perfect insect has made its escape. Germinated, swollen, burst, bruised grains, as well as the admixture of other kinds of grain and seeds, are easily detected by the eye.

(1492.) Difference of opinion exist in regard to the *best mode of preserving wheat in granaries*. The usual practice is to shovel the heap over from the bottom every few weeks, according to the dryness or dampness of the air, or heat or coldness of the atmosphere. In this mode of treatment, a free ventilation of the air is requisite in the granary, and the worst state of the atmosphere for the grain is when *moist* and *warm*. Extreme heat or extreme cold are preservatives of grain. The practice of others is not to turn over their wheat at all, but to keep it in very thick masses, reaching from the floor to the ceiling, and quite in the dark. No doubt, if air could be excluded effectually from a granary, the grain could be preserved in it without farther trouble; and a good plan of excluding the air entirely seems to be to heap the wheat as thick together as possible. There is as

little doubt, however, that wheat which has been kept long in heap without turning, retains its color in a fresher state than that which is frequently turned; and a good plan for preserving the color seems to be to keep wheat in the dark. The ancients used to preserve grain many years, to serve for food when years of famine overtook them. When Joseph was in Egypt, wheat was preserved for seven years in the stores; but this might not be a difficult matter in so dry a climate as Egypt; and in Sicily, Spain, and in the northern parts of Africa, pits were wont to be formed in the ground to preserve grain; and the Romans were so impressed with the necessity of preserving grain, that they took great pains in the construction of their granaries, which are related to have keep wheat for 50 and millet for 100 years.* But as to the farmer, the question how wheat is best preserved in granaries should little affect him, as the best way of keeping his wheat is in the straw in the stack; and when the stacks are threshed for the straw, he should dispose of his wheat immediately, and take the current market prices. In a series of years, during the currency of a lease, this is his safest practice; and besides securing him, in the long run, of an average price, it saves him a great deal of trouble in looking after the grain, and a great deal of vexation when prices fall below their expected amount. Two friends of mine, farmers, were both great losers by keeping wheat of their own growth on speculation. They each stored three years' crop, and though offered £6 a quarter for it, they kept it with the view of obtaining more, but were never offered so much again; and after prices dropped gradually to 65s. and were not likely to rise immediately, they sold off the whole stock. Such is most likely to be the fate of most farmers who speculate in wheat, even of their own growth; but when they venture on purchasing the wheat of others, they forego their proper profession, and become merchants, and thence become involved in the intricacies of trade, of which they must be quite ignorant; and probably only become sensible of their ignorance after feeling the effects of their temerity.

(1493.) Wheat is prepared for the use of man by being ground into *flour*. The machinery used for grinding wheat, consists of a number of parts, each of which performs its separate work, and they are all strongly constructed. The first process which wheat undergoes in grinding, is in being put through the *sheeling cylinder*, which rubs off any extraneous matter belonging or adhering to the outer skin of the grain, and separates every foreign matter from the wheat. In this process the wheat is made shorter in length, brighter in color, and freed from every impurity. The quantity of black, suffocating dust which flies off from the cylinder in the process of sheeling, and the seeds and other substances which are separated from the grain, are collected together, surprise every one, who has never witnessed the process, how such impurities can have proceeded from an *apparently clean sample*. After the sheeling, the prepared wheat is put into a large hopper, which conveys it to two millstones of French burr, to be ground.† In the grinding, the wheat is converted into flour, which still contains all the ingredients of the wheat, and has acquired a high degree of temperature. In order to cool it, which should be done as quickly as possible, it is immediately carried to the well ventilated cooling-room, to be spread upon its wooden floor, and turned frequently over with a wooden shovel, should the grist have been so large as to cause it to be laid thick on the floor. After it has been thoroughly cooled, it is made to descend from the cooling-room, by a hopper, into the *bolting or dressing cylinder*, in which it is separated into its respective parts by being brushed through wire-cloth of different sizes. These parts usually consist of *firsts*, or fine flour; of *seconds*, or second flour; of *thirds*, or sharps; of *broad* or coarse bran, and of *fine* bran. Sometimes the coarse bran only is taken from the flour, which is then said to be ground *overhead*, and makes good coarse household bread. Sometimes the fine bran is taken out from the overhead flour, and the coarse flour makes a sweet coarse bread. On the other hand, a smaller quantity of the fine is taken out of the bulk of flour, in order to make the finest as fine as possible, and this is used for pastry and fancy bread; and in this case, the seconds flour becomes finer, and makes the seconds loaf of superior quality. More or less of fine flour is taken out in dressing, by merely shifting a hinged board under the dressing cylinder, so as to embrace a larger or smaller space of the upper or finer portion of the wire-cloth of the cylinder. When a large proportion of the bulk is made into first flour, this flour is not fine, and the seconds flour is thereby reduced in quantity, and made coarser. The sharps, or that portion which consists of the heart of the grain, and which is broken and escapes from between the millstones, are used by biscuit-bakers. The first or broad bran is used for bran-mashes, and mixing with horse-corn, and the fine bran is employed to feed poultry and pigs. As you have seen that the butchers of London cut up carcasses of meat in a greater number of pieces than those of this country; so the millers there dress the flour in a greater number—no less than seven distinct—sorts. These sorts are thus divided from the flour of a quarter of wheat of 8 bushels:†

Fine flour	5 bushels	3	pecks.	Bran	3 bushels	0	pecks.
Seconds	0 ..	2	..	Twenty-penny	3 ..	0	..
Fine middlings	0 ..	1	..	Pollard	2 ..	0	..
Coarse middlings	0 ..	0½	..				
Total					14 bushels	2½	pecks.

So that grinding nearly doubles the bulk of flour and bran above that of the wheat‡

(1494.) Whether flour is properly *ground*, is judged of on being taken into the hand as it falls

* Dickson's Husbandry of the Ancients, vol. ii.

† See Ure's Dictionary of the Arts, art. Millstones, for an account of this remarkable substance.

from the spout leading from millstones. It is rubbed by the thumb against the side of the fore-finger, and if it feel pleasantly smooth, without being greasy or rough, it is well. When the outer edges of the millstones are set too close, the flour feels greasy, because it has been too much bruised—or *killed*, as it is termed—and it does not then easily rise with yeast in the making of bread. When the stones are set too far asunder, the grain accumulates under the eye of the millstone, and is there *broken*, which breaking prevents the skin of the grain being separated from the substance, and the consequence is, that the bran feels thick, rough, and heavy, and there is much waste of substance. Whether flour is properly *dressed*, is ascertained in the same way, by rubbing the fine flour between the thumb and fore-finger, and if it feel smooth and even, not in the least rough or gritty, it is well. To judge still farther whether the flour has been perfectly dressed, if, on being pressed with a polished article, such as the back of a plain gold or silver watch, or the back of a silver spoon, the smooth-pressed surface present no minute brown spots of bran to a good sight, it is clean dressed; and if any such cannot be detected by a good magnifying-glass, it is as perfectly dressed as practicable with the present form of the machinery. When the large bran is inspected, and it is found to be entirely skin and no white substance of the wheat adhering to it, the grinding has been well executed; and in this state the bran, on being thrown upward, will fall lightly toward the ground, being in large, thin flakes. The small bran has always a part of the substance of the wheat attached to it: because it is chiefly derived from the groove which forms the bosom of the grain, and is only generated after the large bran has been sloughed off, and a portion of the grain itself ground down to the level of the groove. There is no means of judging whether any parcel of flour will make good bread, the *flour* of the opaque and flinty wheats being undistinguishable from one another, and it is perhaps this difficulty which induces bakers to buy wheat, and get it made in flour on their own account; otherwise the simplest plan for them would be to buy the sort of flour they want. On account of this practice of the bakers, many of the flour millers in Scotland grind only on hire.

(1495.) Flour is put up in what are called *sacks* of 280 lbs., or 20 stones [of 14 pounds] imperial. It is rendered firm in the sack by the sack being occasionally beaten against the floor by means of a fork-lever, when filling at the spout leading from the dressing machine. Of wheat weighing about 64 lbs. per bushel, 4½ or 5 bushels will be required to make a sack of fine flour. Of the fine crop of 1815, I remember of the late Mr. Brown, Whitsome Hill, Berwickshire, selling to Mr. Mackay, of Clarabud Mill, in the same county, 800 bolls, or 4,800 bushels of red Dantzic creeping wheat, which weighed 27 stones per boll, or 63 lbs. per bushel, and yielded 24 stones of fine flour, and only 3 stones of refuse—that is, only one ninth of refuse of the entire weight.* I find the fine white wheat used by the bakers of Edinburgh yields 13¼ stones of 14 lbs. of flour from 4 bushels, weighing 18 sts., and 2 stones of odd, seconds, parings, sharps, and waste, and 2¼ sts. of bran.

(1496.) Many devices are practiced to *adulterate flour*. I remember a miller in Cornwall being fined in very heavy penalties for adulterating his flour with the washed felspar obtained from the disintegration of the granite of his neighborhood. Potato flour and bean flour are mixed with wheat flour, and though not positively unwholesome, or perhaps unlawful, are frauds when so used, as being articles of inferior value to the flour of wheat. There are modes, however, of detecting any kind of adulteration. "If potato flour be added," says Dr. Ure, "which is frequently done in France, since a vessel which contains 1 lb. of wheat flour will contain 1¼ lbs. of potato flour, the proportion of this adulteration may be easily estimated. If gypsum or ground bones be mixed with flour, they will not only increase its density still more, but they will remain after burning away the meal." "Bean or pea flour may be detected by pouring boiling water upon it, which develops the peculiar smell of these two substances." "Nitric acid has the property of coloring wheat flour of a fine orange yellow, whereas it does not affect the color of potato flour." "Pure muriatic acid colors wheat flour of a deep violet, but dissolves potato fecula." "As fecula absorbs less water than flour, this affords a ready means of detection." "Alum may be detected in bread by treating the bread in water, and pouring a few drops of nitrate or muriate of barytes in it, when a heavy white precipitate will follow, indicating the presence of sulphuric acid."† "Guaiacum," says Dr. Thomson, "is rendered *blue* by various animal and vegetable substances. It becomes blue, according to Tadei, when rubbed in the state of powder with gluten of wheat, or with the farina which it contains."‡ If a little of this gum and water be put among flour, it is a very good and easy test of its soundness when the flour becomes *blue*. "It has been found so difficult to detect the adulteration of flour," remarks Mr. Babbage, "and to measure its good qualities, that, contrary to the maxim that Government can generally purchase any article at a cheaper rate than that at which they can manufacture it, it has been considered more economical to build extensive flour mills, and to grind their own corn, than to verify each sack purchased, and to employ persons in continually devising methods of detecting the new modes of adulteration which might be resorted to."‖

(1497.) Any one may analyze flour in this way: "A ductile paste is to be made with 1 lb. of flour and a sufficient quantity of water, and left at rest for an hour; then having laid across a bowl a piece of silken sieve stuff a little below the surface of the water in the bowl, the paste is to be laid on the sieve, on a level with the water, and kneaded tenderly with the hand, so as merely to wash the starchy particles out of it. . . . . The water must be several times renewed, until it ceases to become milky. The gluten remains on the sieve."§

(1498.) The analysis of wheat and flour by the celebrated Vauquelin gave the following results. It may be observed, however, of the wheat and flour subjected to this analysis, that they were of foreign growth, and the results cannot be adopted for practical purposes in this country, as if they had been obtained from British wheat and flour. "In general," says Davy, "the

* As an instance of the great fluctuation in the price of wheat occasioned by a difference in seasons, I may mention that part of this fine wheat was sold in 1815 for 32s per boll of 6 bushels, or 5s. 4d. per bushel; and in August, 1816, a very wet season, part was sold for 105s. per boll, or 17s. 6d. per bushel.

It appears that Odessa wheat contains more sugar than French wheat. The gluten mentioned here is a mixture of gluten and albumen. The gum has a brown color, and contains azote. It is the gluten which gives to a mixture of flour and water its tenaciousness, ductility, and elasticity, and forms the nourishing property of loaf-bread. Gluten has a great resemblance to animal tendon or membrane, containing no less than 14½ per cent. of azote. When subjected to fermentation, which is of a peculiar character, and has thereby obtained the appellation of *panary* fermentation, a considerable volume of carbonic acid gas is evolved, but which is retained in the mass of the dough by the tenacity of the gluten. Thus confined during its evolution, the gas expands the dough to nearly double its pristine volume, and gives it its vesicular texture; and it is the infinite number of these cellules filled with carbonic acid gas, and apparently lined with a glutinous membrane of a silky softness, that gives to the well-baked loaf that light, elastic, porous constitution which *good* bread always possesses.‡

(1499.) *Leaven* was at first used to produce the fermentation spoken of in dough. It is nothing more than a piece of dough kept in a warm place until it undergoes a process of fermentation, swelling, becoming spongy, or full of air bubbles, at length disengaging an acidulo spiritous vapor, and contracting a sour taste. A much better promoter of the panary fermentation is *yeast*, which is the viscid froth that rises on the surface of beer in the first stage of its fermentation.

(1500.) With good wheaten flour, the proportion given by the bakers to make bread is ⅔ weight of flour and ¼ of yeast, water, and salt. The bread loses 1-7 of its weight in baking. With these proportions, a sack of flour of 280 lbs. yields 92 loaves of 4 lbs. each. [368 pounds.]

(1501.) It is not unusual for farmers to bake their household bread, and it may be done in this way: Take, say 24 lbs. of flour, whether fine or ground overhead, and put it in a hollow clay dish. Make a deep hollow in the middle of it; and sprinkle a handfull of salt over it. Then take ½ a pint of thick, sweet, fresh, well washed yeast, about 5 quarts of milk-warm water, from 65° to 70° Fahr. and a pint of bran, and stir them together in a pitcher. Too hot water will stop, and too cold will prevent fermentation. Pour the water and yeast over the flour through a sieve, and, mixing all lightly together, set the mass before the fire, covering it with a cloth. Light the oven fire, and bring it to a due heat. In about an hour the sponge will have risen sufficiently, when it should be kneaded with considerable force for about 15 or 20 minutes. The dough should not be worked too stiff, though it requires to be a little stiffer when the loaves are fired on their own soles than when fired in pans. The kneaded dough is again set before the fire, and covered with a cloth as before, when a new fermentation ensues, which will have proceeded far enough when the dough increases half more in bulk, that is, in about an hour, when the dough is portioned out into the size of the loaves desired, and placed in the oven to be fired. If the oven is too hot, the dough will be incrusted on the surface too much and too soon, and if too cold, the bread will be heavy, and not rise sufficiently in the firing. Experience must teach these particulars. This quantity will make 31 lbs. of bread.

(1502.) The danger of making the bread *sour* is incurred between the first and second processes of fermentation. In the first it is the vinous fermentation, which of itself is innocent, but if increased heat is applied, or the sponge allowed to stand too long, it is apt to run into the acetous fermentation. This tendency is checked during the first process by kneading the dough in time. If, however, the second fermentation is allowed to continue longer than it should be, the acetous fermentation will rapidly appear, and then the bread will inevitably be sour unless some counteracting expedient is adopted, such as the application of an alkali, as carbonate of soda, or of an alkaline earth, as magnesia or chalk. It is certainly better to employ these neutralizing ingredients than to allow the batch of bread to become sour, but better still to use the means of making the batch into sweet bread than to rectify that acidity in it which ought never to have overtaken it; and the means of avoiding acidity are, to make the sponge fresh in the morning, a short time before the bread is to be fired, and not to allow it to stand over night in the kitchen, in a low temperature. I speak from experience, and can safely aver that with these precautions not a sour

[‡ Under more appropriate heads, shall we note the results of a great variety of more modern experiments and analyses, touching this important subject in every light. Professor Johnston is of opinion that the quantity of gluten contained in English Wheat has generally been stated much too high. He concludes, on a view of all that has been said and done, that the quantity of gluten in English flour is seldom more than ten per cent.] *Ed. Farm. Lib.*]

* Davy's Lectures on Agricultural Chemistry, Edition of 1839.

† Thomson's Organic Chemistry, *Vegetables.*

loaf was seen in my house for many years. I do not say that a sponge left over night *must* become sour, but only that it is much *more apt* to become so than when fresh made. When the second fermentation is allowed to proceed too far, both the lactic and acetic acids are formed; the former most sensibly affects the taste, and the latter the smell; and both combine to make bread sour.

(1503.) Brewer's barm makes the lightest and best *yeast* for family use, and what of it may not be used at one time may be kept sweet for some weeks in the following manner. "As this substance works out of the barrels, it should be placed in deep pans, and left to settle for a day or two. The thin fluid should then be poured off, and the pan filled with cold fresh spring water, stirring the thick yeast well up. Every day this operation is to be repeated, and occasionally it ought to be strained through a sieve into another vessel. It will thus always be ready for use." Experience alone can tell whether the scent or appearance of yeast procured at a brewery are those the most desirable; but these hints may prove useful. "If it be fit for the purpose, it will smell rather fragrant; if stale it will have a strong acid, and slightly putrid scent. In this state, we have known it to be recovered and rendered available, by adding a tea-spoonfull of flour, the same of sugar, a salt-spoonfull of salt, and a tea-cupfull of warm water, to a ½ pint of yeast, and setting it near the fire to rise, having well stirred it. This should be done about an hour before it is intended to be mixed with the flour; for that time is required in order to watch whether the fermentative principle is strong enough to work the bread. In a quarter of an hour, the mass will have nearly reached its hight, and a fine head will have formed. This must be looked at carefully. If it continue up and appear opaque, it may be trusted; but if it 'go back,' that is, sink, look hollow and watery, and the bubbles break, it will infallibly spoil the batch; it must be thrown away. *Bran ought always to be used*, however fresh and good the ferment may be found. Bran contains an acid principle which tends to subdue the bitter taste of the hop, and it also possesses much fermentative matter that assists the action of the yeast." In this way, "we have ourselves baked bread that was made with the barm for our own home-brewed beer for six successive weeks; not from necessity, but in order to ascertain the extent of time to which yeast might be kept sweet."*

(1504.) It is assumed by some people, that a mixture of potatoes among wheaten flour renders bread lighter and more wholesome. That it will render bread whiter I have no doubt; but I have as little doubt that it will render it more insipid, and more than this, it is demonstrable that its use is less economical than wheaten flour. Thus, take a bushel of "seconds" flour, weighing 56 lbs. at 5s. 6d. A batch of bread, to consist of 21 lbs., will absorb as much water, and require as much yeast and salt, as will yield 7 loaves, of 4 lbs. each, for 2s. 4d. per loaf. "If, instead of 7 lbs. of the flour, the same weight of raw potatoes be substituted with the hope of saving by the comparatively low price of the latter article, the quantity of bread that will be yielded will be *but a trifle more than would have been produced from* 14 lbs. *of flour only*, without the addition of the 7 lbs. of potatoes; for the starch of this root is the only nutritive part, and we have proved that but 1·7 or ¼ of it is contained in every pound, the remainder being water and innutritive matter. Only 20 lbs. of bread, therefore, instead of 28 lbs., will be obtained; and this, though white, will be comparatively flavorless, and liable to become dry and sour in a few days; whereas, without the latter addition, bread made in private families will keep *well* for 3 weeks, though, after a fortnight, it begins to deteriorate, especially in the autumn." The calculation of comparative *cost* is thus shown:—

Flour, 14 lbs., say at 1½d. per lb.	=	1s. 5½d.
Potatoes, 7 lbs., say at 5s. per sack	=	0 2
Yeast and fuel	=	0 4½
		2s. 0d.

The yield 20 lbs., or 5 loaves of 4 lbs. each, will be nearly 5d. each, which is dearer than the wheaten loaves, which were 4d. each, and the bread besides of inferior quality. "There are persons who assert—for we have heard them—that there is no economy in baking at home. An accurate and constant attention to the matter, with a close calculation of every week's results for several years—a calculation induced by the sheer love of investigation and experiment—enable us to assure our readers that a gain is invariably made of from 1½d. to 2d. on the 4d loaf. If *all* be intrusted to servants, we do not pretend to deny that the waste may neutralize the *profit*; but, with care and investigation, we pledge our veracity that the saving will prove to be considerable."† These are the observations of a notable housewife.

(1505.) The microscope has ascertained the *structure of wheaten flour*. "The largest grains of the fecula of wheat," says Raspail, "do not generally exceed .002 of an inch in size. They are spherical, and along with them we see empty and torn membranes, resulting from the bruising of the grains by the mill. They are much smaller, rounder, and better preserved, when they are extracted from the grain while it is greenish, and not ripened on the stalk." "Panification," he observes, "is a process whose object is to burst all the grains of fecula, which are in the farina, associated with a very fermentable substance called gluten. The finest and best baked bread is what is made of farina abounding in an elastic gluten; for this gluten, rising in large blisters by the dilatation of the gases imprisoned within it, allows each feculent grain to participate in the communication of the heat, and to burst, as it would by boiling. Hence, after panification, if the paste has been well kneaded, we do not find a single grain of fecula entire. The bread will be duller and less properly baked, if it contains less of this gluten. This is the reason why, other circumstances being alike, the bread of rye and barley is less nourishing than that of wheat. Wheaten bread will likewise be heavier and less perfect, according as the flour has been more or less mixed with other grain or with fecula. It has been observed," he continues, "that the more of foreign fecula we mix with flour the less increase of weight does

* Quarterly Journal of Agriculture, vol. ix. † Ibid. vol. ix.

the bread acquire. Thus, 6 lbs. of flour produce 8 lbs. of bread; but 3 lbs. of fecula of the potato, with 3 lbs. of flour, produce only 6 lbs. of bread. The reason of this is the following:—The grains of fecula do not imbibe the water, but only are moistened by it; in other words, it only adheres to them. The gluten, on the other hand, imbibes it as a sponge would do, and the more it is kneaded the more it imbibes, and the water thus imbibed adds to the weight of the bread. There are two reasons, then, against this sort of mixtures; and this adulteration, though it be not a crime, is still a fraud, because the immediate result of it is to diminish at once the weight and the nutritive quality of the bread." Thus the minutest scientific research corroborates facts evolved by practice.

(1506.) *Wheat contains more gluten* than any of the other grains, and it is this substance which confers the relative value on wheat as an article of food. It is most developed when used in the form of bread. "If we prepare two masses of gluten by kneading," says Raspail, "we shall not be able to make them unite by simple contact; but if we tear open the side of each, and bring the edges together, the smallest effort will be sufficient to unite the two masses into one. The object of kneading, then, is to press the two edges of the glutinous parcels against each other. Hence the quantity of gluten will vary according to the mode of kneading employed. Thus Beccaria, who contented himself with placing the farina in a sieve, and keeping it under a stream of water, but without stirring it, obtained less gluten than Kesselmeyer, who, in the first place, made a paste of the farina, and then kneaded it continually under a stream of water, till the water ceased to pass off milky. In the former process, the weight of the water falling on the farina brought a few parcels together, but kept asunder or disunited the greater number, which consequently passed through the sieve. In the second process, on the contrary, the hand in kneading compressed, turned in every direction, and brought together by every point of contact, the scattered parcels, and scarcely allowed the water to carry off anything but the round and smooth grains of fecula. I have ever found that, in this process, we obtain more or less gluten, according as the paste is pressed in different ways; for when it is merely compressed perpendicularly, we lose a good deal more of the gluten than when it is rolled upon itself with some force."

(1507.) In regard to the *nutritive properties of gluten*, there is no doubt they are of a superior order, though not for the reason ascribed by Magendie, who concluded that gluten is nutritious because sugar, which contains no nitrogen, could not support dogs in life beyond a certain time; while Parmentier was led to infer that gluten remains undigested. "But who does not perceive," justly asks Raspail, "that animals till then accustomed to live on flesh, must suffer on being all at once deprived of this aliment, just as a horse would suffer from being fed on flesh instead of hay; for as digestion is a complex operation, why should we seek to study it by violating its elements? Sugar will not ferment by itself—why, then, expect that it should ferment without albumen in the stomach? If this mode of experimenting entitle us to erase sugar, oil, and gum from the list of nutritive substances, we must also erase pure gluten and even pure albumen; for if an animal be fed on them alone it will die just as certainly as if it had been fed exclusively on sugar. This is one of these questions," he concludes, "in which both sides are wrong, and the truth lies in blending the opposite opinions together. Neither gluten nor sugar, taken singly, is nutritive; but they become alimentary when united."

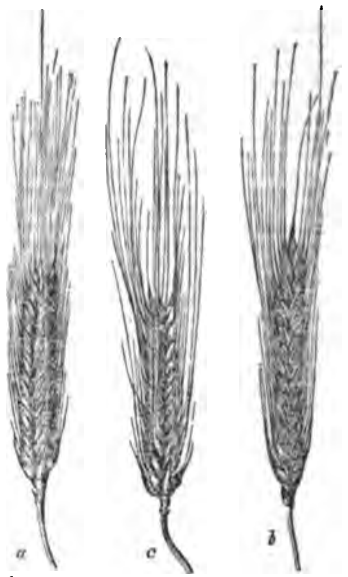
(1508.) Wheat is used in *starch* making. "In starching linen," says Raspail, "the fecula of the potato, of the horse-chestnut, &c. may be used, as well as that of wheat; and it may be used either hot or cold, in the state of starch or of powder. The effect will be the same, provided the irons used be sufficiently heated. It is sufficient to mix the fecula with a little water, to dip the linen in it, clapping it with the hand, and to apply the hot iron while the linen is still moist. The grains of fecula will burst from the action of the heat, the membranes will dilate as they combine with a portion of the water that is present, the soluble mass will be freely dissolved in the rest of it, and the linen will be starched and dried by one process." Fecula is used in making size for paper as well as glue; and "it is known that weavers are obliged, in order to preserve the humidity of the *batter* used in dressing the threads, to work habitually in low, damp, and consequently unwholesome places. Dubuc, an apothecary at Rouen, proposed to add to the dressing a deliquescent chloride, which, by attracting the moisture of the air, might prevent the drying of the batter, and thus admit of the workman carrying on his labor in drier and more healthy places. Vergnaud recommends the use of the fecula of the horse-chestnut, which contains a proportion of potash sufficient to prevent the batter from drying."* "The wheat of the south of Europe, in consequence of the larger quantity of gluten it contains, is peculiarly fitted for making *macaroni* and other preparations of flour, in which a glutinous quality is considered as an excellence."† The macaroni is formed into different sized tubes, by the dough being pressed from a machine in broad fillets, the edges of which are brought into contact and adhere, while the dough is yet moist. Macaroni makes the finest flavored dish with *Parmesan* cheese.‡

[* It seems proper to advise the reader here, that this chapter does not embrace, by any means all that is said by the author on the subject of Wheat. It will, hereafter, be treated under the heads—Insects and Diseases affecting—Proper Degree of Ripeness for Cutting—Cutting and Stooking—Carrying in and Stacking—Comparative Weights of Grain, Straw, and Roots—Autumn Sowing, Plowing land for it—various modes of doing this—Importance of Thorough Draining—Preparation of the Seed and Sowing—Best Varieties—Sowing by Dibbling—By Transplanting—Expenses of this, and Sowing of Seed—Description of the Process and Germination &c. All these points will be embraced in this volume, and we could wish to introduce them now, in reference to the coming season; but there are obvious reasons why we cannot break in upon the systematic arrangement of the author.] [*Ed. Farm. Lib.*

* Raspail's Organic Chemistry. † Davy's Lectures on Agricultural Chemistry, Edition of 1839.

(1509.) *Barley.**—Its botanical position is the 3d class Triandria, 2d order Digynia, genus Hordeum of the Linnæan system, and in the natural order of the *Gramineæ*. Professor Low divides the cultivated barley into two distinctions, namely the 2-rowed and the 6-rowed, and each of these comprehends the ordinary, the naked, and the sprat or battledore forms.† Mr. Lawson describes 20 varieties of barley;‡ while the Museum of the Highland and Agricultural Society contains specimens of 30 varieties.‖ The natural classification of Barley by the ear is obviously of three kinds, 4 rowed, 6-rowed, and 2-rowed. Fig. 304 represents the three forms, where *a* is the 4-rowed, or bere or bigg; *c* is the 6-rowed; and *b* the 2-rowed; all of which figures represent barley in half its natural size. Of these the bere or bigg was that which was cultivated until a recent period, when the 2 rowed has almost entirely supplanted it, and is now the most commonly cultivated variety, the 6-rowed being rather an object of curiosity than culture.

Fig. 304.



4-ROWED BERE OR BIGG. 6-ROWED BARLEY. 2-ROWED CHEVALIER BARLEY.

(1510.) In classifying barley by the *grain*, there are just two kinds, *bere* or *bigg*, and *barley*; and though both awned, are sufficiently marked to constitute distinct varieties. In the bere, the median line of the bosom is so traced as to give the grain a twisted form, one of its sides appearing larger than the other. In the barley the line passes straight, and divides the grain into two equal sides. They are both represented in fig. 305, where *a* is the bigg, with the twisted-like grain, and lengthened point from which the awn has been broken off; and *b* is the barley, whose shortness and plumpness give it a character of superiority. Both these clusters of grain are of the natural size. The bigg has long been recognized in Scotland, and even a 2-rowed variety, under the name of common or Scotch barley, has long been in cultivation; but several of the English varieties are now naturalized, and in their new sphere show a brighter and fairer color, plumper and shorter grain, quicker in the property of malting, though less hardy and prolific, than the common barley. The crenulated or shriveled skin across both sides of the median line in the English barleys is a good criterion of malting; and as most of the barley raised in this country is converted into beer or spirits, both of which require malt to produce them of the finest quality, it is not surprising that those varieties which yield the greatest return of malt should always realize the highest prices.§

Fig. 305.

ENGLISH BARLEY. SCOTCH BERE OR BIGG.

(1511.) A good crop of barley yields a return of from 48 to 60 bushels the imperial acre. Good barley weighs from 55 lbs to 59 lbs. per bushel. A crop of 60 bushels per acre will yield of straw, in the vicinity of a town, 176 stones of 14 lbs. to the stone, or 1 1-10 ton, and the weight of the grain of that crop, at 56 lbs. per bushel, will be 1½ tons. It takes of bigg 111 grains to weigh 1 drachm; of 6-rowed barley, 93; and of Chevalier barley, 80 grains. Of the three kinds, the Chevalier is much the heaviest.

(1512.) By far the largest proportion of the best barley grown in this country is converted into *malt* for making malt liquor and spirits, and barley is also used for distillation in a raw state. In three years, the following quantities of malt paid duty, viz.:

	ENGLAND.	SCOTLAND.	IRELAND.	TOTAL
	Bushels.	Bushels.	Bushels.	Bushels.
1834.....	34,949,646	3,580,758	1,776,883	40,307,287
	£4,449,745	£462,514	£229,514	£5,141,775
1835.....	36,078,855	3,604,816	1,825,300	41,508,971
	£4,660,185	£465,622	£235,767	£5,361,574
1836.....	37,196,998	4,168,854	1,872,104	43,237,956
	£4,804,612	£538,477	£241,813	£5,584,902

[* The Barley Crop of the U. States, by the last Census, was 4,161,504 bushels, much more than half of which was grown in New-York. Maine produced 355,161; Ohio, 212,440; Pennsylvania, 209,893; Michigan, ☞ 127,802; and Virginia *only* 87,430. *Ed. Farm. Lib.*]

[§ Professor Johnston, in his Table of the nutritive matter of different kinds, from an acre of the usually cultivated crops, puts down Barley thus: Gross produce, bushels 35—pounds 1800—Husk or woody fibre, 270—Starch, Sugar, &c., 1,080—Gluten, &c., from 210 to 260—Oil or Fat 36 to 54—Saline matter, 50. *Ed. Farm. Lib.*]

† Low's Elements of Practical Agriculture. ‡ Lawson's Manual. ‖ Catalogue of the Museum.

Pot and pearl barley are made from barley for culinary purposes; and both meal and flour are manufactured from barley for the purpose of making unleavened bread, which is eaten by the laboring class in some parts of the country, and barley bannocks are esteemed a luxury by people in towns. Porridge of barley-meal, with rich milk, is accounted a pleasant and light supper, and less heating than that of oatmeal.

(1513.) The *barley has received great attention from the chemist*, both on account of its importance as a fermentable substance, and partly to discover its constituent parts. "The following are the proportions of the constituents obtained by Einhoff from 3,840 parts of barleycorns:

Volatile matter	430	Meal	2,690
Husk	720	Total	3,840

From the same quantity of barley-meal he obtained—

Volatile matter	360	Gluten	135
Albumen	44	Husk, with some gluten and starch	260
Saccharine matter	200	Starch, not quite free from gluten	2,580
Mucilage	176	Loss	76
Phosphate of lime, with some albumen.	9		
Total			3,840

Besides these substances, Fourcroy and Vauquelin ascertained the presence of phosphates of lime and magnesia, and of silica and iron; and I found in it phosphate of potash and nitrate of soda. Barley-meal, on being macerated, yields an oil, which is supposed to give its peculiar flavor to spirits from raw grain. If this opinion is well founded, the oil must be dissipated or destroyed by the process of malting."*

(1514.) The grains of the fecula of the barley are very fine, not exceeding .00098 of an inch in size. Barley flour only contains 3 per cent of gluten, and is therefore much less nutritive than wheaten flour. The *hordein*, ascribed by Proust to act so important a part in the germination of barley, is asserted by Raspail to be nothing more, under the microscope, than bran. "That this is the case," he says, "is proved by dissection; for if we make a transverse slice of each of the grains of wheat and barley, we shall perceive that the pericarp of the wheat peels off entire like a circular band, while that of the barley can only be detached in very small fragments. Now, what takes place under the edge of the scalpel," he alleges, "will also happen under the pressure of the millstone; consequently the bran will be much more minutely divided in the farina of barley than in that of wheat. In bolting flour, therefore, it will remain in the sieve; while, in the other, its almost microscopic fragments will pass through with the fecula and gluten, and will be almost inseparable, by mechanical means, from the farina." Hence, if pearl barley "be ground, we obtain from it a farina as white as that of wheat, and containing only a very minute portion of hordein, equivalent to the amount of those fragments of the pericarp which had been protected by their situation in the posterior groove of the grain." †

(1515.) "The meal so highly commended by the Greeks was prepared from barley. . . . . It was not until after the Romans had learned to cultivate wheat and to make bread, that they gave barley to the cattle. They made barley-meal into balls, which they put down the throats of their horses and asses, after the manner of fattening fowls, which was said to make them strong and lusty. Barley continued to be the food of the poor, who were not able to procure better provision; and in the Roman camp, as Vegetius has informed us, soldiers who had been guilty of any offence were fed with barley instead of bread corn." ‡

(1516.) *Malting.*—This process produces a considerable change in the constitution of the grain. The barley is steeped in cold water for at least 40 hours, according to law. Here it imbibes moisture, increases in bulk, and emits a quantity of carbonic acid gas, not exceeding 2 per cent. The moisture imbibed is 0.47, that is to say, every 100 lbs. of barley, when taken out of the steep, weighs 147 lbs. The increase of bulk is 1-5, that is, 100 bushels of grain measures out 120 bushels. The steep-water dissolves from 1-50 to 1-100 of the husk of the barley, and hence barley becomes paler by steeping. The steeped barley is then put on a floor in a heap 16 inches deep, to remain so for 26 hours. It is then turned with wooden shovels, and diminished in depth to a few inches by repeated turnings. In 96 hours the grain becomes 10° hotter than the air, and then *sweats*, when it is frequently turned, the temperature being preserved in the grain from 55° to 62°. The roots now begin to appear, the stem called *acrospire* springs from the same end, and advances within the husk to the other end of the grain; but the process of malting is stopped by kiln-drying before the germ has made much progress. The kiln, at first 90°, is raised gradually to 140°. The malt is then cleaned, and the rootlets removed, as they are considered injurious, and are called *comins*. Malt is from 2 to 3 per cent. greater in bulk than the barley, and it loses 1-5 or 20 per cent. in weight, of which 12 per cent. is loss by drying; so the real loss is only 8 per cent., accounted for by the steep-water carrying away 1½ per cent., dissipated on the floor 3 per cent., roots cleaned away 3 per cent. and waste ½ per cent. The roots take away the glutinous portion of the grain, and the starch is converted into a sort of sugar.

(1517.) *Beer.*—Beer is a beverage of great antiquity. "The earliest writer who mentions *beer*," commences Dr. Thomson in his account of the process of malting, of which the foregoing paragraph is the substance, "is Herodotus, who was born in the first year of the 74th Olympiad, or 444 years before the commencement of the Christian era. He informs us that beer was the common drink of the Egyptians, and that it was manufactured from barley, because wines did not grow in their country. In the time of Tacitus, whose treatise on the *Manners of the Germans* was written about the end of the first century of the Christian era, beer was the common drink of the Germans. Pliny mentions beer as employed in Spain, under the names of *cælia* and *ceria*

* Thomson's Organic Chemistry, *Vegetables*. † Raspail's Organic Chemistry.
‡ Phillips's History of Cultivated Vegetables, vol. i.

and in Gaul under the name of *cervisia*. Almost every species of corn has been used in the manufacture of beer. In Europe it is usually made from *barley*, in India from *rice*, in the interior of Africa, according to Park, from the seeds of the *Holcus spicatus*. But whatever grain is employed, the process is nearly the same, and it is usual in the first place to convert it into malt." * †

(1518.) *Oats.*—Oats are cultivated on a large extent of ground in Scotland, and it is believed that no country produces greater crops of them or of finer quality. The plant belongs to the natural order of *Gramineæ*, and it occupies the 3d class *Triandria*, 2d order *Digynia*, genus *Avena*, of the Linnæan system. Its ordinary botanical name is *Avena sativa*, or cultivated oat. The term oat is of obscure origin. Paxton conjectures it to have been derived from the Celtic *etan*, to eat.‡ There are a great number of varieties of this grain cultivated in this country. Mr. Lawson describes 37; ‖ and 54 are deposited in the Highland and Agricultural Society's Museum.§ The natural classification of this plant by the *ear* is obvious. One kind has its panicles spreading and equal on all sides, and tapering toward the top of the spike in a conical form. The other has its panicles shortened, nearly of equal length, and all on the same side of the rachis. Fig. 306 represents both

Fig. 306.

THE TARTARIAN OAT. THE POTATO OAT.

the kinds, *a* showing the first and *b* the second, where they both appear somewhat confined or squeezed toward the rachis, the object being to exhibit the grain in the straw as taken from the stack, rather than when pulled green from the field. *a* is the prolific potato oat, which is beardless, commonly cultivated in Scotland for the sake of its meal, and *b* is the white Tartarian oat, which is bearded, and extensively cultivated in England for horse-corn. The natural classi-

[† For a valuable Essay on the culture of Barley in the United States, from the pen of H. S. RANDALL, Esq., see THE FARMERS' LIBRARY AND MONTHLY JOURNAL OF AGRICULTURE, Vol. II., page 233. It will be farther treated in this "Book of the Farm," under the heads—Insects and Diseases incident to it—Stooking—Precautions necessary against its Heating in the Stack—Quantity annually Malted in Great Britain—Its Chemical Composition, and that of Barley Meal—Grinding and Malting—Comparative Weight of Grain, Straw and Roots—&c. *Ed. fication by the grain consists also of two forms; the one a round, plump grain, like *a*, fig. 307. and an elongated, thin grain, having a tendency to show awns, as at *b*; the *a* kind being cultivated on the best lands in the low country, the other on poorer soils and in high districts. The first is tender, and liable to shake with the wind; the other is hardy, and able to resist the tempest. The former is cultivated chiefly for human food, yielding meal largely, the latter being raised chiefly for the food of horses. The straw of the former kind is strong and inclined to reediness; that of the latter is fine, pliable, and makes an excellent dry fodder for cattle and horses, there being a good deal of saccharine matter in the joints; the former is considered late in coming to maturity, the latter early, and is consequently so designated,

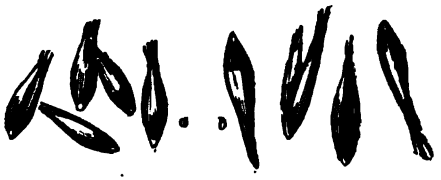
Fig. 307.



THE POTATO OAT. WHITE SIBERIAN EARLY OAT.

(1519.) The *crop* of oats varies from 40 to 75 bushels per imperial acre, according to the kind and the circumstance of soil and situation. Oats vary in weight from 36 lbs. to 48 lbs. per bushel. Whiteness, of a silvery hue, and plumpness, are the criterions of a good sample. The potato oat, 47 lbs. per bushel, gave 134 grains to 1 drachm; the Siberian early oat, weighing 46 lbs. per bushel, gave 109 grains; and the white Tartarian oat gave 136 grains. A crop of potato oats, yielding 60 bushels to the acre, at 47 lbs. per bushel, will weigh of grain 1 ton 5 cwt. 20 lbs., and will yield of straw 1 ton 5 cwt. 16 lbs., in the neighborhood of a large town; or, in other words, will yield 8 kempies of 40 windlings each, and each windling 9 lbs. in weight. But I have been made acquainted with a crop of Hopetown oats near Edinburgh of no more than 60 bushels to the imperial acre, yielding 2 tons 18 cwt. 16 lbs. of straw. The common oats yield more straw in proportion to the grain than the potato variety.

(1520.) The portion of the oat-crop consumed by man is manufactured into *meal*. It is never called flour, as the millstones are not set so close in grinding it as when wheat is ground, nor are they usually made of the same material, but most frequently of sandstone. Oats, unlike wheat, are always kiln-dried before being ground; and they undergo this process for the purpose of allowing the thick husk, in which the substance of the grain is enveloped, to be ground off, which it is by the stones being set asunder; and the husked grain is then winnowed by fanners, which blow away the husk and retain the grain, which is then called *groats*. The groats are ground by the stones closer set, and yield the meal. The meal is then passed through sieves to separate the remaining husk from the meal. The meal is made in two states; one *fine*, which is the state best adapted for making into bread, in the form called oat-cake or bannocks; and the other is coarser or *rounder* ground, and is in the best state for making the common food of the country people, porridge, *Scotice*, parritch. A difference of practice prevails in respect to the use of these two different states of oatmeal in different parts of the country, the fine meal being best liked for all purposes in the northern, and the round or coarse meal in the southern counties; but as oat-cake is chiefly eaten in the North, the meal is there made to suit the purposes of bread rather than of porridge: whereas, in the South, bread is made from another grain, and oatmeal is there used only in the shape of porridge. There is no doubt that the round meal makes the best porridge when properly made, that is, when boiled as long as to allow the particles to swell and burst, when the porridge becomes a pultaceous mass. So made, with rich milk or cream, there are few more wholesome meals for any man, or upon which a harder day's work can be wrought. Children of all ranks in Scotland are brought up on this diet, verifying the poet's assertion,

"The halesome parritch, chief o' Scotia's food."—BURNS.

(1521.) In regard to the *yield of meal* from any given quantity of oats, it is considered that when they give what is called *even meal* they yield half their weight of meal; that is, supposing that a boll of oats of 6 bushels weighs 16 stones, it should give 8 stones of meal, and, of course, 8 stones of refuse; but the finer class of oats will give more meal in proportion to weight than this, more nearly 9 stones, and some even 12 stones. The market value of oats is thus estimated by the meal they are supposed to yield, and in discovering this property in the sample millers become very expert. When oats yield less than even meal they are considered to give ill, and are disposed of for horses, or kept at home for that purpose.

(1522.) The *oat* has *not* received that attention from the *chemist* as the barley or wheat. The principal characteristic of oatmeal is, that it contains a large proportion of starch. "Vogel found that 100 parts of oats consisted of meal 66, and of husk 34. The dry meal yielded

Fat yellowish-green oil	2	A gray substance like albumen	4·3
Bitter extract and sugar	8·25	Starch	59·0
Gum	2·5	Moisture and loss	23·95
Total			100·00"*

"The farina of the oat seems, to the unassisted eye, cottony, or as it were felted, from the presence of an innumerable quantity of hairs with which the seeds are covered. The grains of the fecula have a size of about .00276 by .0018 of an inch. They appear in general yellowish, and strongly shaded. Some of these have the appearance, but not the form, of the fecula of the potato."†

(1523.) "We find no mention made of oats in Scripture," says Phillips, "which expressly states

* Thomson's Organic Chemistry—*Vegetables*. † Raspail's Organic Chemistry.

that Solomon's horses and dromedaries were fed with barley:" but "the use of oats as a provender for horses appears to have been known in Rome as early as the Chistian Era, as we find that that capricious and profligate tyrant Caligula fed *Incitatus*, his favorite horse, with *gilt oats* out of a golden cup." Oats are mixed with barley in the distillation of spirits from raw grain; and "the Muscovites make an ale or drink of oats, which is of so hot a nature, and so strong, that it intoxicates sooner than the richest wine."*†

(1524.) *Rye.*—Botanically, this plant occupies the same place, both in the natural and sexual systems, as the other grains which have been described. It is the *Secale cereale* of the botanists, so called, it is said, *à secando*, from cutting, as opposed to leguminous plants, whose fruits used to be gathered by the hand. A figure of the spike of rye may be seen at *e*, fig. 358. It is a narrow small grain, not unlike shelled oats. There is only one species of this plant, which is said to be a native of Candia, and was known in Egypt 3,300 years ago; but there are several varieties which are raised as food, 4 of which are described by Mr. Lawson‡ and 7 to be seen in the Museum of the Highland and Agricultural Society.‖ The produce of rye may be about 24 bushels per acre, and the weight of the grain is stated at from 52 lbs. to 57 lbs. per bushel; the number of grains in 1 drachm weight being 165.

(1525.) The rye is not much cultivated in this country, particularly in Scotland, where only a patch here and there is to be seen. It is, however, extensively cultivated on the Continent, especially in sandy countries, and indeed forms the principal article of food of the laboring classes. I have been in many parts of Germany where none but rye bread could be purchased. Rye bread is denser than wheaten bread, and darker in color, and, when baked in the sweet state, is rather agreeable to the palate; but when baked sour, in which state it is commonly used in many places, it requires custom to make one become reconciled to its taste. Horses on the Continent get it on a journey in lieu of corn, and seem very fond of it.

(1526.) Einhoff analyzed rye-seeds and meal with great care: 3,840 parts of good rye-seeds were composed of

Husk	930	Pure Meal	2520
Moisture	390		
Total			3840

100 parts of good rye-meal contained

Albumen	3·27	Saccharine matter	3·27
Gluten, not dried	9·48	Husk	6·38
Mucilage	11·09	Loss	5·42
Starch	61·09		
Total			100·00

"But the proportion of these substances must vary extremely according to the soil, the climate and the age of the rye. The gluten of rye differs in several particulars from that of wheat. It is less tenacious and more soluble. When it is allowed to ferment, Einhoff perceived a strong smell of nitric acid, which is peculiar to this species of gluten. The starch of rye bears a striking resemblance to that of wheat. Like this last, it does not form a colorless solution with boiling water, and always precipitates at last, when the solution is left a sufficient time to rest."§

(1527.) The grains of the fecula of rye-meal are peculiarly shaped. "The largest grains of this fecula," says Raspail, "are about .002 of an inch in size; but what distinguishes them from all the other varieties is, that they are flattened, and with sharp edges like disks, and for the most part, marked on one of their sides with a black cross, or three black rays united at the center of the grain."¶ **

(1528.) *Beans.* Beans belong to a very different tribe of plants to those we have been considering. They belong to the natural order of *Leguminosæ*, because they bear their fruit in legumes or pods; and in the Linnæan system they occupy the class and order *Diadelphia decandria*

[* The oat crop of the United States, as set down in the last Census, was 123,071,341 bushels. A close run between New-York, 20,675,847, and Pennsylvania, 20,641,819. The next largest producer was Ohio, 14,393,103, Virginia being the fourth on the list—13,451,062 bushels. Professor JOHNSTON may be here quoted, thus:

SPECIAL MANURE FOR OATS.—To replace 100 pounds of the inorganic matter of the oat, according to the mean composition of its ash, the following mixture is adapted:

Bone-dust	86	132 lbs.
Sulphuric acid	44	
Carbonate of potash, (pearlash)	18	..
Carbonate of soda	10	lbs.
Carbonate of magnesia	14	..
Total	174	lbs.

Five bushels of oats contain 6 pounds of inorganic matter. A crop of 50 bushels, therefore, will carry off 60 pounds, and will require 105 pounds of the above mixture to replace it.

This grain will be farther discussed under the heads—Diseases to which subject—Insects attacking it—Weeds to which it is subject—How to remove them—Cutting, Stooking and Stacking—Average Crop yielded by it, and its Value—Its Straw—Comparative Weight of Straw, Grain and Roots—&c. *Ed. Farm. Lib.*]

[** Rye crop of the United States in 1839, 18,645,567. Here Pennsylvania runs far in the lead, growing 6,613,873, while the next on the list, New-York, gives but 2,979,323. Strange to say, the

¶ Raspail's Organic Chemistry.

Their generic term is *Faba vulgaris*; formerly they were classed among the vetches and called *Vicia Faba*. The common bean is divided into two classes, according to the mode of culture to which they are subjected, that is, the field or the garden. Those cultivated in the field are called *Faba vulgaris arvensis*, or as Loudon calls them, *Faba valgaris equina*, because they are cultivated chiefly for the use of horses, and are usually termed horse-beans. The garden bean we have nothing to do with, though some farmers attempt some of the garden varieties in field culture, but I believe without success. All beans have butterfly or papilionaceous flowers. Mr. Lawson has described 8 varieties of the field bean; and 10 varieties are placed in the Highland and Agricultural Society's Museum.* The variety in common field culture is thus well described by Mr. Lawson. "In length the seed is from ¼ to ⅜ of an inch, by ¼ in breadth, generally slightly or rather irregularly compressed and wrinkled on the sides, and frequently a little hollowed or flattened at the end; of a whitish or light-brown color, occasionally interspersed with darker blotches, particularly toward the extremities; color of the eye black. Straw from 3 to 5 feet in length. There is perhaps," continues Mr. Lawson, "no other grain over the shape and color of which the climate, soil, and culture, exert so much influence as in the bean. Thus, in a dry, warm summer and harvest, the sample is always more plump and white in color than in a wet and cold season; and these more so in a strong, rich soil, than in a light, and more so in a drilled crop than in one sown broadcast."† I omitted to mention in the proper place, under the head of our subject of barn-work, that, as the bean is easily separated from its pod, the fast motion of the threshing-machine should be put on when beans are to be threshed, and in case, even with the fast motion, the straw, being brittle, should be much broken, the best plan to avoid this effect is to feed the sheaves thin *sideways*, instead of lengthways, into the feeding-rollers. The pods being covered with a sort of down, which becomes black on winning the crop, the threshing throws off this down like a thick black, impalpable dust, which entering the mouth and nostrils and blackening the clothes, makes the threshing of beans a disagreeable process; and the noise occasioned by their impinging against the iron lining of the drum-case, is almost deafening, and almost overpowering to human speech.

(1529.) The produce of the bean crop varies from 20 to 40 bushels per imperial acre, much of the prolificacy of the crop depending on the nature of the season. The average weight may be stated at 66 lbs. per bushel. It only requires 5 beans to weigh 1 drachm. I have not cultivated the bean so much as to enable me to ascertain the weight of a good crop of straw or haulm, in comparison with that of the grain, for it is seldom that the same season gives the largest return of both; but I have seen it stated that "it has been known to yield 2 tons per acre."‡ A crop of 50 bushels, at 66 lbs. per bushel, gives 1 ton 3 cwt. 64 lbs. per acre.

(1530.) Beans are administered to the horse either raw, whole, or boiled whole or bruised. They are given to cattle in the state of meal, that is, husk and grain ground overhead, and that not very finely. Beans, however, can be ground into fine flour; and in this state are used to adulterate the flour of wheat. Their presence is easily detected by the peculiar smell arising from the flour when warm water is thrown upon it. Beans are of essential service to support horses that have fatiguing work. "If beans do not afford more nutriment," says Stewart, "weight for weight of oats, they at least produce more lasting vigor. To use a common expression, they *keep the stomach longer*. The horse can travel farther; he is not so soon exhausted. . . . . In the coaching stables, beans are almost indispensable to horses that have to run long stages. They afford a stronger and more permanent stimulus than oats alone, however good. Washy horses, those of slender carcass, cannot perform severe work without a liberal allowance of beans; and old horses need them more than the young. The quantity varies from 3 to 6 lbs. per day; but in some of the coaching stables the horses get more, 1 lb. of oats being deducted for every 1 lb. of beans. Cart-horses are often fed on beans, to the exclusion of all other corn, but they are always given with dry bran, which is necessary to keep the bowels open, and to insure mastication, and for old horses they should be always broken." "There are several varieties of the bean in use as horse-corn; but I do not know that one is better than another. The small, plump bean is preferred to the large, shriveled kind. Whichever be used, the bean should be old, sweet, and sound; not mouldy, nor eaten by insects. New beans are indigestible and flatulent; they produce colic, and founder very readily. They should be at least a year old."‖

(1531.) Einhoff carefully analyzed the small field-bean. "From 3,840 parts of the ripe beans he obtained the following substances:

Volatile matter	600	Albumen	31
Skins	386	Extraction, soluble in alcohol	136
Starchy, fibrous matter	610	Gummy matter	177
Starch	1312	Earthy phosphate	37
Vegeto-animal matter	417	Loss	133
Total	3840		

Vauquelin could detect no sugar in it. He and Correa de Serra found in the *skins* of the beans, *tannin* striking a blue with the persalts of iron, *azimo-vegetable matter* mixed with tannin, insol-

comparatively small State of New-Jersey, with her sandy soil, comes in next, before Virginia, giving 1,665,820 bushels—Virginia, 1,482,799. Kentucky next—1,321,373.

SPECIAL MANURE FOR RYE.—The following mixture is adapted to the composition of the ash of the grain of rye:

Bone-dust	190	286 lbs.
Sulphuric acid	95	
Carbonate of potash, (dry)	32	lbs
Carbonate of soda, (dry)	20	..
Carbonate of magnesia	23	..
Total	359	..

Ed. Farm. Lib.]

* Catalogue of the Museum.
† Lawson's Agriculturist's Manual. ‡ British Husbandry, vol. ii. ‖ Stewart's Stable Economy.

uble in water, but soluble in potash. The *cotyledons* contained a sweet-tasted substance, starch legumen, albumen, an uncombined acid, with carbonate of potash, phosphates of lime, magnesia and iron. The *germen* of the bean contained white tallow, legumen, albumen, phosphate of lime and iron."*

(1532.) The grains of the fecula of the bean "are egg or kidney shaped, often presenting an interior grain, as if inclosed in the principal one. Some of them are found broken down and empty They attain the size of ·002 of an inch."†

(1533.) The ancients entertained some curious notions in regard to the bean. The Egyptian priests held it a crime to look at beans, judging the very sight unclean. But the bean was not everywhere thus contemned, for Columella notices them in his time as food for peasants, and for them only.

"And herbs they mix with beans for vulgar fare."

"The Roman husbandmen had a religious ceremony respecting beans somewhat remarkable: When they sowed corn of any kind, they took care to bring some beans from the field for good luck's sake, superstitiously thinking that by such means their corn would return home again to them. The Romans carried their superstition still farther, for they thought that beans, mixed with goods offered for sale at the ports, would infallibly bring good luck to the seller." They used them, however, more rationally, when beans were employed "in gathering the votes of the people, and for electing the magistrates. A *white* bean signified absolution, and a *black* one condemnation. From this practice, we imagine, was derived the plan of *black-balling* obnoxious persons."‡ It would appear, from what Mr. Dickson states, that the *faba* of the Romans, a name, by the way, said to be derived from *Haba*, a town of Etruria, where the bean was cultivated, is the same as the small bean of our fields.‖§

(1534.) *Peas.*—The pea occupies a similar position in both the natural and artificial systems of botany, as the bean. The plant is cultivated both in the field and in the garden, and in the latter place to great extent and variety. The *natural* distinction betwixt the field and garden pea is found in the flower, the field pea always having a red-colored, and the garden pea almost always a white flower; at least the exceptions to this mark of distinction are few. The botanical name of the pea is *Pisum sativum*, the cultivated pea, and those varieties cultivated in the field are called in addition *arvense*, and those in the garden *hortense*. The name is said to have been given to it by the Greeks, from a town called Pisa, in Elis, in the neighborhood of which this pulse was cultivated to great extent. Mr. Lawson has described 9 varieties of the field pea, and the Highland and Agricultural Society's Museum contains 14 varieties.¶ Of these there are a late and an early variety cultivated, the late kind, called the *common gray field-pea*, or *cold-seed*, is suited for strong land in low situations, and the early, the *partridge*, *gray maple*, or *Marlborough pea*, is suited for light soils and late situations, and it is superseding the old gray Hastings, or *hot-seed* pea. The gray pea is described as having "its pod semi-cylindrical, long, and well-filled, often containing from 6 to 8 peas. The ripened straw indicates 3 varieties—one spotted with a bluish-green ground, one light blue, and one bluish green without spots." The partridge pea has its "pods broad, and occasionally in pairs, containing from 5 to 7 peas, of a medium size, roundish, and yellowish-brown speckled, with light-colored eyes. The ripe straw is thick and soft like, leaves large and broad, and average hight 4 feet."**

(1535.) The produce of the pea crop is either in abundance or a complete failure. In warm weather, with occasional showers, the crop may amount to 46 bushels, and in cold and wet it may not reach 12 bushels the acre. The grain weighs 64 lbs. the bushel, and it gives 13 grains to 1 drachm. In threshing it, the feeding-rollers are put on the fast motion, and the sheaf is allowed to be taken in by them, while the feeder holds on by the sheaf, and pulls it thinner and thinner. Peas are as easily threshed out as beans; but the process does not create such an offensive dust, though the noise attending it is very great. Peas are riddled with the oat-riddle, the refuse generally being small clods of earth and shriveled grains, which are left in the riddle, and given to the pigeons.

(1536.) Chemists have examined the pea. "From ripe peas, by macerating them in water, and employing a mode of analysis similar to that used in ascertaining the constituents of barley, Einhoff obtained the following products; the quantity employed was 3,840 parts:

Volatile matter	540	Albumen	66
Starchy fibrous matter, with the coats of the peas	840	Saccharine matter	81
Starch	1265	Mucilage	249
Animo-vegetable matter	559	Earthy phosphates	11
		Loss	229
Total			3840"

In regard to the substance named *animo-vegetable matter*, "it approaches most nearly to gluten;

[§ The reader may judge of the dependence to be placed on the Census as a presentment of our National Industry and the amount contributed to the public wealth by the cultivators of the soil, by noting the fact that no mention is made in it whatever of beans, peas, feathers, flax-seed, corn-fodder, &c. The corn-fodder, according to the lowest estimate that can be made, may be valued at more than $50,000,000. We have no means of estimating the amount of the bean and pea crop, but looking at the returns for the State of New-York alone, taken in 1845 under the State Law, we find the Beans put down at 162,171 bushels from 16,211 acres, being 10 bushels to the acre. *Ed. Farm. Lib.*]

** Lawson's Agriculturist's Manual.

but as it differs in several particulars from gluten and from all other vegetable constituents, we must consider it as a peculiar principle." "When dried, it assumes a light-brown color, and the semi-transparency of glue, and is easily reduced to powder. Einhoff remarks that he has seen the gluten of wheat assume this appearance. I have observed the same thing," says Dr. Thomson, "twice. In both cases the wheat was very inferior in quality, and had been the growth of a very rainy season."*

(1537.) "The grains of the fecula of the pea are nearly of the same size as those of the bean, and of the form of those of the potato. When fresh they are as strongly shaded at the edges as those of the bulbs of the *Alstræmeria pelegrina*. Their surface is unequal. The largest of them is about ·002 of an inch."†

(1538.) The pea was formerly much cultivated in this country in the field, and even used as food, both in broth and in bread, *peas bannocks* having been a favorite food of the laboring class; but since the extended culture of the potato its general use is greatly diminished. It is now chiefly given to horses, but is also split for domestic purposes, such as making pea-soup—a favorite dish with families in winter. Its flour is used to adulterate that of the wheat, but is easily detected by its peculiar smell, which is given out with hot water. Peas-meal in brose is administered in some cases of dyspepsia. Peas-pudding is eaten as an excellent accompaniment to pickled pork. It used to be customary in the country to burn a sheaf of peas, by which the peas were roasted, and, when mixed with butter and served up while hot at supper, were eaten as a treat under the name of *carolins*. In some towns where ancient customs still linger, roasted peas are sold in winter in the hucksters' stalls. Pigeons are excessively fond of the pea, and I have heard it alleged that they can eat their own weight of them every day. "The ancients gave peas to stallion horses, on account of a particular virtue which they were thought to possess."‡‖

(1539.) These are the *constituents* in 100 lbs. of the *ashes* of the different sorts of grain we have been treating of. Instead of giving the constituents of each separately, I have collected them together, in order to show their comparative proportions:

Constituents.	Wheat.	Barley.	Oats.	Rye.	Beans.	Peas.
	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.
Potash	19	12	6	51	19½	32¾
Soda	20½	12	5		38½	30
Lime	8	4½	3	10¾	7¾	2½
Magnesia	8	8	2½	4½	7½	5½
Alumina	2	1	0½	2½	1½	0½
Oxide of iron		a trace.	1½	4		0½
Oxide of manganese				3½		
Silica	34	50	76½	15¾	6	16½
Sulphuric acid	4	2½	1½	2½	4½	2½
Phosphoric acid	3½	9	3	4½	13¾	7¾
Chlorine	1	1	0½	1	1¾	1½
Total	100	100	100	100	100	100

On comparing the numbers in these columns we may observe how much more potash peas contain compared to beans; now beans contain double the quantity of soda to that of potash; how there is as much magnesia as lime in the bean; how large a quantity of the oxides of iron and manganese are found in rye compared to all the rest of the grains; how large a proportion of silica the oat contains in comparison of the rest of the grains; and how large a proportion of phosphoric acid the bean contains to other grains. The following statement exhibits the *weight of ashes* left by 100 lbs. of the sorts of grain spoken of above, according to the analysis of Sprengel:

The grain of wheat leaves			1·18 lbs. per cent. of ash.		
..	barley	..	2·35	..	..
..	..	..	dried at 212 °	2·52	..	..	..
..	oats	..	2·58	..	..	..
..	beans	..	2·14	..	..	..
..	peas	..	2·46§	..	..	..

(1540.) *Straw.*—As the straw of the various kinds of grain which I have just treated of, possess different properties, and as they are *best* applied to different purposes, a few remarks on their peculiarities may be useful.

(1541.) *Wheat-straw.*—Wheat-straw is generally long. I have seen it upward of 6 feet in length in the Carse of Gowrie, and it has always strength, whatever may be its length. Of the two sorts of wheat, white and red, the straw of white wheat is softer, more easily broken by the threshing-mill, and more easily decomposed in the dunghill. Red wheat-straw is tough. The straw of some sorts of wheat of both kinds possess their respective properties in a greater and less degree than others. The strength and length of wheat-straw render it useful in thatching, whether houses or stacks. It is yet much employed in England for thatching houses, and perhaps the most beautiful thatchers are to be found in the County of Devon. Since the general use of slates in Scotland, the thatching of houses with straw has almost fallen into desuetude in that country.

[‖ This crop, as already stated, is not noticed in the Census. The crop in New-York in 1845 was 1,761,487 bushels, gathered from 113,020 acres, or 15 bushels to the acre. Both this and the bean will be yet much more fully treated hereafter, in other points of view not necessary to particularize. *Ed. Farm. Lib.*]

* Thomson's Organic Chemistry, *Vegetables*. † Raspail's Organic Chemistry.
‡ Phillips's History of Cultivated Vegetables, vol. ii.
§ Compiled from Johnston's Elements of Agricultural Chemistry, and Lectures on Ag. Chem.

An existing thatch-roof may yet be repaired in preference to the adoption of a slated one, but no new roof is thatched with straw. Wheat-straw makes the best thatching for corn-stacks, its length and straightness insuring safety, neatness, and dispatch in the process, in the busy period of securing the fruits of the earth. It forms an admirable bottoming to the bedding in every court and hammel of the steading. As littering straw, wheat-straw possesses superior qualities. It is not so suited for fodder to stock, its hardness and length being unfavorable to mastication; yet I have seen farm-horses very fond of it. Horses in general are fond of a hard bite, and were wheat-straw cut for them by the chaff-cutter of a proper length, I have no doubt they would prefer it to every other kind of straw as fodder. The *chaff* of wheat does not seem to be relished by any stock; and is therefore strewn on the dunghill, or upon the lairs of the cattle within the sheds. When it ferments, it causes a great heat, and on this account I have supposed that it would be a valuable ingredient in assisting to maintain a heat around the frames of forcing-pits. The odor arising from wheat-straw and chaff fresh threshed is glutinous.

(1542.) *Barley-straw* is always soft, and has a somewhat clammy feel, and its odor, with its chaff, when new threshed, is heavy and malt-like. It is relished by no sort of stock as fodder; on the contrary, it is said to be deleterious to horses, on whom its use is alleged to engender grease in the heels. Barley-chaff, however, is much relished by cattle of all ages, and rough as the awns are, they never injure their mouths in mastication. Barley-straw is thus only used as liter, and in this respect it is much inferior to wheat straw either for cleanliness, durability, or comfort. It does not make a good thatch for stacks, being too soft and difficult to assort in lengths, apt to let through the rain, and rot. Barley-chaff soon heats in the chaff-house, and if not removed in the course of two or three days, dependent on the state of the air, decomposition will rapidly ensue. Barley-straw and chaff seem to contain some active principle of fermentation.

(1543.) *Oat-straw*.—This straw is most commonly used as fodder, being considered too valuable to be administered in litter. It makes a sweet, soft fodder, and, when new threshed, its odor is always refreshing. Its chaff is not much relished by cattle. Oat-straw is very clean, raising little or no dust, and so is its chaff; and on this account, as well as its elasticity, the latter is very commonly used in the country to make beds with tickings, for which purpose the chaff is riddled through an oat-riddle, and the larger refuse left in the riddle thrown aside. Sheep are very fond of oat-straw, and will prefer it to bad hay: and even on the threatening of a coming storm, when on turnips, I have seen them prefer it to good hay. Of the different sorts of oat-straw, that of the common oats is preferred, being softer, sweeter, and more like hay than that of the potato-oat. When oats are cut a little green, the straw is much improved as fodder.

(1544.) *Rye-straw*.—This kind of straw is small, hard, and wiry, quite unfit for fodder, and perhaps would make but uncomfortable litter in a stable, though it would, no doubt, be useful in a court for laying a durable bottoming for the dunghill; but it forms most beautiful thatch for houses, and would, of course, do for stacks, if it were not to expensive an article for the purpose. It is much sought for by saddlers for stuffing collars of posting and coach-horses, and in default of this wheat-straw is substituted. It is also in great request by brick-makers, who, as stated by a writer, gave as much as £5 per load for it in the neighborhood of London in the winter of 1834-5, but from what particular reason is not mentioned.* Its ordinary price is £2 per load. The plaiting of rye straw for hats was practiced so long ago as by even the ancient Britons, and was certainly not out of use in Shakspeare's days, who thus notices the custom of wearing this elegant head-gear on holidays:

> "You sun-burned sicklemen, of August weary,
> Come hither from the furrow, and be merry:
> Make holy-day; your rye-straw hats put on,
> And then fresh nymphs encounter every one,
> In country footing."
>
> THE TEMPEST.

I have seen very useful hats and bonnets for field-work made by laborers and field-workers from the upper joint of wheat-straw. Bee-hives and *rutkies*—that is, baskets for supplying the sowers with seed—are beautifully and lightly made of rye-straw; but where that commodity is scarce, which it usually is in Scotland, wheat-straw is substituted.

(1545.) *Peas and Bean-straw, or haulm*.—It is difficult in some seasons to preserve the straw of the pulse crops, but, when properly preserved, there is no kind of straw so great a favorite as fodder with every kind of stock. An ox will eat peas-straw as greedily as he will hay; and a horse will chump bean-straw with more gusto than ill-made rye-grass hay. Young cattle are exceedingly fond of bean and peas chaff; and sheep enjoy peas-straw as much. These products of the pulse crops are considered much too valuable to be given as litter. Since bean-chaff is so much relished by cattle, there is little doubt that bean and pea haulm, cut into chaff, would not only be relished, but be economically administered; and were this practice attended to in spring, the hay usually given to horses at that season might be dispensed with on farms which grow beans and peas. It is said that when work-horses are long kept on bean-straw their wind becomes affected.

(1546.) Of all the different sorts of straw, it appears that wheat, oats, peas, and bean-straw are used for fodder, and that barley-straw is fit only for litter; and that where there is a sufficiency of oat and bean-straw, wheat-straw might also be dispensed with as fodder. This being the relative positions of the different kinds of straw, their supply should be so arranged as to prevent the waste of fodder-straw in litter, and this may be easily accomplished by having oat-straw in the straw-barn with barley or wheat-straw. The procedure should be in this wise: In the early part of the winter, the grain chiefly in demand is barley. Barley-straw should therefore be supplied, stack after stack, until all the stock, with the exception of the seed-corn, is disposed of. During winter, the corn for the horses should be threshed, and laid up in granary, and, as common oats are usually given to horses, the best sort of fodder could thus be supplied simultaneously with the litter.

* British Husbandry, vol. ii.

straw of barley. After the barley is disposed of, toward spring, the demand for wheat commences, and then the wheat-straw should come in lieu of that of the barley for litter. Farther on in spring, the bean-straw comes in lieu of oat straw for fodder. In this way the time may pass on until grass is ready for stock. See (13).

(1547.) The color of the fodder-straw affects the color of the dung of the various animals; thus, peas and bean-straw and chaff make the dung quite black, wheat-straw gives a bleached appearance to the dung of horses, and oat-straw gives it a yellow hue.

(1548.) I do not know that the specific gravity of straw has ever been ascertained by experiment; but I should say, judging only by surmise, that oat-straw is the lightest, and wheat-straw heaviest.

(1549.) It may be interesting to you to give the constituents of the different sorts of straw spoken of. These consist of organic and inorganic substances. The organic substances resolve themselves ultimately into the four elements of oxygen, hydrogen, carbon, and nitrogen. The inorganic consist of a considerable number, a tabular view of which is here given under each sort of straw, for the purpose of comparison. According to the analysis of Sprengel,

1000 lbs. of wheat straw leave			35·18 lbs. of ash.		1000 lbs. of rye-straw leave			27·93 lbs. of ash.	
..	barley	..	52·42	..	..	bean	..	31·21	..
..	oat	..	57·40	..	..	pea	..	49·71	..

And 100 lbs. of the *ash* of each of these sorts of straw gave the following constituents:

Constituents.	Wheat Straw.	Barley Straw.	Oat Straw.	Rye Straw.	Bean Straw.	Peas Straw.
	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.
Potash	0¼	3¼	15	1	53½	4¾
Soda	0¾	1	a trace.	0½	1½	—
Lime	7	10½	2¾	6	20	54¾
Mrgnesia	1	1½	0½	0½	6½	6¾
Alumina	2¾	3	a trace.	1	0¼	1¼
Oxide of iron	..	0½	a trace.	..	0¼	0½
Oxide of manganese						0¼
Silica	81	73½	80	82½	7	30
Sulphuric acid	1	2	1½	6	1	6¾
Phosphoric acid	5	3	0¾	2	7½	4¾
Chlorine	1	1½	a trace.	0¾	2¾	0¼
Total	100	100	100	100	100	100

On comparing the numbers in these columns, we cannot fail to remark how much potash there is in the straw of the bean; how small a trace of soda there is in all the straws; how large a proportion of lime there is in the straw of the pea, compared to that of the bean; how large it is compared to that in the grain of the pea itself; how much more silica in the straw of the pea than in that of the bean; but how much more phosphoric acid in bean-straw than in that of the pea.

(1550.) "The inorganic matter contained in different vegetable productions varies from 1 to 12 per cent. of their whole weight. The following Table exhibits the weight of ash left by 100 lbs. of the dry straw of the more commonly cultivated plants, according to the analysis of Sprengel:

Dry straw of wheat	3·51 lbs. per cent.			Dry straw of rye	2.79 lbs. per cent.			
..	barley	5·24	..	..	beans	3·12	..	
..	oats	5·74	..	..	peas	4·97 "*	..	

(1551.) Such are the kinds, uses, and constitution of the straw usually found on farms; and the proper management of them, so as to confer the greatest comfort to stock, and procure the largest amount of manure to the farm, is a matter deserving much consideration. I fear there is too much truth in the observation of Sir John Sinclair, when he says on this subject, that "the subject of straw is of greater importance than is commonly imagined; and the nature of that article, taken in the aggregate, entitles it to more attention than has hitherto been bestowed upon it. Farmers are apt to consider it as of little or no worth, because it is not usually salable, and is rarely estimated separately from the yearly produce of the soil. But though seldom salable, except in the vicinity of towns, it has an intrinsic value as a fund for manure, and a means of feeding stock."†

(1552.) The proper management of straw which I allude to, is that the respective kinds shall always be appropriated to their best uses—that is, the straw best adapted for litter shall not be administered as fodder, for if it be, the animals will thereby be rendered discontented; if barley-straw, for instance, is put before cattle that have been, or should have been, accustomed to oat-straw, they will not only not eat the usual quantity of fodder, but eat that which they are obliged to eat with disrelish. On the other hand, if fodder-straw is strown abroad for litter, it is not used to the best advantage, being partly wasted. Again, if more straw is threshed at a time than can be consumed in a few days in fodder, what of it remains to the last becomes dry and brittle, and unfit for the use of stock; and even litter straw, if kept for a long time before it is used, becomes much lighter, and, of course, loses a portion of its value. So far, therefore, as the straw is concerned, it is bad practice to stack up threshed straw for a long time, as some farmers seem fond

* Compiled from Johnston's Lectures on Agricultural Chemistry. † Sinclair's Code of Agriculture.

of doing, for it then certainly wastes some of its properties as fodder or litter. The plan is, to thresh the straw when and as often as it is required, both for fodder and litter, and it will be always in the freshest state for use in both ways. But to follow out this plan successfully requires the previous consideration whether there is a sufficient number of stacks in the stack-yard, for the purposes of fodder and litter throughout the season, and if there is, then those should be selected which are best suited, of the respective kinds, for those purposes, during the winter, when the utility of good straw is most appreciated. The remainder can be used for the inferior purposes of bottoming the courts and stacks of the ensuing crop and season. Should the whole quantity of straw, however, seem inadequate to the demands upon it, then it should be threshed only as required, and dealt out with an economical and judicious hand, so that no part of the season should be worse or better supplied than the rest. Do these considerations usually engage the attention of farmers? I fear not, but certainly not so much as they deserve. I am aware that it may here be observed, that it is of much greater import for the interest of the farmer to study the state of the market for grain, than to lose that advantage by not threshing out the straw. This is feasible, but, at the same time, is the farmer aware how much injury he may receive by loss of condition in stock, and deterioration in dung, by being inattentive to the state of his straw? I suspect the subject has received but little of his consideration.

(1553.) It was at one time a prevalent notion that straw could not be converted into good manure, unless it were consumed by cattle and horses; and the celebrated Bakewell carried this idea to such a hight that if he had not stock sufficient of his own to consume his straw, he took in those of others for the purpose. But he lived to see his error. Opinion changed to the opposite extreme, so that many farmers persuaded themselves into the belief that straw *consumed* by stock was wasted, and that it should only be used as litter. This latter opinion is nearer the truth than the former, but goes beyond the truth; for although it is quite correct to say that stock ought to *depend* on green crops for food to fatten them, yet it is also true that that food is much assisted in its assimilation into the animal system by a participation of fodder. It is not merely that the stomach requires to be distended by food, but sweet, dry fodder is an agreeable change to the ox after a hearty meal of turnips. Feeding stock really consume very little fodder; and when it is placed before them at pleasure, they may either partake of it, or pick out a few choice straws, or let it alone altogether; thus affording creatures as much liberty of choice in their food as their confined situation will admit.

(1554.) The *value* of straw may be estimated from the quantity usually yielded by the acre, and the price which it usually realizes. Arthur Young estimated the straw yielded by the different crops—but rejecting the weaker soils—at 1 ton 7 cwts. per English acre. Mr. Middleton estimated the different crops in these proportions:

	Cwts.	Lbs.			Cwts.	Lbs.	
Wheat straw	31	or 3,472	per acre.	Beans	25	or 2,800	per acre.
Barley	20	2,440	..	Pease	25	2,800	..
Oats	25	2,800	..				
Average rather more than	25				25	2,862	per acre.

or 1 ton 5 cwts. per English acre. Mr. Brown, Markle, East-Lothian, computed the produce of straw as follows, in stones of 22 lbs. per Scotch acre, which I have contrasted with the imperial:

	Stones.	Lbs.	Cwts.	Lbs.	
Wheat-straw	160	or 3,520	or 31	48	per Scotch acre.
Barley-straw	100	2,200	19	72	..
Oat-straw	130	2,860	25	60	..
Beans and Peas	130	2,860	25	60	..
Average	130	or 2,860	or 25	60	per acre.

or 1 ton 5 cwts. 60 lbs. per Scotch acre, or 1 ton 0 cwt. 76 lbs. per imperial acre.* In the immediate vicinity of Edinburgh, the produce, both in Scotch and imperial measures, per acre, is this:

				Stones.	Lbs.	Cwts.	Qrs.	Lbs.
Wheat-straw....9	kemples of 16 sts.	of 22 lbs.		= 144	or 3,168	or 28	1	4
Barley-straw....7	..	..	..	= 112	2,464	22	0	0
Oat-straw.....8	..	..	..	= 128	2,816	25	0	16
Average.....8	..	..	..	= 128	or 2,816	or 25	0	16

or 1 ton 5 cwts. 16 lbs. per Scotch, or 1 ton 0 cwt. 13 lbs. per imperial acre. On comparing this result—from the vicinity of a large town where a large supply of manure can always be obtained—with Mr. Brown's general estimate for the whole country, and finding the quantity less, we must conclude that Mr. Brown's estimate is above the mark as an average one for the country; and unless the production of straw be very much greater in England than in Scotland, we must also conclude that the estimates of both Arthur Young and Mr. Middleton are above the general average; 1 ton the imperial acre of weight for straw is too high an average for Scotland.

(1554.) In regard to the market value of straw, it being usually prohibited to be sold except in the vicinity of towns where manure can be received in return, it is only from the value received for it in towns that we can form an estimate of its value. In Edinburgh, the usual price for wheat-straw is 12s. per kemple of 16 stones of 22 lbs., or 9d. per stone; and for oat-straw 10s. the kemple, or 7½d. per stone. This statement brings out and contrasts the values in Scotch and imperial measures:

* Sinclair's Code of Agriculture.

Wheat-straw, 144 sts. of 22 lbs. at 9d. per st. = £5 6s. 4d. per Scotch acre of 10 bolls of 4 bushels, = 10s. 7d. per boll.
Oat-straw, 128 sts. of 22 lbs. at 7¼d, per st. = £4 per Scotch acre of 10 bolls of 6 bus. = 8s. pr boll.

Equivalent to

Wheat-straw, 181 sts. of 14 lbs. at 5¾d. per st. = £4 6s. 9d. per imperial acre of 8 bolls of 4 bushels, = 10s. 9d. per boll.
Oat-straw, 161 sts. of 14 lbs. at 4¾d. per st. = £3 4s. per imp. acre of 8 bolls of 6 bushels = 8s. per boll.

In those parts of the country where straw, with its corn, is allowed to be sold on foot—that is, as it grows in the field—but prohibited from being sold by itself, the price for wheat-straw is 6s. per boll of 4 bushels, and 5s. per boll of oat-straw of 6 bushels. The quantity of straw per boll and per bushel will stand thus:

Wheat-straw,	14 sts.	8 lbs.	of 22 lbs.	per boll of	4 bushels	=	3 sts.	11 lbs.	per bushel.
Oat-straw,	12 ..	17	.. ..	..	6 ..	=	2 sts.	3	.. ..
Or Wheat-straw,	18 ..	1	.. 14	..	4 ..	=	4 sts.	7	.. ..
Oat-straw,	16 ..	1	.. ..	..	6 ..	=	2 sts.	9	.. ..

(1556.) The Romans used straw as litter, as well as fodder, for cattle and sheep. They considered millet-straw as the best for cattle, then barley-straw, then wheat-straw. This arrangement is rather against our ideas of the qualities of barley and wheat-straw; but very probably the hot climate of Italy may improve the quality of the barley-straw by making it drier and more crisp, and render that of the wheat too hard and dry. The haulm of pulse was considered best for sheep. They sometimes bruised straw on stones before using it as litter, which is analogous to having it cut with the chaff-cutter, as has been recommended.

(1557.) Where straw is scarce, they recommend the gathering of fern, leaves, &c., which is a practice that may be beneficially followed in this country, where opportunity occurs. Varro says: "It is the opinion of some that straw is called *stramentum* because it is strewed before the cattle."*

4. THE WAGES OF FARM-SERVANTS.†

"The husbandman that laboreth must be first partaker of the fruits."
ST. PAUL.

(1558.) Winter is the time in which *wages in kind* are paid to farm-servants; and the part of that season chosen for the purpose is about the end of the year. It is requisite that harvest shall be completely over in the latest season, and every preparatory operation connected with the accommodation of stock, either on turnips or in the steading, be gone through, before the business of threshing the crop in a regular order be commenced. In connection with threshing the crop, a plan should be adopted for supplying straw for fodder and litter, as recommended in (1457), as well as for placing a quantity of new oats in the granary, to be drying and to be ready for use by the time the perhaps small stock of old corn shall be consumed. After all these preparatory operations incidental to winter have been accomplished, and before much of the new crop has been disposed of at market, farther than to ascertain its general quality

[† We need not say that in copying this chapter, we suppose that there is much, if any of it, susceptible of adaptation to our country—still, the system of farm wages is one so obviously and intimately interwoven with the agricultural economy of every country that every gentleman may be presumed to be curious to know how these systems differ in different parts of the world. The high price of wages in this country, and the scarcity of that and capital in their proportions to the price of land, not only prevent the restoration of exhausted lands in the old Atlantic States, but are fruitful sources of exhaustion and abandonment of States comparatively new—as Western New-York for example.

What constitutes of itself a great advantage in favor of laboring people in the United States is, that they are almost invariably "found," or boarded by their employers, and in the Free States in most cases eat at the same table, three times a day, with the farmer and his family. For a head man on a farm, $12 may be put down as the usual wages, and for hands or "helps" by the month from $8 to $10. *Ed. Farm. Lib.*]

* Dickson's Husbandry of the Ancients, vol. ii.

and price, the first leisure afforded by them is taken for paying the farm-servants their yearly wages of corn; and as the quantity distributed is considerable on a large farm, and as all the servants should receive their wages at the same time, to avoid jealousy, there will be a considerable quantity of threshed grain in the barn before the distribution takes place. The servants receiving a variety of corn, that kind should be first distributed which is found most convenient for the farmer to thresh; and each kind should be delivered, and the barn cleaned out, before another is interfered with.

(1559.) I have already enumerated the different classes of laborers employed on a farm from (241) to (252); and I may here mention generally, that the wages of all may be classed under three heads: 1st, Those consisting chiefly of *kind*, that is, of the produce of the farm, and but a *small* sum in *cash;* 2d, Those consisting of a *large* proportion of *cash* and *small* amount of *kind;* and, 3d, Those which consist *entirely* of *cash*. The recipients of the first and third classes may be engaged on the same farm, and the third class may be found exclusively on a farm, but the first and second classes are never found together; and as all three modes of paying wages coëxist in this kingdom, though in different parts of it, they afford a criterion for judging which is the best mode for all parties, for master and servant; which the most convenient for the master, which the most conducive to the servants' comfort and moral habits. *Plowmen* or *hinds* constituting the principal or staple class of laborers on a farm, like the battalion-men in a regiment, the terms of their wages are taken as a standard of comparison for those of the rest.

(1560.) *Plowmen's wages.*—These are paid in all the three modes enumerated above (1559), the first mode being in general adoption in the border counties of England and Scotland; the second mode being practiced in the midland and northern counties of Scotland; and the third having long been adopted in the southern counties of England.

(1561.) Wages in *kind and money* differ, in their constituent items, in different counties, but only in a slight degree; the aggregate items affording sufficiency of food to support a plowman and his family. I shall enumerate the particulars received by the plowmen of Berwickshire and Northumberland:

In Berwickshire.

		£	s.	d.
10 bolls = 60 bushels	oats, at 12s. 10½d. per boll	6	8	9
3 .. = 18 ..	barley, at 19s. 10½d. ..	2	19	7½
1 .. = 6 ..	peas at 23s. 3d. ..	1	3	3
12 .. = 1200 yards	potatoes at 4s.	2	8	0
A cow's keep for the year		8	0	0
Cottage and garden		1	10	0
Carriage of coals		2	0	0
Cash		4	0	0
Equal to 10s. 11¼d. per week		£28	9	7½

In Northumberland.

		£	s.	d.
6 bolls = 36 bushels	oats, at 12s. 10½d. per boll	3	17	3
4 .. = 24 ..	barley, at 19s. 10½d.	3	19	6
2 .. = 12 ..	peas, at 23s. 3d	2	6	6
3 ..	wheat, at 47s. 2d. per quarter	0	17	8½
3 ..	rye, at 29s. 4d.	0	11	0
40 ..	potatoes, at 1s	2	0	0
24 lbs. of wool, at 1s		1	4	0
A cow's keep for the year		9	0	0
Carriage of coals		2	0	0
Cash		4	0	0
Equal to 11s. 5d. per week		£29	15	11½

To the money value of both particulars I attach no importance, farther than giving to them a tangible form; for the *prices* of agricultural pro-

duce affect neither master nor servant in their relation to one another, the point simply being, that the master supports the servant in an adequate manner. Any difference, therefore, shown in the weekly wages between 10s. 11¼d. and 11s. 5d. as brought out in estimating the money value of the particulars does not in fact exist, because the plowmen of both counties live equally well. Instead of taking an imaginary rate of prices, I have selected the aggregate average, as given in the Universal Corn Reporter of 20th January, 1843. Besides working a pair of horses, the plowman is bound to supply a field-worker, whether a woman or a boy, usually the former, whenever the farmer requires her services, and who receives for her work 10d. a day, and in harvest 2s. 6d. a day, besides victuals. In harvest-wages there is a difference between the two counties, and it is explained in this way. In Northumberland, it will be observed that the rent of the house and garden is set down at £3 a year, while the plowman receives 2s. 6d. a day, and victuals, for the field-worker in harvest; whereas, in Berwickshire, the plowman is bound to work the harvest as rent for his house and garden, receiving only victuals, which I have estimated at that season at 1s. a day for 30 days, which is as long a period as harvest may be expected to last, and which should be deducted from £3 of rent. There is also a difference in the cow's keep. In Berwickshire, the allowance is 60 stones of 22 lbs. of hay in winter in lieu of turnips; but turnips are always preferred, and these are given to the amount of 6 double horse-loads, 3 of white and 3 of Swedes. In Northumberland, 10 cart-loads of white turnips are given, or 5 of white and 3 of Swedes; or, in lieu, 1 ton of hay, or 100 stones of 22 lbs.; so that the Northumberland cow is better off by £1 in winter than the Berwickshire, and the difference is certainly so far an improvement on the condition of the English kind. Both cows have as much straw as they can use. The grain which the plowman can claim is next in quality to the seed-corn; and in Berwickshire he receives it in advance at the end of the year, which is in the middle of the year's engagement from Whitsunday (May) to Whitsunday. In Northumberland, the corn is paid in advance once a quarter. The corn is ground in any way the plowman pleases, at one of the small mills of the country, for the mere miller's multure; so he saves the profits of the retail dealer. If he cannot consume all his corn, the farmer willingly takes what he has to spare at the current market price. The produce of the cow, over and above what is required to serve the plowman and his family, may be disposed of; and if the cow is a good one, and the season favorable, and the wife a good dairymaid, a considerable sum may be realized from the cow during the year. Her calf, if early and gotten by a well-bred bull, will fetch £2, and perhaps more; if late, it may still be worth 20s. The refuse of the dairy, of the garden, and the house, enables the plowman to fatten two pigs every year; one for his own use, and the other to dispose of. The cow is the plowman's own property; and to lose her by death is a serious affliction upon him. I have seen men with families much injured by such a loss, and could never refrain from rendering the poor fellows some assistance. To avert so serious a calamity to a poor man, *cow-clubs* have been established, to purchase cows for the members who may have the misfortune to lose them. Farmers subscribe according to their number of plowmen, and each plowman who wishes to enjoy the benefit subscribes 1s. a quarter to the funds of the club.

(1562.) Wages, *more in cash than in kind,* are more extensively given in Scotland than the plan which I have just described. Those who receive this species of wages are chiefly single men, living either in the farmer's house, or in a house by themselves called a *bothy.* The practice of

allowing farm-servants to take their meals in the farmer's house is falling fast into desuetude, and its abandonment is much to be regretted, for it is a far better plan for the comfort of the men themselves than the bothy system. But married men are also supported in this form of wages, though their condition is not so good as that of the plowmen on the preceding plan, but it is certainly preferable to the bothy system.

(1563.) The portion of wages received in *kind* consists of oatmeal and milk. The meal amounts to 2 pecks per week for each man, that is, 1 stone of 17½ lbs., which makes 6½ bolls per annum, or 65½ stones of 14 lbs.; and this at 1s. per peck gives a money value of £5 4s. a year. The milk is supplied either fresh from the cow or after the cream has been skimmed off, according to agreement. In the former state it is given to the amount of 1 Scotch pint or 2 quarts a day; and in the latter state, 3 quarts are given in summer, and 2 in winter. The value of the milk is usually estimated at £4 a year. In some cases a cow or cows are supplied to the men, who milk them, and are exchanged for others when they go dry; but supplying milk is the least troublesome plan for the master. These items of *kind*, with from £10 to £14 a year of cash, varying with the rate of wages in the country, or according to the skill of the plowman, constitute the earnings of a plowman on this system. It is only in the amount of cash that these wages vary at any time, for what is given in kind is considered invariable, being no more food than a stout man can consume; but some cannot consume it all, and save a part of the meal, which they either dispose of to the farmer or to dealers. In strict fairness, the meal should be given to the men every week, but to save trouble, it is dealt out once a month or once a fortnight. The milk, of course, is supplied every day.

(1564.) Besides these principal ingredients, the married men get a house and garden rent free, and coals are driven free to their house. The single men are provided with a room containing a number of beds, which are occupied each by two men; and the bed-clothes, consisting of a chaff ticking and bolster, blankets, sheets and coverlid, are provided by the master, and replaced clean every month. This room is called the *bothy*, and it usually forms both the sleeping-chamber and cooking-apartment of all its inmates, which may amount to as many men as there are plowmen employed on the farm. The men are supplied with fuel all the year round, with which to cook their victuals, and which they do for themselves. The fuel consists of wood, brushwood, or coal, according to the supplies of the locality; but in winter, coal is always laid in to the extent of 1 ton each man. Salt is also provided by the master; and he also furnishes a pot for cooking in, a dish for holding milk, and some forms and perhaps a table; but this last article of furniture is often dismissed from the bothy with little ceremony, a form, or the lap, making a much more desirable dinner-board. A few potatoes are generally given in winter.

(1565.) The oatmeal is usually cooked in one way, as *brose*, as it is called, which is a different sort of pottage to porridge. A pot of water is put on the fire to boil, a task which the men take in turns; a handfull or two of oatmeal is taken out of the small chest with which each man provides himself, and put into a wooden bowl, which also is the plowman's property; and on a hollow being made in the meal, and sprinkled with salt, the boiling water is poured over the meal, and the mixture receiving a little stirring with a horn spoon, and the allowance of milk poured over it, the brose is ready to be eaten; and as every man makes his own brose, and knows his own appetite, he makes just as much brose as he can consume. The bowl is scraped clean with the spoon, and the spoon licked

clean with the tongue, and the dish is then placed in the meal-chest for a similar purpose on the succeeding occasion. The fare is simple, and is as simply made; but it must be wholesome, and capable of supplying the loss of substance occasioned by hard labor; for I believe that no class of men can endure more bodily fatigue, for ten hours every day, than those plowmen of Scotland who subsist on this brose thrice a day.

(1566.) The plowmen who receive *cash for wages*, are in the same condition as day laborers, who receive their earnings once a week and purchase their subsistence at retail dealers' in country towns and villages. This, I believe, is the condition of most of the plowmen in the southern counties of England. There is one obvious remark, occasioned by this statement, which cannot fail to be considered by every farmer, which is, that unless money wages adapt themselves to the fluctuating prices of the commodities upon which farm-servants subsist, servants so paid must suffer much privation on a rise in the price of provisions; and on the other hand, when prices again fall, they receive higher wages than they are entitled to. They are thus subjected to vicissitudes in their condition, from which the former two classes of plowmen are exempt.

(1567.) The *wages of stewards* are in all respects similar to those of the plowmen of whom they have the charge, the only difference being in the amount of cash received, which is always greater than that given to the plowmen. Instead of £4, given to the former class of plowmen, they may receive £12 or £15, and instead of £12 or £14 given in cash to the latter class, they may receive from £20 to £25; and if there is any difference in the size or situation of the servants' houses, the best is appropriated to them. In most cases the steward is exempt from attendance on the farm on Sundays, while in others he takes his turn along with the other men, which latter is the better plan for the master, as the steward can then have much better opportunity of observing whether the men fulfill their duties properly.

(1568.) The *shepherd* receives the same amount of kind and money as the plowman; but as he is accounted a skillful servant, and his hours of attendance extend every day from sunrise to sunset, he has leave to keep a small flock of sheep of his own, which is maintained by his master, and the produce of which he is entitled to dispose of every year. His flock consists of breeding-ewes, which vary in number from half a score, such as of Leicester ewes in the low country, to perhaps twoscore of Black-faced ewes in the highest districts. About $\frac{1}{5}$ of the number of the ewes being disposed of every year, he is entitled to retain as many ewe-lambs of his flock as will maintain the full number of his breeding-ewes. The shepherd's dog is his own property, often purchased at a high rate, and trained with much trouble and solicitude.

(1569.) The *hedger*, being considered a day laborer or spadesman, gets a smaller proportion of kind than the first class of plowmen, and more money, and generally no cow's-keep; and where the second class of plowmen exist, no hedger is kept as a hired servant, but is viewed in the light of a day-laborer, and is paid money-wages accordingly. Being a skillful man, the hedger never receives less than £40 a year in value, and more frequently £1 a week. He can sow corn, build stacks, and do anything that the steward can, and sometimes all that the shepherd can besides.

(1570.) The *cattle-man*, being viewed as a laborer, receives some of his wages in kind and the rest in cash, and is seldom indulged with a cow. Being generally a person somewhat advanced in life, the rate of his wages is not high—perhaps 9s. a week; and it is well when such a post as this

can be given on a farm to an old and faithful plowman or shepherd, whose growing infirmities disable him from undertaking his former active duties.

(1571.) The *field-worker* is simply a day-laborer, and receives 10d. a day, without any wages in kind, from the farmer. This person is usually a woman. The first class of plowmen are each bound to supply a field-worker for the farm during the year, they receiving the wages earned by the workers in that time. They hire the women in the public markets and support them in their houses with bed and board and wages. Should the field-worker obtain constant employment on the farm, the plowman may profit by the arrangement. On large farms field-workers are almost constantly employed. The practice had, no doubt, arisen at a time when few women could be persuaded to work in the fields; and the circumstance of plowmen being bound by agreement to supply such laborers, these latter have long been designated by the odious name of *bondagers*, an epithet no doubt left us in legacy by our feudal forefathers. The practice has been found fault with, and even represented as a species of slavery, probably because of the odious designation given to the condition of the women; but the truth is, there is no more binding or slavery about the matter than in the case of the plowmen themselves, and even less, for they are bound by agreement to work for a year, whereas the *bondager's* term is only for six months. The epithet is a nick-name, and should be relinquished for the proper name of field-worker; but the practice is good, because it enables the farmer to command a certain number of hands at all times, and also to accomplish his ends by his own resources, independent of extraneous aid. It is no answer to say that women may be hired out of villages when their services are required, because many large farms are situate far from any village; and even the vicinity of a village will not secure a supply of field-workers, as I have myself experienced to my vexation; for whenever trade is brisk, manufacturers not only pick up all the hands they can procure, but the work which they supply being done by the piece, at which greater wages than at field-work can be earned in long hours of labor, a temptation is presented to women laborers to desert the fields; and to such a degree of stringency is this monopoly of labor carried by manufacturers that they will not allow their people to go and assist at harvest. A resource of labor like the Border system should, therefore, not be yielded by the farmer, until a better, or one as efficient, can be substituted. Its hardship, however, is not imputed to the workers themselves but to the plowmen who must hire them; but if there is any hardship in it to the plowmen, they nevertheless engage in it voluntarily with all its inconveniences, rather than abandon their profession; though, no doubt, if a man have no family, and the work is but limited, the support of a field-worker may press hard upon his gains, but there is this alleviating circumstance, even in such a case, that the burden is imposed upon a man who has no family to support; whereas, a family of daughters is a great source of income to a plowman, one doing the bondage work, others being paid for their labor, and all contributing to the support of a common fund. The system has no bad effect on the bondagers themselves; for they are cheerful and happy at work, and are well clad on Sundays. Nor are they ever put to any labor beyond their strength; for as to the alleged "*unfeminine* practice of females driving dung-carts,"* the practice is not more unfeminine than helping to fill dung-carts, or turning dunghills; but the fact is, women do not *drive* carts, in the usual sense of that term; they only walk beside the cart, in the absence of *the driver* at more laborious work, to and from the dunghill to the place of its destination,

* Report of the Cottage Improvement Society of North Northumberland for 1849.

merely to keep the carts clear of one another, and when so employed they have nothing to do with the yoking or loosening of the horse, or filling or emptying of the cart, or turning in or out of the landings. In the northern counties of Scotland no such obligation exists on the plowmen, nor indeed can be, for it would be impossible to coëxist with the bothy system, where a plowman has not a house for himself, far less for any worker; and hence in those parts of the country field-labor, in as far as the *manual* operations are concerned, is very much inferior to that executed on the Borders, because of its being performed by casual laborers instead of those who have been steadily trained up to it from early youth; and as long as *no means* are used to initiate young people, especially young women, who are admitted to be more nimble in the fingers than men, in the several varieties of field-labor, so long will they be imperfectly executed.

(1572.) Now, on taking a retrospect of the actual condition of all the laborers of the farm, as I have endeavored to represent it, and comparing the condition of the first class of plowmen with the others, the question that naturally occurs to the mind is—Which is the best? I have not the slightest hesitation in expressing my conviction of the superior position of the plowmen in the Borders. Let us look into one of their cottages of an evening. I grant that their cottages might be made much more comfortable and much more convenient, and much better suited to the wants of their inhabitants, than they are; and this I shall endeavor to show in due time; but in the mean time I may say that a determination exists for improvement in this matter evinced by parties most able to do it, namely, the landlords, and its good effects will be seen in the course of a few years; but look into one of their cottages, such as they are, during a winter evening, and "you will probably see," to use the words of Mr. Grey, Dilston, on this subject, in the letter and spirit of whose sentiments I cordially concur, "assembled the family group round a cheerful coal-fire—which, by the way, is an inestimable blessing to all classes, but chiefly to the poor of this country—females knitting or spinning—the father, perhaps, mending his shoes—an art almost all acquire—and one of the young ones reading for the amusement of the whole circle." Contrast this with the condition of those plowmen in England who receive their wages entirely in cash, and who have to go to a distance to purchase the necessaries of life. "Contrast this," continues Mr. Grey, "with the condition of many young men employed as farm-servants in the southern counties, who being paid board-wages, club together to have their comfortless meal in a neighboring cottage, with no house to call their home, left to sleep in an outhouse or hay-loft, subject to the contamination of idle companions, with no parent's eye to watch their actions, and no parent's voice to warn them of their errors; and say which situation is best calculated to promote domestic comfort, family affection, and moral rectitude?" Contrast this also with the bothy system, which perhaps Mr. Grey has never witnessed, or no doubt it would have met with his reprobation; contrast this with a system which, although it supplies the necessaries of life in a convenient enough form, presents them in uncomfortable circumstances affording no assistance to cook the food and clean out the chamber; affording no one to admonish thoughtless young men, many of whom are in the practice of wandering at night after a long day's toil, and returning home only in the morning, to begin a day's work, with wearied limbs and depressed spirits. In the winter evenings, too, the bothy is a scene of lewd mirth, excited by the company of females who have come perhaps from a distance to visit their acquaintances, and who are treated most probably with a stolen fowl, entertained with profane jests and songs, and afterward conveyed homeward amid darkness and wet.

(1573.) "One very obvious benefit," observes Mr. Grey justly, in regard to married plowmen, "arising to the hind from this mode of paying in *kind*, besides that having a store of wholesome food always at command, which has not been taxed with the profits of intermediate agents, is the absence of all temptation which the receipt of weekly wages and the necessity of resorting to a village or a town to buy provisions, hold out of spending some part of the money in the ale-house, which ought to provide for the wants of the family; and to this circumstance, and to the domestic employment which their gardens afford in their leisure hours, we are probably much indebted for the remarkable sobriety and exemplary moral conduct of the peasantry of the North." And further, "this mode of engaging and paying farm-servants is not only more conducive to their welfare and social comfort than the weekly payment of money-wages—which go but a little way in purchasing the necessaries of a family, are injudiciously laid out, and sometimes wastefully squandered—but it has, besides, a strong and apparent influence upon their habits and moral character, it possesses the advantage of giving to the peasant the use of a garden and cow, with the certainty of employment; it gives him a personal interest in the produce of his master's farm, and a desire to secure it in good condition; it produces a set of local attachments, which often lead to a connection between master and servant, of long continuance."*

(1574.) Beneficially as this system of paying farm-servants in kind has long operated both for master and servant, it has been stigmatized by persons even in Parliament, as being only another form of the *truck-system*, which has been made to act so prejudicially against the interests of operatives in England. But what *is* the truck-system? After hearing the proper answer to this question, we shall be the better able to judge whether the plowman's wages paid in kind can truly receive that appellation. Of the truck-system, Mr. McCulloch says that it is "a name given to a

* Journal of the Royal Agricultural Society of England, vol. ii.

practice that has prevailed, particularly in the mining and manufacturing districts, of paying the wages of workmen in goods instead of money. The plan has been for the master to establish warehouses or shops; and the workmen in their employment have either got their wages accounted for to them by supplies of goods from such *dépôts*, without receiving any money; or they have got the money, with a tacit or express understanding that they were to resort to the warehouses or shops of their masters for such articles as they were furnished with."* If this be anything like a correct account of the properly reprobated system, it is clear that it has no affinity to the system in *kind*, in which the hinds are paid their wages, inasmuch as this has no reference to the *money value* of any article which the hinds receive, and therefore they *always receive the same amount of kind*, and of course the same rate of wages; whereas the truck-system has undoubted reference to the *money value* of the articles dealt out to, or purchased by, the operatives; and that money value is fixed by the master whose interest it is, of course, to keep it at as high a rate as practicable, or else to give out articles of inferior quality at the price of those of more value; and hence the artisan does not always receive the same amount of goods, nor the same rate of wages.

5. CORN MARKETS.

"Thus all is here in motion, all is life;
The creaking wain brings copious stores of corn."
DYER.

(1575.) The surplus grain of the farm is disposed of to corn-merchants, millers, bakers, distillers, and brewers. These attend on the market-day in the market-town. If the market-town is a seaport, most of the corn-merchants and brewers reside in it permanently, and have their granaries there. When the market-town is situate in the interior of the country, the merchants and brewers attend the market there from the nearest seaport. The purchase of grain is chiefly carried on in winter, when the farmer has his crop to dispose of. Brewers and distillers chiefly buy barley for malting, millers and bakers chiefly wheat and oats, and merchants every species of grain. The market for barley commences the season, wheat and oats being then disposed of according to the demand for them; but after March the demand for both increases, to supply the consumption until next harvest. In a corn district, from which most of the produce is carried away to large towns or manufacturing districts, it is most convenient for the shipment of grain that corn-merchants reside in seaport towns.

(1576.) Corn markets are of two kinds, *stock* or *sample* markets. A *sample-market* is that in which farmers bring hand samples of the grain they wish to dispose of, exhibit them to purchasers, and deliver the stock or bulk at an appointed time.

(1577.) A *stock market* is where farmers bring in the grain they have to sell in bulk upon their carts, exhibit a bagfull of it, sell the quantity brought, deliver it to the purchasers immediately after the sale is effected, and then receive the money for it. A merchant who *sells* grain in a stock-market does so by sample, and never thinks of bringing *his* stock, which perhaps consists of granaries-full, to the market-place; and there is nothing to prevent farmers also to sell their grain by sample in a stock-market.

(1578.) When sold by sample, the grain is *delivered* by the farmer in his own carts in the course of the few days allowed him for the purpose, either at the granaries of the merchant, brewer, or distiller, or at the mill of the miller. Water-proof tarpaulins are required to cover the sacks in the carts when grain is delivered in a a rainy day, but it is better to defer the delivery until fair weather, if not otherwise inconvenient.

* McCulloch's Commercial Dictionary, art. *Truck-System*.

(1579.) When sold in bulk, corn is delivered immediately after the sale at the granaries of the merchants on the spot, or at the brewery, or distillery, or mill in the country, according to agreement.

(1580.) The *payment* for grain sold by sample is only made on the market-day after the delivery has been effected; but the payment of that sold in bulk is due, and is generally received, on the day it is sold, soon after its delivery at the granaries.

(1581.) Of the two modes of selling grain, each has its advantages and disadvantages to the farmer. It is *very convenient* to take a quantity of grain to market, sell it, deliver it on the spot, and receive the cash for it immedidiately afterward. It enables the farmer to transact his market business at once, and saves him the trouble of attending next market-day on purpose to receive the cash, when he may have no other occasion to be there. It obliges, in a great degree, merchants to provide granaries for the reception of grain in the interior market-towns; as farmers may refuse to deal with a purchaser who wishes the grain delivered at a distance from the market-town, the fatigue to their horses being thereby probably much increased. This mode of selling grain has also the advantage of securing the farmer against bad debts, because he may deliver the grain and receive the value for it simultaneously. On the other hand, it is attended with this great disadvantage, that in case the farmer does not sell his grain on the day he has brought it to the market-place, he is either obliged to take it home again, or put it into a granary until the next market-day, when, of course, granary-rent must be incurred, and the additional expense also incurred of either hiring carts to deliver the grain next market-day, from the temporary granary to that of his purchaser, or of sending a cart of his own to do it; and as he must keep the grain so accommodated in sacks, he may be deprived of the use of his sacks at a time when he may have a large quantity of corn in his barn to measure up, and which, where lying in a loose state, may be an inconvenience. Or to avoid these manifold and obvious inconveniences he must take the price offered for his grain. Another disadvantage is, that his horses must stand in the market-place, exposed for hours to cold blasts, after perhaps being heated on their way to the market-town. The exhibition of corn in bulk gives power, however, to the purchaser to inspect the cleaning of every sack before purchasing it, and it also gives him the command of a quantity of corn immediately after its purchase.

(1582.) The *advantages* of a hand sample-market to the *farmer* are, that he is independent of the rate of price of any market-day; for if it does not satisfy him, he can put his sample into his pocket again. His men and horses cannot lose a day's work, and are not exposed to the weather in waiting in the market-place. He need not, moreover, clean his grain before selling it, and should he be induced to sell more than what is threshed, he has time to thresh more and clean the whole quantity at once, thereby making the stock of uniform quality, and cleaned agreeably to the particular taste of the purchaser. The *disadvantages to the farmer* are inability to receive cash for the grain he sells until the next market-day after its delivery, and the risk he thereby runs of incurring bad debts with the merchant, to whom the stock is delivered some days before he pays for it. The *advantage* of a sample-market to the *merchant* is, that should the sample please him, he can purchase as large a quantity of grain as the farmer pleases to dispose of, and thus make up a cargo of uniform quality; and the *disadvantage* which he experiences, which, by the way, is felt most strongly by the brewer, distiller and miller, is that he cannot obtain possession of the grain immediately after purchase.

(1583.) Of the two species of corn-markets, I prefer selling by the sample, chiefly because I dislike to see horses standing for hours with a load in the market-place, and most probably in bad weather, for none else can be looked for in winter. Such a stand cannot be for their advantage, and, in my estimation, the peculiar advantages of a stock-market are insufficient to counterbalance the risk thus incurred in the safety of the horses. This inconvenience is perhaps appreciated by some farmers, and a modification of the plan is followed, such as delivery in the course of a few days of a larger quantity of grain than what was actually presented in the market-place; but no modification can take place of the sale of grain by sample, in that it is simply the presentation of the hand sample in the market, the sale of the bulk therewith, and its consequent delivery at the specified time. It would be curious to observe the particular diseases to which horses are most liable, that are made to stand in a market-place for hours together, and to ascertain if these are of the class most commonly contracted from exposure to weather.

(1584.) Were all men honest, it would be immaterial which mode were adopted for the sale of grain, in so far as the *state* of the grain is concerned; but to the shame of the farmer be it spoken, it sometimes happens that the stock is delivered of an inferior quality, or not so well cleaned as the sample that was shown in the market. Some farmers acquire a character for this species of fraud, and so blinded do they become by their cupidity, that they cannot discover the advantage which they thereby confer on the merchant to reduce the price of the bargain made between them. It is curious that men cannot at once believe that ill-cleaned corn cannot be so heavy, bulk for bulk, as well-cleaned. While such people, therefore, think they are taking advantage of the merchant by giving him light corn among the good, they are in fact cheating themselves, for no purchaser will pay the stipulated price of good corn when ill-cleaned corn is delivered to him instead. Many farmers, I apprehend, deliver stock inferior to sample, from no intention of committing fraud, but because they cannot deliver the stock so clean as the sample shown, it having been differently treated from the stock. They are in the habit of pulling out a sample from the stack, rubbing out the grain from the ears, blowing away the chaff with the mouth, and picking out the light corn. Now no winnowing machine can clean corn in this style. Or a sample is taken from the unwinnowed bin on the barn-floor, and treated in a similar manner. Sample and stock can only agree exactly when both are derived from a similar state of the same parcel of grain.

(1585.) On the other hand, I must say, in justice to the farmer, that some corn-merchants are very fastidious on receiving stocks of grain that have been sold them by sample. The stock is objected to at the granary, because it is inferior to the sample; and when this plea cannot be substantiated on comparison, the bulk is declared deficient in measure, which objection cannot be rebutted without measuring over the whole quantity, and on this being done, and this objection also proving groundless, it is rejected because the grain is lighter than that guarantied by the farmer. But the object is to *set up* the grain anyhow, to give the merchant an opportunity to reduce its price. To show how such a circumstance as this can happen, I may observe that the merchant seldom witnesses the delivery of grain at his granaries, this duty being deputed to the man who has charge of the granaries, and its delivery cannot of course be witnessed by the farmer. So if the merchant's foreman receive the clue to make objections, these are easily made to appear effective to the farm-servants delivering the grain, who of course know nothing of the conditions of the bargain. The

corn is then *set up*, that is, set down in the sacks on the floor, and remains there unemptied until an explanation takes place; on which, if the farmer has committed an error, he suffers a considerable reduction in price, but if he can maintain his own rectitude, the merchant concedes the point, and throws the blame on his stupid foreman, who, after all, is justified for the interruption he had given, by the allegation that he had only done his duty to his master. I have heard of both these species of fraud being attempted to be committed, and have also heard a remark connected with one of them, that merchants are most likely to be fastidious in regard to the quality of the grain they receive, when prices happen to fall between the period of purchase and that of delivery. Unfortunately, no such motive can be urged to justify the farmer in his attempts to pass off inferior grain. In a stock-market no such occurrence can happen. Let me say here, that my sole object in alluding to so painful a subject is to make you aware of the tricks of trade.

(1586.) Every species of grain is directed by the Weights and Measures Act, (5th Geo. IV., c. 74, sec. 15,) to be sold by the imperial *bushel*, containing 2,218.192 cubic inches, and not 2,150.42 cubic inches, as erroneously given in that paragraph, this latter number being the contents of the old Winchester bushel, which is now obsolete, and there is no such recognized quantity as a quarter, boll, coom, or load. The practice has settled into measuring grain into half-quarter sacks of 4 bushels, which forms a convenient size of load in the barn, as well for carriage on men's backs as in carts, Plate XVIII.

(1587.) Granaries in town are frequently situate in inconvenient places for access to carts, such as narrow streets and lanes; and some are so inconveniently high that four or five flights of steps have to be surmounted ere the floor be attained which is to contain the corn; and these stairs are not unfrequently too narrow or too steep, or the steps so worn away in front as to endanger the safety of the persons who carry loads up them. But the risk is fully greater to those who have to bring loads down them, when the contents of the granary are emptying for the loading of a ship. For the carriage of corn in such a case, I have seen a convenient form of *bag* used. It consisted of a short sack, capable of holding rather more than two bushels, drawn together at the bottom, where a short piece of thick pliable rope is attached, the mouth being formed like any other sack. The person who is to carry the bag, folds the mouth together when filled so as to cover the corn, and at the same time leaves a portion of the sack loose, by which he holds firmly with his right hand. On assistance being given him to lift the sack, when filled, he turns himself quickly round with his back to it, and brings the part by which he holds on, over his head; and holding on there with one or both hands, as he chooses and feels most convenient in the circumstances, literally runs with the load to the ship's hold, where, on a man seizing the short rope at the bottom of the sack, the carrier hitches the sack off his back, and the grain is poured into the hold, while the man all the time retains hold of the short rope.

(1588.) For long in Scotland, grain used to be sold by *measure alone*, and for long it used to be sold in Ireland by *weight alone;* but both ways are liable to objection. When the measure alone is used, there is a temptation to measure the corn before it is properly cleaned, especially if the corn is sold; and when sold alone by weight, there is also a temptation to retain light corn among the good, with the view, in both cases, of disposing of the inferior grain at as good a price as the fine. But a check has of late years been established against both species of fraud, by a statement of the weight along with the bulk. Merchants know the weight

of grain by its appearance and feel, and therefore, by trying the weight of a 4-bushel sack, they can easily ascertain whether the grain is in as clean a state throughout the whole bag as at its mouth. But the introduction of the weight has given rise to a species of deceitful dealing as regards the public. The purchaser offers a certain price for every so many pounds weight of grain, without direct reference to the contents of the bushel; and some farmers are induced to sell on this plan, in the vain hope of being able to boast that they have sold their grain at such a price, wishing it to be believed that the price applies to the true quarter, when in fact it is given for so many pounds weight, and to deliver the number of pounds for the specified sum the bushel is heaped. This is pitiful work. The fair and common practice is to ask such a price for the grain per quarter, stating its weight by the bushel; and, of course, the heavier the grain, and better the quality, the purchaser will give the higher price for it.

(1589.) The usual denominations of corn measures, based upon the imperial bushel, the standard of capacity, are these;

4 gills	= 1 pint,	contain	34⅔	cubic	inches.
2 pints	= 1 quart,	..	69⅓	..	..
4 quarts	= 1 gallon,	..	277⅓	..	..
2 gallons	= 1 peck,	..	554⅔	..	..
4 pecks	= 1 bushel,	..	2218⅔	..	..
8 bushels	= 1 quarter,	..	10⅔	..	feet.
5 quarers	= 1 load,	..	51⅓	..	..

(1590.) In regard to the sale of corn, these settled points in law may prove useful for you to know. "In sale by sample, the buyer may decline the bargain, if the bulk does not correspond with the sample (Parker, 4 Barn. and Ald., 387). The delivery of the sample does not transfer the property of the bulk (Hill, Jan. 26, 1785, M. 4200). The *price* must consist in current money, either of Great Britain or some foreign country, which has a determinate value put upon it by the tacit consent of the State; if in goods it will be barter and not sale; and if illusory, it will be donation. The price must be certain, as well as the subject sold. It is generally fixed by the parties themselves at striking the bargain. Where a purchaser of oats, payable on delivery, temporized with the seller, and delayed to take delivery for a fortnight, during which period the price of oats rose, it was held that he was not entitled to delivery to demand delivery (Craig, May 29, 1822, 2 S. D. 347). . . . In sales of grain, the price is sometimes fixed by the Sheriff's fiars. In the case of Leslie (Jan. 27, 1714, M. 1419 and 1678), where there was an agreement to purchase grain without a price specified, it was held, *inter alia*, that fiars' prices may be presumed the sale between landlord and tenant; and that merchants are presumed to contract according to the current prices of the country where the bargain is made. As to the risk of the sale after the subject is sold, the loss is to the purchaser, as in the case of Campbell (July 15, 1748, M. 10,071), and in the case of Tarling (1827, 6 Barn. and Cres. 361). But it was held in the case of Milne (Feb. 1, 1809, F. C.), that where the seller takes upon himself the delivery of goods at a certain place, it throws the risk of the goods, while *in transitu* to that place, on the seller. . . . Where the seller has delayed delivering the subject to the purchaser when bought, he is liable for the risk; but it is not considered delay when the purchaser declines paying the price. Also, when a landed proprietor sells a certain quantity of grain of a particular crop to a merchant, without specifying any particular parcel, and the whole crop is destroyed, the loss is to the seller; but after such quantity of grain is measured, or otherwise prepared for delivery, the risk will be transferred to him; so found in the case of Hinde (6 East. 558.); Erskine, iii. 3. 7." In regard to the landlord's hypothec over corn, restitution was given in the case of Scot (June 11, 1673. M. 6223.). of corns bought from a tenant while under hypothec. Though, when bought in public market, where they have been brought in bulk, the purchaser is not liable in restitution; if brought only in samples, the landlord is entitled to restitution. This was held in the case of Smart, Dec. 10, 1793, and Earl of Dalhousie, Feb. 27, 1828, 6 S. D. 626."* So that a stock-market is safer for a purchaser to buy in, and a sample-market is safer for the hypothec of a landlord.

6. FORMING OF DUNGHILLS, AND LIQUID-MANURE TANKS.

"If frost, returning, interrupt the plow,
Then is the time, along the hardened ridge,
To drive manure——" GRAHAM.

(1591.) Toward the close of winter, the dung will have accumulated so high in the large courts I and K, figs. 3 and 4, Plate III. and IV., as to become nearly level with the feeding-troughs *z*, and thereby making them

* The Farmer's Lawyer.

inconveniently low for cattle; but before this inconvenience occurs, the dung should be removed and formed into dunghills in the fields intended to be manured in the ensuing season. The court K, besides its own litter and the refuse from the corn-barn C, contains the litter of the work-horse stable O, and the pig-sty *b*; and the court I contains the litter of the servants'-cow byre Y, besides its own. The dung from the cows'-court *l* should also be taken away, to save annoyance to cows heavy in calf wading in deep litter; and that from the courts of both the hammels M and N, if not from under the sheds, should also be taken away, for the same reason as given above in the case of the courts, that the feeding-troughs become too low, especially in the hammels M of fattening cattle.

(1591.) I am thus particular in detailing the contents of each court, because, differing in their constituent parts, they should be appropriated to the raising of the crop best adapted for each sort of manure. For example, the court K contains a large proportion of stable-litter, and not a little from that of the pig-sties; so its contents are somewhat of a different nature from those of the court I, which contains nothing but the litter of cattle. If it is desired to raise a large extent of that crop which thrives best with a considerable proportion of horse-dung, the contents of the court K should of course be preferred to that of the other court I; and if any crop is best raised with cattle-dung, the contents of the court I and the cows'-court *l* should be used for it. Or should the manure required consist of an average proportion for raising of general crops, then the contents of all the courts should be mixed together. This method of appropriating the dung of a farm is not so much practiced by farmers as it deserves; and it is not urged by me as a mere theoretical suggestion, but as practically being the best mode of appropriating manure to raise each crop to the best advantage. To make my meaning more intelligible, I shall illustrate it in this way. Suppose that carrots were desired to be raised on a field of light land, then the land should be dunged in the autumn with the contents of the court K, because it contains a large proportion of horse-litter. When potatoes are attempted to be raised on heavy soil, which is not their natural one, they most likely to succeed with horse-litter also. Turnips, on the other hand, grow best with cow-dung, and therefore a mixture of the courts I and *l* would be best for them. Should carrots not be raised, and the soil is naturally favorable to the potato, and therefore horse-dung will not be specially wanted, the best way is to mix all the sorts of dung together, and form dunghills of average properties.

(1592) There is another matter which deserves consideration before the courts are begun to be cleared of their contents; which is the position the dunghill or dunghills should occupy in the field, and this point is determined partly by the form which the surface of the field presents, and partly from the line of access to the field. In considering this point, which is of more importance than it may seem to possess, it should be held as a general rule, that the dunghill should be placed where the horses will have the advantage of going down-hill with the loads from it. *Wherever practicable, this rule should never be violated, as facilities afforded to labor in a busy season are of the utmost importance.* If a field, then, has a uniformly sloping surface, the dunghill should be placed at the upper or highest side, but then the access to the field may only be at the lowest side. And it may be impracticable to reach the upper side by any road. In such a case, the loads should be taken up a ridge of the field; and when a field is so inconveniently placed, frosty weather should be chosen to form the dunghill in it, as the wheels and horse's feet will then have a firm bearing. But should it be found impracticable to lead dung to its upper side, by reason of the

soft state of the land or steepness of the ascent, then the dunghill should be formed at the side nearest of access. If the field has a round-backed form, the dunghill should be placed on the top of the hight; and in order to supply the ridges down both slopes from it with manure, a ridge, by way of head-ridge, should be formed along the crest of the hight, at the time the stubble is plowed. In a level, or nearly a level field, it is immaterial which side the dunghill occupies.

(1594.) The fields to which the dung should be carried, are those to be fallowed the ensuing season; that is, set apart for the growth of green crops, such as potatoes and turnips, and for the part which receives more cleaning than a green crop admits of, namely, a bare fallow. The potato culture coming first in order, the land destined for that crop should have its manure carried out and formed into the first dunghill. The turnips next come in hand; and then the bare fallow. The dunghills intended for potatoes and turnips should of course be made respectively of such a size as to manure the extent of land to be occupied by each crop. The manure for bare fallow not being required till much farther on in the season, may be deferred being carried out at present. The proportions and nature of the soils best suited for potato and turnip culture, will be treated when we come to speak of those crops respectively, so that any remarks on these particulars would be irrelevant here.

(1595.) Then the precise spot which a dunghill should occupy in a field is not a matter of indifference. I have seen a dunghill placed in the center of a field which it was intended wholly to manure. From this point, it is obvious, the carts must either traverse every ridge situate between the one that is in the act of being manured and the dunghill, or go direct to a head-ridge, and thence along it to the ridge to be manured. This latter alternative must be adopted if the dung is to be deposited in drills; for if not, the drills will be much cut up by the passage of the carts across them—a practice which should never be allowed when neat work is desired. The dunghill should be placed on a head-ridge or a side-ridge of the field; and of these two positions I would prefer the side-ridge, because, when the head-ridge is occupied in the length of a dunghill, the ends of all the ridges abutting against its side cannot be plowed or drilled in their entire length; and if there be more than one dunghill on the same head-ridge, a considerable number of head-ridges may thus be curtailed of their fair proportions. The dunghill on a side-ridge affects only a part of the single ridge which it occupies. Should a field be large and require two dunghills, the one first to be used should be placed *along a ridge*, at a distance just *beyond* the space of ground the manure it contains will cover, so that the ridge occupied by it may be plowed to its end before it is manured; and the second dunghill should be placed along the farthest off side-ridge. The ridge occupied by the farthest dunghill can be easily reached at a time when the earth is hard; but should the weather continue fresh, and the ground soft, a dunghill should be made on the side-ridge nearest the gateway; and should no frost happen, this dunghill should be made large enough to manure the whole field. A large dunghill in one place will no doubt cause more labor to manure the field at the busy season than would two dunghills at different places; but in soft weather and soil it is better to incur the risk of future inconvenience than allow the horses to drag only a half-load, axle-deep, along a soft head-ridge. When proper sites can be chosen for dunghills in fields, the loads, in the busy season, will not only be insured a passage down hill, but the dung be situated at the shortest distance from the place it is wanted, and the plowed and prepared land be uninjured by cart-wheels and horses' feet.

(1596.) Some consideration is even required in *littering the courts*, and especially the large courts, I and K. No one would believe that any care is requisite in laying down straw in a court; but those who have witnessed the inconvenience and loss of time incurred in removing dung from courts will easily perceive that this may be the case. The courts are usually cleared during frost, when time is erroneously regarded of little value, and when, as our motto implies, the plow is rendered useless; but notwithstanding this common opinion, a loss of a small portion of time, even at this season, may have a material effect upon some future operations. For example: the hard state of the ground may favor the carriage of manure to a distant field, to gain which, most of the time is spent upon the road. Suppose frost continued as long as to allow time to carry as much manure as would serve the whole field, provided ordinary diligence were used, and no interruption met with in the courts. Suppose farther, on manuring the field in summer there was found to be less manure in the dunghills by a small quantity than was wanted, and that half-a-day, or at most a whole day's driving from the steading would supply the requisite quantity, it is clear that the day's driving could have been accomplished in frost at much less trouble than at the season when the manure was wanted. But this sacrifice of time *must* be made at the instant, or the field be deprived of its just proportion of manure. This is no hypothetical case; it has occurred in every farmer's experience. Now, what is the primary cause of this dilemma? Either too much time had been spent upon the road in driving the manure, or much interruption had been experienced in the courts. To which of these two causes should the waste of time be ascribed? With regard to driving, farm-horses get into so regular a pace upon the road at all times, that little loss or gain of time can be calculated on in this particular; and besides, when a head of carts is employed at any work, every one must maintain its position in the routine, otherwise it will either be overtaken by the one behind, or be left far behind by the one before. The probability, therefore, is that the loss of time is incurred in the courts, and for this reason. The usual mode of taking away wetted litter from the work-horse stable is to roll it together with a graip, and then to throw it into a barrow, in which it is wheeled into the court, and there emptied on any spot to get quit of it in the shortest time, and left in heaps to be trampled down by the cattle. Back-loads of thatchings of stacks, some of which are not very dry, are carried into these same courts, put down anywhere, and partially spread. Long straw-ropes, which bound down the thatching of stacks, are pulled along the top of the litter. In doing all this, and it is not all done at one time, no plan is followed with the view of *facilitating the lifting of the straw* afterward, but as if it was to remain there always; but so far from this being the case, it is again lifted before it becomes short by fermentation, and there is considerable difficulty in doing so. Long, damp straw is seized in one part by a graip, and the other parts, being coiled in the heap it was first laid down, cannot be separated without much exertion on the part of the plowman, pulling it this way and that; and it is too soft to admit of its being cut with the dung-knife. Another graip encounters a long straw-rope, which, after much tugging, is broken or pulled out, and thrown upon the cart with its ends dangling over. In short, not a single graipfull is easily raised, and the business is not expedited when a heap of chaff evades the action of the graip. Add to this the few hands generally sent to assist the plowman to fill the carts, and the consequent time spent by the team in the court, and some idea may be formed of the causes which incur much loss of time in this necessary work. It is easy to conceive that in this way as much time

might be lost in cleaning all the courts as would give all the carts a half or whole day's driving, which was just what was required to remove the inconvenience felt when the field was manuring. The only method of preventing the recurrence of so great delay in carrying out manure is to put down the litter so as it may be easily lifted, and to afford as much assistance in the court as to detain the horses but a short time, and rather keep them moving on the road; for though their walking was constant in a short winter day, it will not overcome them with fatigue.

(1597.) *The litter should be laid down in this manner* in the large courts I and K. On fixing on the gate of the court through which the loaded carts should pass to the nearest road to the fields requiring the manure in the ensuing season, and after covering the ground of the court evenly with straw, the litter should be laid above it in small quantities at a time, beginning at the end of the court farthest from that gate. The litter should be spread with the slope of its lower part toward the gate, and carried gradually forward every day until it reaches the gate; and every kind of litter, whether from the work-horse stable, the stack-yard, or straw-barn, should be intermixed and treated in the same manner. The straw-ropes, as I mentioned before, should be cut into small pieces and spread about. Thus layer above layer is laid, until they form a mass of manureof sufficient hight to be carried out and formed into dunghills in the fields.

(1598.) When the time has arrived for *emptying the carts*, the process is *begun at the gate* through which the loaded carts are to pass, and, on lifting the litter it will come up in sloping layers, having an inclination from the ground to the top of the dung-heap, not in entire layers of the whole depth of the dung-heap, but in successive small, detached layers, one above the other, and succeeding one after the other, from the gate to the farther end of the court. The empty cart enters the court by the other gate, and, without turning, takes up the position of the loaded cart before it, which has just passed through the gate appointed for it. When there is only one gate to a court, and the court not very large, and a large lot of beasts in it, it is better for the empty cart to wait on the outside until the loaded one has gone away. When the court is large, with only one gate, the empty cart should go in and turn round to succeed the one that is being filled. On dropping work at mid-day, it will save time at starting again after dinner, to fill the first cart returning empty from the field, that has not time to reach it again loaded and return before dinner-time, and to allow it to stand loaded, but without horses, until the time for yoking, when the horses are put into it, and the first load thus started for the field immediately at the hour of yoking.

(1599.) On clearing a court, or any part of it, it should be *cleared to the ground;* because the manure made from a dung-heap that has been simultaneously formed, will be more uniform in its texture than that made from a heap composed of new dry straw on the top, and old wet straw at the bottom. Besides, it is much better for the future comfort of the cattle, that the court receive its fresh dry littering from the bottom, than if the wet bottoming were retained.

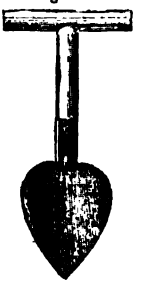
(1600.) Sometimes cattle get injured by a cart or horse when the court is emptying, and, to avoid this risk, it is not a bad plan to confine them under the shed as long as the people are at work in the court. The mode of confining them in the shed I have already alluded to in (18).

(1601.) On *forming a dunghill in the field*, some art is requisite. One of a breadth of 15 feet, and of four or five times that length, and of proportionate hight, will contain as much manure as should be taken from one spot in manuring a field quickly. Suppose that 15 feet is fixed upon for

the width, the first carts should lay their loads down at the nearest end of the future dunghill, in a row across the whole width, and these loads should not be spread thin. Thus load after load is laid down in succession upon the ground maintaining the fixed breadth, and passing over the loads previously laid down. After the *bottom* of the dunghill has thus been formed of the desired breadth and length, the farther end is then made up with layer after layer, until a gradual slope is formed from its nearest to its farthest extremity. This is done with a view to effecting two purposes, one to afford an easy slope for the loaded carts to ascend, the other to give ease of draught, for horses and carts to move along the dunghill in all parts, in order to compress it firmly. Every cart-load laid down above the bottom layer is spread around, in order to mix the different kinds of dung together, and to give a uniform texture to the manure. To effect this purpose the better, a field-worker should be employed to spread the loads on the dunghill, as they are laid down. When the farther end has reached the hight the dunghill is thought will contain of the desired quantity of manure, that hight is brought forward toward the nearest end; but the center of the dunghill will necessarily have the greatest elevation, because a slope at both *ends* is required to allow the carts to surmount the dunghill and then to come off it. It is an essential point to have the whole dunghill equally compressed, with the view of making the manure of similar quality throughout. After the carting is over, the scattered portions of dung around the dunghill should be thrown upon the top, and the top itself leveled along and across its surface.

(1602.) The *object aimed at by the compression* of the dunghill by the loaded carts, is to *prevent immediate fermentation.* So long as the temperature continues at its average degree in winter of 45°, there is little chance of much action in the interior of a dunghill; but toward spring when the temperature increases, it may be expected to show symptoms of action, but even then a temperature of 65° is required to begin the second stage of fermentation. Some advocate the covering of dunghills in the field with a thick layer of earth, with the view to exclude the air and check fermentation; but such an expedient is unnecessary in the coldest months of winter, though it would be of service in spring to a dunghill which is not to be turned until the season is still farther advanced. Others lay up the dunghill in a loose manner at once in graipfulls from each cart-load, giving the dung in fact a turning, and then cover it with earth, and trim round the sides with the spade. This form of dunghill looks neat, and, if the manure is to be used early, it is a good plan for obtaining it partially fermented for an early crop, such as beans; but for dung that is to be used at an advanced period of the season, when the temperature will have gradually increased to a considerable hight during the day, the process is too promotive of rapid fermentation.

Fig. 308.



DUNG-SPADE.

(1603.) The litter in the courts of the hammels, and especially in those of the hammels M, will be found much more compressed than that in the large courts I and K, in consequence of heavy cattle being obliged to move over it frequently within a limited space. It is sometimes so compressed as almost to resist the entrance of the graip. To enable it to be easily lifted, it should be cut in parallel portions with an implement called the *dung-spade*, fig. 308. This consists of a heart-shaped blade of steel thinned to a sharp edge along both sides; and its helve with a cross-head is fastened with nails in a split socket. The hight of the spade is 3 feet, length of

cross-head 18 inches, length of helve 18 inches, length of blade 16 inches, and breadth 10 inches. It is kept sharp with a scythe-stone. In using this spade, it is lifted up with both hands by the cross-head, and its point thrust with force into the dung-heap, and it is then used like a common spade while rutting turf, with the foot upon the upper part of the blade. This part, it will be observed, is rounded and not left square with ears like a common spade, because when this spade is used to cut a dung-heap of greater depth than the length of its blade, the round edge is not so apt to catch the litter as square ears, on the instrument being pulled up. A man's strength is required to use this spade effectively, a woman's arms being too weak for the purpose. Another form of instrument for cutting dung is like the common hay-knife, and is used in like same manner, and which will be figured afterward; but it is not so efficient as this instrument, as will be shown when we come to speak of the cutting of hay in spring.

(1604.) It is a practice of some farmers to keep the dung from the cow-byres in a loose state in the court. A space in the center of a court is inclosed with a stout wall 3 or 4 feet in hight, into which the dung is wheeled as it comes from the byre, and the dung-heap is accumulated to the hight of the wall, or even more, by means of a plank as a roadway for the barrow to ascend. The dung managed in this way never requires turning, and soon becomes in a state fit for use for potatoes or turnips. This plan saves the trouble of turning the dung, but this saving is not unattended with a disadvantage, for the dung must be led direct from the court to the field at a season when labor is precious, and when the field to be manured is far off, the extra time spent in leading out the manure to it may more than counterbalance any saving in the cost of turning. This dung, might, it is true, always be reserved for the nearest field, but even the nearest may be at a considerable distance.

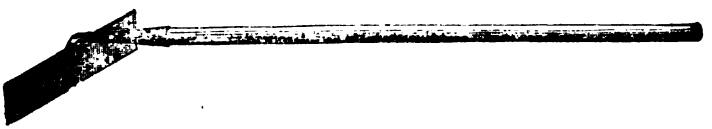
(1605.) Of late years the method of carting out a dunghill as described in (1601) has been objected to, because it is alleged that many of the gases useful to vegetation are thereby dissipated. I do not see the strength of this objection in the winter season, when certainly no *decomposing* process can naturally originate or proceed. The water contained in the dunghill, it is true, may begin to evaporate at a very low temperature, even below 50°, but what harm can accrue from this? But as the fact is, that fermented dung must be prepared for some species of crops, of what avail would means to prevent fermentation be at a period not earlier than would be required to begin to ferment the manure so as it may be sufficiently so when applied? To obviate waste arising from fermentation, it has been theoretically suggested to make dunghills under sheds instead of in the open air: but how the mere screening afforded by a shed should *prevent* fermentation, though it may ward off rain, and keep the straw drier, and thereby *retard* fermentation, I cannot imagine. If the mode is proposed solely with the view to keep the litter dry, its fermentation will no doubt be retarded, but dry litter will never make *good* manure, as the usual state of litter under sheds can testify, which is in a state approaching to being *fire-fanged*, as it is termed, that is, in a smouldering, heated state. Until a better mode of making dunghills in the fields shall *prove* the present one erroneous, we must continue to follow it, encouraged by the success which has hitherto attended it.

(1606.) An ingenious suggestion has been made by Mr. Kirk, Preston Mains, East-Lothian, to *check the spread of the seeds of weeds among manure.* His suggestion is founded on the general law of the growth of plants, that certain classes of soils affect certain classes of plants. The suggestion is

to put the manure of the straw obtained from one kind of soil on another kind of soil. Thus, the straw obtained from clay soil, that is, wheat land, should be made into manure and applied to soil of light quality, that is, turnip soil; and as, according to this law, natural plants, called by farmers weeds, which throve upon the clay soil, would not do so upon the light, it appears to be within the power of the farmer to prevent, or at least to check, the propagation of weeds. Putting this suggestion into practice would be attended with some difficulty, for although Mr. Kirk seems to think it easy "to make all the straw grown on one kind of soil into manure by itself," and which, he conceives, "might be accomplished with very little additional trouble to the farmer, where several hammels are employed in the feeding of cattle,"* yet in large courts it would be almost impracticable to prevent the mixture of straw of one stack off clay land with that of the succeeding one perhaps off light land; and even in the small courts of hammels it would not be easy to devise a plan by which a stack of straw off clay land should be used in them, while straw from light was in use for litter in other courts; and besides, the best fodder being obtained off light land, the cattle while using it could not be littered with straw off clay land, without running the risk of destroying the object in view. The suggestion, however, being founded on correct theory, might be subjected to *experiment*, which alone can ascertain its practicability.

(1607.) Immediately after a rainy day, when the land is in such a state of wetness as to prevent any work upon it, and the horses have nothing particular to do upon the road, two or three of the men should each take a *mud-hoe* or *harle*, such as in fig. 309, and rake the loose straws and liquid

Fig. 309.



THE MUD-HOE OR HARLE.

mud on all the roads around the steading to the lowest side of the roads, and as much as possible out of the way of carts and people passing along; while the rest should take graips, fig. 257, and shovels, figs. 149 and 176, and form the raked matter into heaps, to be led away when it will bear lifting to the compost heap or field, as may best suit the purpose at the time. Where there is plenty of straw, as on carse-farms, some farmers put it upon the roads around the steading, to be trampled down and become wetted with rain, and then lead it away to the dunghill in the field. The object aimed at in so far as wetting the straw is attained, but such a littering makes walking upon the roads very damp and plashy. The best state for roads near steadings in winter is to have their surface *hard* and *smooth*, and with such an inclination as to cause the water to run easily away into some ditch hard by. A scraping now and then with the mud-hoe will make such a road dry and comfortable.

(1608.) I must now say a few words on tanks, liquid manure, and compost heaps. In fig. 4, Plate IV., may be seen the *liquid-manure tank k'*, great in length and in breadth, inside narrow, and its depth under the soles of the liquid-manure drains should not exceed 4 feet, for the reasons given below, its length being only extended to increase its capacity. The

* Quarterly Journal of Agriculture, vol. viii.

drains are marked by dotted lines from the tank toward *x*, in all directions, preserving them straight as practicable. Drains in straight lines, for a sluggish liquid, present fewer obstructions in their course than curved or angular ones. The form and dimensions of these drains may be seen in fig. 26, and (75 2d). At *x*, fig. 4, Plate IV., is an opening over the drains to allow the liquid manure to descend into them, and every such opening is protected by a grating such as is figured and described in fig. 25 and (75 1st). The liquid manure percolates through the grating, passes along the drains, and finds its way into the tank, out of which it is pumped with a cast-iron pump (76) into a liquid-manure cart, described below in fig. 310, in which it is carried to the field and distributed over its surface.

(1609.) *Tanks need not be built on every species of farm.* On *carse-farms*, where there is much straw and little green food, there can be no liquid manure; and on *pastoral-farms* the stock confined in winter in the steading are too limited in number to afford much of that material. On *dairy-farms*, on the other hand, where many cows are maintained and much green food consumed by them in byres, tanks might be constructed with advantage to the grass land. The practice of the farmers of Flanders might be usefully followed on such farms by having a small tank constructed under ground in connection with every byre, and the contents of which might be enriched with additions of rape-cake and other valuable ingredients. The enriched contents, employed as a top-dressing on pasture and forage land, appropriated to the support of the cows, might increase their produce very considerably. In collecting liquid manure on *farms of mixed husbandry*, if the steading is properly furnished with conveniences and the stock well supplied with litter, I do not see much can be done. I had a tank of 12 feet in diameter and 4 feet deep, connected with well-planned courts by neatly-built drains provided with good gratings; and, at the same time, I had the courts defended from being deluged with rain-water by capacious rain-water spouts, and care taken that the cattle were always provided with a sufficient quantity of litter; having all these—which every well-constructed and well-conducted steading should never want—I can say that the tank was not filled in the course of the season above three times, a quantity not worth while providing a liquid-manure cart to take it to the field; and even this small quantity was solely ascribable to heavy rains and melting snows, for a few days, falling directly into the courts, and causing a surplus of water which was readily conveyed into the tank by the drains. The usual supply of the liquid manure came merely in a few drops from the sole of the drain into which all the other drains immerged. The sole was only 4 feet above the bottom, and, except after rain or snow, the liquid manure never reached that hight. I conceive that a small tank might be usefully constructed by a cotter possessing a small piece of ground, or large garden, and a cow, provided the cow were fed within doors in all seasons with green and soft food, as an excellent means of collecting manure that would otherwise be lost. Mr. Milburn, Thorpefield, Thirsk, mentions "an instance of a small receptacle of this kind, where the owner has but one pig; he manages, however, by its aid in his garden to grow astonishing crops, and his garden produce is both earlier and superior to most of his neighbors." There is no question that much may be done in this way at farm-houses, hinds' houses, and villages, to collect matter, both solid and liquid, that would make valuable manure. A necessary might easily be constructed in connection with the liquid-manure tank at a steading to receive the supply.

(1610.) Tanks *need not be expensively constructed.* Mr. Milburn gives this statement as the expense of constructing a tank dug out of the ground

13½ feet in length, 6½ feet in width, and 6 feet deep, inside measure, with brick in length and mortar, and plastered with Roman cement:

"Length within	13 feet 6 inches.		
Width	6 .. 6 ..		
Depth	6 .. 0 ..	=19½ cubic yards.	
Cutting 31 cubic yards at 3d. per yard		£0	7 9
Walling, including bricks in length, and mortar around them, 31 cubic yards, at 4s. per yard		6	8 0
Plastering and cement		0	16 0
Covering and flags		2	15 0
Total		£10	6 9"

"A tank," continues Mr. Milburn, "might be made under a shed, and composed of clay, and covered with slabs or boarding, or any refuse boarding. The expense of such a receptacle would be somewhere as under, dimensions the same as in the preceding case, viz:

"Cutting 31 cubic yards at 3d. per yard		£0	7 9
Clay and carting		0	14 0
Board and covering		0	5 0
Total		£1	6 9"

A tank of this nature, Mr. Milburn suspects, would be subject to suffer in frosty and in very dry weather, as well as be liable to be perforated by worms. The frost and drouth are serious objections to this particular construction of tank; but the worms might be prevented perforating the clay, were a little quicklime mixed with it;* but the true principles on which all tanks should be constructed are stated below.

(1611.) Winter is considered a favorable period for the *application of liquid manure*, both because it is then most abundant, and because the ground is in that loose and moistened state which readily receives and allows the liquid to incorporate with it. Any evaporation at that season is very limited, and is solely confined to the water contained in this liquid, and does not affect its more solid parts. Liquid manure may be applied either to grass or to bare soil, but is preferred for the former. It is distributed over its surface in the manner described under fig. 310, and the quantity required is from 800 to 1,200 gallons the imperial acre. Its effects are sensibly felt both on old pasture, new grass, and on meadow; but where the quantity of the liquid is small, I would prefer applying it to the small paddocks, which are to be found on most farms, and which are usually in pasture and appropriated as a hospital, breeding-ground, or a place of safety for young stock. The results of the application of liquid manure are best appreciated in summer, in which season we will revert to the subject.

(1612.) The space of ground adjoining the liquid-manure tank is a good site for the formation of *composts of various kinds*. Winter is not a favorable season for making composts, fermentation being then in a dormant state. I may state here, however, in general terms, that the carriage of *mould*, as the principal ingredient of a compost, is a laborious piece of work. Such a compost is best made on the spot where the soil is found; but when the foundation of a new building of any kind affords mould which would be removed at any rate, it should be used in compost, and will well repay the trouble of removal. Other materials than mould may, and indeed must, be carried, to form bases for composts, such as saw-dust, spent tanners'-bark, boggy turfing that had been cast in summer and left to dry. These may be mixed with lime, or other fermentable substances, or beneficially watered with liquid manure. The haulm of potatoes, couch-

* Prize Essays of the Highland and Agricultural Society, vol. xiv.

grass gathered from the fallow-ground in summer, dried leaves, and other vegetable refuse, form valuable and substantial ingredients for composts, and when placed beside the tank may be enriched with liquid manure.

(1613.) On laying down haulms of potatoes or quicken for compost, it is usual to throw down the loads without the least regard to order, because the excuse is, that when the potato crop is taken up, every hand is too busily employed to do other things; and in summer, every hand is also put into requisition to gather weeds from fallow-ground. In as far as the potato crop is taken up and the weeds gathered in a proper manner, there can be no objection; but these are no reasons why the refuse created by these operations should be neglected and cause future labor and expense. The usual practice is to throw down the haulms and quickens in haste, and leave them in unequal masses to produce unequal decomposition. Instead of this, a field-laborer should be stationed at the compost-stance to throw them up with a graip into a heap of regular shape, when the materials will not only occupy the least space of ground, but be in the best state to receive any additions of liquid or solid matter, and when the most perishable portions of the materials are covered with the more durable, they are placed in the best state to preserve their properties. The neglect I complain of, of apparently unimportant materials, arises from this cause. There is too frequently a great tendency in farmers and stewards, when conducting labor in fields, to do what they consider the least important part of the work in a hasty and unthinking manner, evidently forgetting that correction of hasty work always creates afterward more labor than the part of the work for which it was neglected is probably worth. Many instances might be given of this sort of *two-handed work*, as it is termed, that is, work which has to be done over again; but I shall confine myself to the case before us. For example, were a field-worker or two placed at the spot where the haulms of potatoes are carried to form a future compost-heap, they could form it according to previous instructions from the cart-loads as they were thrown down; and in this way, when the carriage of the refuse was finished, so would also be the nucleus of the future compost-heap. But if the same materials are laid down at random in a scattered and confused manner by plowmen anxious to get quit of their loads, considerably more labor will be required to place them in the same form of heap; and to do it equally well, more hands and longer time will be required; because the materials have not only to be separated from a confused and compressed state, but to be collected together from a distance into the confined space upon which the heap is desired to be formed. Thus, 1 woman, favorably placed, will throw up with a light graip as much loose material, laid down before her in a small quantity at a time, as 3 or 4 women would place the same quantity and in the same position of materials thrown down and scattered as I have described them.

(1614.) Winter is the season which supplies the greatest quantity of *sea-weed for manure*. On farms adjoining the sea-coast, this manure is carefully collected whenever it is thrown upon the shore after a storm, or by a heavy ground-swell of the sea. Sea-weed is very succulent, and feels mucilaginous, and when, exposed to the summer's sun, is easily dried to ⅓ its bulk, so little solid matter is contained in it. There are 4 species very common on our coast, and these are the *Laminaria saccharina*, consisting of a single linear elliptic leaf, without any mid-rib: the *Laminaria digitata*, or common tangle, a cylindrical stem, sometimes as thick as a walking-stick, and about 2 feet long: the *Fucus vesiculosus*, consisting of a double stem with the edges of the leaf entire, and in the disk of which, near the edges, are immersed a number of air-bladders—or crackers, as they are

vulgarly called—about the size of a hazel-nut, and the use of which seems to be to cause the leaf to float in water: and the *Halidrys siliquosa*, consisting of a waved coriaceous stalk about 4 feet long, greatly branched, dark olive when fresh, but quite black when dry; is also furnished with air-bladders or crackers.

(1615.) The constitution of these plants is very complicated, affording no fewer that 21 ingredients. The first species, *Laminaria saccharina*, afforded the following substances to the analysis of Gaultier de Claubry in 1815:

A saccharine matter—manna.	Hyposulphite of soda.
Mucilage, in considerable quantity	Carbonate of potash.
Vegetable albumen.	Carbonate of soda.
Green coloring matter.	Hydriodate of potash.
Oxalate of potash.	Silica.
Malate of potash.	Subphosphate of lime.
Sulphate of potash.	Subphosphate of magnesia.
Sulphate of magnesia.	Oxide of iron, probably united with phosphoric acid.
Muriate of potash.	Oxalate of lime.
Muriate of soda.	
Muriate of magnesia.	

The composition of the other species, together with the *Fucus serratus*—which is like the *F. vesiculosus*, but without air-bladders—and the *chorda filum*, or thread tangle, is very similar to the one here given.*

(1616.) Sea-weed is applied in a *fresh state to grass land* that is intended to be plowed up for a crop, and it is laid on as thick as to cover the ground. Being applied in winter it does not soon become dry, and the rain and snow that may happen to fall upon it carries the saline ingredients with which it is accompanied into the ground, or among the roots of the grass. The large quantity of mucilage which sea-weed contains, and the numerous salts which it affords, may be the causes of its utility as a top-dressing and as an active manure. It has been recommended to dry sea-weed for the sake of being easily carried into the interior of the country; but this trouble seems unnecessary, because winter, when it is most abundant, is an unfavorable season to dry it, and because there is no more cast ashore than can easily be used by the farms adjoining the coast. On combustion in a certain way, sea-weed yields an impure alkaline substance called *kelp*, which is used as a manure. So long as this substance was used in the arts, it was too expensive for a manure; but its manufacture was stopped some years ago by the introduction of foreign barilla; and its value as a manure is not so well known as to induce the resumption of that manufacture. Many thousands of persons were employed at one time on the shores of the main land and islands of Scotland, in the manufacture of kelp, who are now deprived of that employment. The same substance is manufactured on the coast of Normandy, and sold by the name of *varec*. Sea-weed, when burned in the open air, leaves ashes, which afford most of the inorganic substances mentioned in the above analysis.

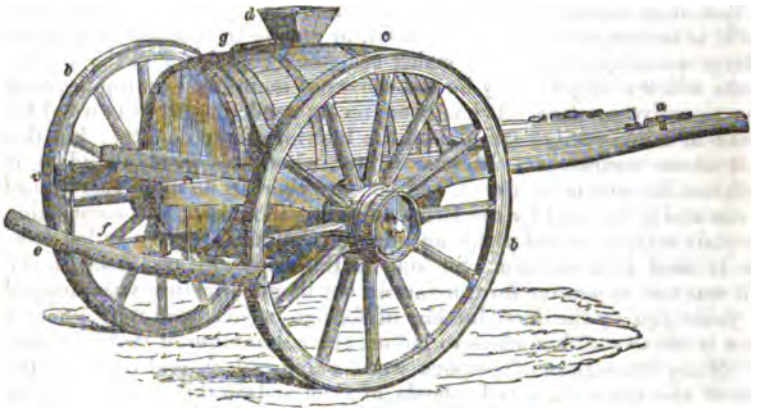
(1617.) [*The Liquid-manure Cart*, for the economical distribution of this valuable manure, the natural production of the farmstead, is now taking its due place among the machinery of the farm. The *water-cart* has been very long in use for the conveyance of water, when the supply of that necessary element for household use has been distant from the steading; and the liquid-manure cart is its offspring, modified by certain additions to adapt it to this change of purpose. The water-cart is usually the naked bed-frame of a cart, mounted on wheels, and surmounted with a cask of a capacity suited to the demands of the establishment. The cask is furnished with a funnel inserted in or attached immediately over the bung-hole; and it is likewise furnished with a spigot or with a stop-cock, inserted into that end of the cask which hangs over the back of the cart. When the water-cart has been drawn to the fountain or the pond from which water is to be conveyed, it is filled either by means of a common pump, raised so high as to deliver the water which it lifts into the funnel of the cask, or the water is lifted with the hand by means of a *scoop*, having a helve of sufficient length to enable the workman to reach the pond on the one hand and the funnel on the other. The scoop best adapted to this purpose is a small wooden pitcher, about 8 inches in depth

* Thomson's Organic Chemistry, *Vegetables*.

and 10 inches in diameter, the helve passing through its sides in an oblique direction, and a little above its center of gravity.

(1618.) The liquid-manure cart, as most commonly used, differs very little from the above, except in its being provided with the distributing apparatus in place of the spigot; but in large establishments the cask is superseded by a covered *rectangular cistern or tank*, which takes the place of a common cart-body. The *watering* of public streets and highways has induced the necessity of the rectangular tank for the distribution of water over the surface of roads, because of the ease with which, by this construction, a greater quantity of water can be put upon one pair of wheels. Here the quantity of water to a given surface is much greater than in the case of a liquid manure, and hence the propriety of a capacious tank for the distribution of *water* on streets, while the same principle, (economy in the expense) leads to the propriety of employing a smaller and less expensive vessel for the distribution of liquid manure, which will not in general be superabundant. For a *liquid-manure cart*, a cask of 120 or 140 gallons contents will be found more economical in first cost than a rectangular tank, and as these machines can be only occasionally in operation, they will, if not very carefully attended to, become leaky while standing unoccupied. In this respect the cask will have a manifest advantage over the tank, for the tightening of a cask is an operation the most simple, by the act of driving up the hoops, while, in the case of the tank becoming leaky, no means of that kind can be resorted to, and the alternative is, either soaking it in water till the wood has imbibed as much of the fluid as will expand its substance and close the leaks, or the vessel must be tightened by some more expensive process. As the more economical of the two, therefore, in point of expense, I have chosen the cask-mounted cart for the illustration. Fig. 310 is a representation in perspective of this cart, of the simplest and most convenient construction. For the more easy means of filling the cask, it is suspended between the shafts of the cart, and this position requires the bending of the axle to nearly a semicircle. The cart is a mere skeleton, consisting of the shafts *a a*, which for this purpose may be made of red pine, their length being about 14 feet. They are connected by a fore and hind bar, placed at such distance as will just admit the length of the cask, while the width between the shafts is suited to the diameter of it. The axle, as already noticed, is bent downward to nearly a semicircle, to receive the cask, and its length will of course be greater than the common cart-axle; even the distance between the caddy-bolts, in a straight line, will be usually greater, but this will depend on the

Fig. 310.

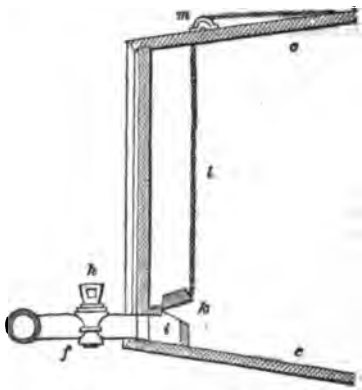


THE LIQUID-MANURE CART

diameter of the cask. A pair of common, broad cart-wheels, *b b*, are fitted to the axle. The cask *c* is suspended on two straps of hoop-iron, 2 inches broad, the ends of which are bolted to the shafts, and the same bolts pass also through the ends of two lighter straps, which pass *over*, and secure the cask firmly in its place. The funnel or hopper *d* is usually fixed upon the top of the cask over the bung-hole, or it may be inserted therein by means of an attached pipe. The distributor *e* may be made of sheet-copper, of cast-iron or malleable iron, or even of wood; the copper will be found the most durable, and it should be at least 1-20 of an inch in thickness. The next best is the patent malleable iron tube; cast-iron, though sometimes used, is not to be recommended; neither is wood desirable, from its liability to choke. The bore of the distributor should be not less than 2 inches, nor is it required to exceed 2½ inches, the length from 7 to 7½ feet, and slightly bent with a uniform curvature, which last property causes it to cover a wider surface of ground than it would do if straight. But in giving the distributor its curvature, care must be taken to avoid increasing the curvature toward the ends, as is sometimes done, to the prevention of uniform distribution of the manure. The ends of the tube must be closed with movable covers, screwed or otherwise fixed, that they may be removed at pleasure, for the purpose of sponging out the tube when it happens to get clogged up with any solid matter. A line of perforations is made along the hinder side of the tube for the discharge of the fluid; these should be at the distance of 1 inch apart, and their opening about ¼ inch diameter. As the area of these discharging orifices cannot be altered at pleasure, nor their amount of discharge altered for any given time it becomes

necessary, in distributing any given quantity per acre, to regulate that quantity by increasing or diminishing the *rate* of traveling the cart over the ground. The distributor is attached to the cask by means of a stem *f* of the same materials and bore as the main tube, and it enters the end of the cask close to the lower chime. A stop-cock is frequently put upon the stem *f* to regulate the discharge, and for this purpose it is very beneficial, serving in a great measure to regulate the quantity per acre, but for the entire setting off or on of the supply, the stem *f* opens into a small chamber inside the cask, which chamber is closed by a flap-valve heavily loaded. This valve when closed stops the discharge, and when lifted the fluid has a free passage to the distributor. The opening of the valve is effected by a small chain attached to the flap, rising to the top of the cask at *g*, where it passes over a small roller, and onward to the fore-part of the cart on the nigh side, where it hangs at hand for the carter to set off or on at pleasure. Fig. 311 is a section of part of the cask, and showing the chamber and valve; *f* is again the stem of the distributor, *h* a stop-cock, *i* the chamber, and *k* the valve, which is the common leather flap or clack-valve well loaded with lead, *c c* is part of the cask, *l* the chain attached to the valve, and passing over the roller *m*.*

Fig. 311.



THE APPARATUS FOR REGULATING THE DISCHARGE OF LIQUID MANURE.

(1619.) When the liquid-manure cart is furnished with a *tank*, the latter can, with equal facility, be placed low for the convenience of filling; thus the axle may be cracked, as in the Liverpool dray-cart, the tank resting on the cranked part of the axle; or the axle may remain straight, and the tank appended below the axle. Such a tank may be conveniently built to contain a ton of the liquid, or about 220 gallons; and the distributing apparatus is the same as for the cask. The prices of these carts vary considerably, partly from construction, and partly from locality. Mr. Crosskil, of Beverley, £25 as the price of the tank cart. In Scotland the average price may be stated at £18, and when mounted with a cask £15: these prices, of course, including wheels and axle.

(1620.) The *cistern* for collecting liquid manure in the farmstead, though apparently simple in its construction, being merely a covered pond or a well, yet serious errors are frequently committed in its formation. The first and most important consideration for the formation of the cistern, is the effect of hydrostatic pressure; inattention to this has caused the failure of many such cisterns. The liquid we have here to deal with, like all other fluids, acts on the bottom and sides of the vessel or body that contains it, with a pressure directly in proportion to the depth at which the fluid stands, without reference to either length or breadth; that is to say, suppose a cistern whose bottom is 12 inches square, and its depth 10 feet, filled with water, every square inch in the bottom will suffer a pressure equal to the hight of a column of water whose base is one inch square and 10 feet, or 120 inches, in hight. The weight of such a column will be 4½ lbs. nearly, and this would be exerted on every square inch on the bottom, or the whole pressure on the bottom would be 625 lbs. the weight of 10 cubic feet of water. There is a natural law that governs the pressure of fluids, which shows us that they press *equally in all directions*, downward, horizontally, and even upward, the last arising from the general statical law, that "*action and reäction are equal and in opposite directions.*" It follows, from these hydrostatical laws, that the lowermost portion of *each side* of our supposed cistern will suffer a pressure from the water equal to that which acts upon the bottom; hence, taking the lowermost inch in the hight of the sides of this cistern, it will be pressed with a force of 52½ lbs. or thereby, or 4½ lbs. on the square inch, and each of the four sides will suffer the same pressure. Suppose, now, that the cistern is elongated in one direction to any number of feet, and again filled to the depth of 10 feet, the pressure on each square foot of the bottom remains the same as before, and so in like manner does it remain the same upon the sides, for the pressure is not altered in any direction, although the proportion of the cistern has been changed. Keeping this in view, it will be seen that length and breadth produce no effect on the pressures that a fluid exerts against the vessel or body that retains it, and that in calculating the resistance to sustain such pressures, *depth* is the only element requiring to be taken into account. It is also to be kept in view that pressure on the bottom or sides is directly as the depth; thus, if our supposed cistern were reduced to 5 feet in depth, the pressure on the bottom would only be one-half, or 2¼ lbs. on each square inch.†

[* As few persons will be at the expense of a cart like this, we recommend the plan of that used at Mr. Wilkinson's Agricultural Institute in Dutchess County, which is found to "work well." *Directions for making it.*—Make an extra portable bottom to the common horse or ox cart, of 1½-inch plank, fastened together by battings on the under side, and groove the upper side longitudinally with ½-inch grooves ½ inch deep, every inch and a half over the entire surface. On this set a hogshead on stocks, and tap the front head, and the liquid will spread over the whole grooved bottom, and by having the back end of the cart the lowest, the liquid will be equally distributed over the land. *Ed. Farm. Lib.*]

[† Must it not occur here to every reader that these are principles which ought to be taught at all our country schools, and with which every farmer's son should be familiar? Suppose a dam to be made, and

(1621.) The conclusion to be drawn from these remarks is that a cistern in the form of a pit or well should be always avoided, unless it can be formed in a natural bed of impervious clay. When such a substratum can be attained, a pit may be adopted, but not otherwise. If such has been found, and the pit dug out, it should be lined with brick, or with stone built in mortar, the bottom being first lined with the same material. When the building approaches to the surface, the wall can gradually be reduced in diameter to a small compass, leaving only an opening of 2 to 3 feet square, which is covered in at small expense, and the saving in this last item is the only apparent advantage that seems to attend the practice of pit-cisterns. Deep cisterns are liable to another inconvenience, of their becoming recipients of spring or of drainage-water; and it is sometimes more difficult to keep such water *out* than to keep the proper liquid *in*, for if springs and their origin lay at considerable hights, their hydrostatic pressure may be so great as to render the prevention of access to their products a process of great difficulty.

(1622.) A *cistern* of moderate depth, not exceeding 4 feet below the out-fall of the drains, may be constructed in any situation, whether in gravel or in clay, and its length can be extended so as as to afford any required capacity; the breadth being restricted to that for which materials for covering it can be most easily obtained, which may be from 3 to 4 feet. Whatever be the stratum in which such a cistern is to be formed, (unless it be perfectly impervious clay,) it should be puddled to the thickness of at least 1 foot with the best clay that can be procured. For this purpose the earthy matters are to be dug out to a depth of 1½ feet lower than the intended sole, and to a width of four feet more than that proposed for the cistern. Two or three thin layers of the prepared clay are then to be compactly laid over the whole breadth of the excavation, and beaten firmly together at all points, making up the depth to 1 foot, and the surface of it brought to a uniform level. Upon this the side-walls are to be founded, and these may be of brick 9 inches in thickness, or of flat bedded rubble-stone 14 inches. The wall should be built in successive courses of about 1 foot in hight, the whole being bedded in mortar, and, as each course is completed, the puddle is to be carefully laid and beaten in behind, in layers of 6 inches or thereby, the first layer being properly incorporated with the foundation puddle, and each succeeding layer with the one immediately preceding it. To prevent the side-walls from being pushed inward by the pressure of the puddle or of the bank, tie-walls of brick or of stone should be formed at every 5 feet of the length of the cistern. These may be 9 inches of brick or 14 inches of stone; and they must have conduits formed at the level of the sole, to allow the liquid to run toward the pump. The sole should be laid all over with brick set on edge, or with strong pavement, the whole having a slight declivity toward one end, where a small well-hole of 9 inches in depth is to be formed to receive the bottom of the pump. The brick, or pavement, as the case may be, is to be bedded on the puddle, and grouted flush in the joints with mortar; and when the walls and sole are built up, they should then be pointed in every joint with Roman cement. The covering is to be effected with strong pavement, of length sufficient to rest on the side-walls, laid and jointed with mortar; or with rough *found*-stones, where such can be procured, and if neither can conveniently be found, a beam of good sound Memel fir may be laid along the middle of the cistern, resting on the tie-walls, and with this bearer, stones of half the length will be sufficient to form a cover. A thin layer of clay may be laid over the stone covers, and upon that a coat of gravel, by which means carts may be allowed to pass over it. To prevent accident, however, it is always desirable to construct the cistern in a situation where it will be as little as possible exposed to the transit of carts; and this may be always obtained at a small additional expense of covered drain to convey the manure from the dunghills to the cistern.

(1623.) The *pump* for lifting the liquid from the cistern to the cart may be either of wood or cast-iron, but the latter is preferable. A common sucking-pump of 3½ inches chamber is quite sufficient; the chamber should be bored out, and the pump-boxes, for durability, should be also of metal, with leathern flap-valves. The hight of the pump should be such as to deliver the liquid freely into the funnel of the barrel, or tank; but if this hight is found to raise the pump-lever above the reach of a man's hand, it is only necessary to joint a light connecting-rod to the lever, its lower end being furnished with a cross handle, and by these means the pump-man will be able to work the pump in the same manner as the lower end of the common pit saw. *Forcing* and *lifting* pumps have been proposed and even employed for the purpose we have here in view, though with questionable propriety; and here it may be proper to explain, that by the term *force-pump* is to be understood a pump that raises water to any hight above the point where the power is applied, by the descent of a solid piston acting in the chamber of the pump, sending the liquid into an ascending pipe, which springs from *below* the piston. The *lifting*-pump differs from this in having a valved piston through which the liquid passes, as in the sucking-pump, on the descent of the piston; and, on its ascent, the valve being now closed, the liquid is *lifted* and forced into the ascending pipe, which, in this case, springs from *above* the piston, the chamber being closed at top with a water-tight stuffing-box. From this brief description the simplicity, both in construction and in management, of the sucking or common pump, as compared with the other two, will be obvious; the cost being also in favor of the first.—J. S.]

water to be collected for a mill, or *fish*, or, as ought to be the case on every farm, for an *ice* pond; how prevalent is the common notion that water covering a large surface would require a strong, wide dam! yet here it is seen that if it covered fifty acres, the lateral pressure would be no greater than if it covered but fifty superficial yards. What we mean to intimate is, what is suggested by every part of this book, and by common reflection to every thinking mind—the wonder that the *landed interest* of the United States does not insist on the establishment of institutions by the General Government, similar to that at West Point—not for the instruction of all directly, for that would be impracticable—but for the *instruction of teachers*, who might be qualified to teach these plain practical principles to as many boys as the military offices can teach the Manual Exercise to the militia. The knowledge taught by the latter may be highly useful where it should alone be used to repel invasion and to suppress insurrection—whereas that taught by honorable and well instructed civil tutors would greatly augment the best sort of power that any nation can possess—the civilizing and blessed *power of Knowledge*. We shall wait anxiously to hear the powerful voice of Governor WRIGHT on this subject, in his Agricultural Address at Saratoga, in September.

Ed. Farm. Lib.]

7. WINTER IRRIGATION.

"Hence Irrigation's power at first was learnt,
A custom ancient, yet but rarely used
In cold and watery climes; though even there
No mode of melioration has been found
Of more effect, or with more ease obtained."

GRAHAM.

(1624.) It is not my purpose here to describe the mode of making irrigated meadows; that being a summer occupation, it will be attended to in due time. At present I shall only describe the watering of meadows in winter. Suppose, then, that the meadows have been formed in a proper manner, and every channel cleaned with proper care, let us at once proceed to let on the water, and regulate its duration so as not only to preserve the vitality of the plants, but to promote their vegetation at an earlier period than the natural call of the season would arouse into action. As the late Mr. George Stephens knew the irrigation of land well, I shall use his words in describing the management of water on meadows in winter. I shall only premise that there are two kinds of water-meadows, one called the *bed-work*, in which the ground is made to decline gently, and the water to flow in the direction of the inclination. The other kind is called *catch-work*, which is only suited to ground having a considerable declivity, and by which the water is brought across the face of the declivity. The object aimed at in both kinds is the greater production of grass. Irrigation, therefore, is one mode of manuring grass-land.

(1625.) "The whole works," as Mr. Stephens directs, "being repaired, and there being generally water enough at this season either for the whole or for part, the sluice should be drawn, when, in the course of half an hour, the conductor and the upper part of the feeders will be nearly filled. The first operation of the irrigator is to adjust the water in the conductor; or, if the meadow is in more parts than one, the water in each conductor must be first regulated. Then he commences anew by regulating the stops in the first feeder; but should there not be sufficient water in the feeder, a little more must be let in, by making the aperture wider or deeper, till the water flows regularly over the sides from one end to the other. From the first he proceeds to the second feeder, and so on, until the water in all the feeders is adjusted. Let the beds of a water-meadow be ever so well formed, yet, by some places sinking more than others, or by the ice raising the surface of the ground, although the water along the banks of the feeders has been ever so nicely adjusted, it often happens that there may be some places between the feeders and drains with too little water, when it will be advisable for the manager to make a third round, redressing inequalities of the surface so as to give *every spot* 1 *inch deep of water*. Every part of the works being regulated, the water should be allowed to run through the whole of October, November, December and January, from 15 to 20 days at a time without intermission. At the expiration of each of these periods, the ground should be made completely dry for 5 or 6 days, to *give it air;* for there are few species of the grasses which form the most nutritive part of the herbage of water-meadows, that will long exist under an entire immersion of water. Moreover, if the frost should be severe, and the water begin to freeze, the *watering must be discontinued*,

otherwise the whole surface will became one sheet of ice; and, *whenever the ice takes hold of the ground, it will undoubtedly draw it into heaps*, which is very injurious to plants." "The object of this early watering of the meadows is to take advantage of the autumnal floods, which bring along with them a variety of putrescent matter, which is found very enriching to land. It is the chief object of the irrigator in those months to collect as much of this manure as possible, and at the same time to shelter the land from the severity of frosty nights. It is therefore requisite to *use as much water as the land will carry without guttering*. I believe it would be difficult to give land, with a dry subsoil and considerable descent, too much water before the weather begins to get warm. It is necessary in those months that the meadows be inspected at least once in 3 or 4 days, to see that the equal distribution of the water is not obstructed by the accumulation of weeds," &c.

(1626.) Simple as these directions are, yet the actual management of the water of meadows is not unattended with difficulty, but requires the exercise of good judgment and great attention. "The adjustment of water flowing over the surface of land," remarks Mr. Stephens, "for the purpose of improving the herbage, is a *very nice operation;* it requires a perfect knowledge of levels and the vegetation of grasses, and *ought never to be intrusted to an unskillful manager*. When the supply of water is, in any state of the stream that supplies it, sufficient for the whole or one-half of the meadow at once, the management becomes pretty easy; for after the works are cleaned, and the water regulated in the autumn, the sluices should be fixed at such a hight as to let in the exact quantity required, when it is allowed to run according to the state of the weather and the season of the year, for 2, 6, 10, or 15 days, without any alteration; and it will be found (unless the water has carried along with it weeds, sticks, or wreck of any kind) to run during that whole period nearly as equally over the surface as when first put on. But when the stream is small, and rising and falling with every shower of rain, the management becomes so much the more difficult that it will require every possible attention of the irrigator to watch and change the water from one part of the meadow to another, or from one bed to another, according to its abundance or deficiency. *Such meadows are indeed ill-managed, although half an hour's work in a day would put everything to rights.* Indeed, let the formation of the meadow be ever so perfect, and the supply of water constant and uniform, yet it is necessary that the manager should survey the whole every 3 or 4 days, to remedy any defect occasioned by the accumulation of weeds, or by a stop being washed away, and thereby cause some places to have too much water, and others too little; so that, in the former case, the grasses might either be killed or very much injured by the generation of scum, or, in the latter case, there would be little or no produce of grass. Small streams are certainly much more at command than large; but if the manager, as is too often the case with a young practitioner, vainly endeavor to water too much ground at a time, he may give one part too much water, and another too little; for on the alteration of the apertures, and adjustment of the water, greatly depend not only the quality but the quantity of the crop."

(1627.) There are many ways of *mismanaging* water-meadows, such as retaining a moist subsoil, or allowing the grass to stand too long before cutting; but there is an error committed at this period of the year, to which I wish to direct your attention, and which is thus characterized by Mr. Stephens. "Another great error generally committed is, allowing the water to run too long at a time, without properly drying the ground. I know some instances where the ground is not attempted to be dried from

the time the water is put on the meadows in autumn till 8 or 10 days before the cutting of the hay; the consequence is that the grass is of the coarsest quality, and the ground becomes so very boggy that the whole crop of grass is obliged to be carried by people to some other place to be made into hay. . . . . A water-meadow," adds Mr. Stephens, "like a garden, will be good for little without due attention. *All dry soils require more attention than moist ones;* for if the water in moist soils should not be so nicely regulated as on sandy or dry land, the crop of grass will *not* be so defective as on *porous soils, where the management has been neglected.* I presume that all dry land that has been converted into water-meadows, in countries where the art of irrigation is not well known, and the supply of water not abundant or regular, is liable to more injury, from imperfect treatment, than land of a moist nature, for plants must have their food at stated times as well as animals, but *this cannot* be the case when the water is irregularly applied."*

(1628.) The mode in which water acts in producing the effects witnessed in water-meadows, has not yet been completely ascertained. It is not the sediment in the water that alone works the charm, for clear water produces similar results; though, no doubt, enriching ingredients carried by the water encourage the growth of plants more rapidly than clear water, as witness the produce of foul-water meadows in the neighborhood of Edinburgh. Professor Low has these observations on the theory of the process: "The *theory* of the process of irrigation," says the Professor, "has not been satisfactorily explained. That the effect is not produced by the mere supply of deficient water, appears not only from the period at which the water is admitted, and when in our climate the soil is always saturated with the fluid, but from the circumstance that *the effect is not produced when the water is allowed to stagnate,* and sink down in the soil, but *when it is kept in a current over it.* When the water is suffered to stagnate, the soil tends to produce carices, junci, and other sub-aquatic plants; but when it is kept in motion, and drained off at intervals, the finest grasses peculiar to the soil and climate are produced. Neither does the fact of the deposition of mud, or other fertilizing sediment, explain the phenomenon; for however such depositions may increase the effect, it is likewise found that water, without the least perceptible sediment, may be employed with success. It has been supposed that the water acts beneficially by maintaining the soil at a higher temperature. Water, at a temperature of 40°, is of greater specific gravity than at a lower temperature; and hence as the water tends to the freezing point, the warmer portion of it is next the ground. Much, however, cannot be ascribed to this cause, in a current so shallow and constant as that which passes over the watered meadow. It is probable, therefore, that the main effect is produced by a mechanical action of the water, acting upon and bringing nourishment to the fibrous roots of the plants."†

(1629.) Although it may be very true, as Mr. Stephens observes, that "however authors may disagree on this interesting subject (the theory of irrigation), I believe all experimentalists acknowledge that early winter watering is necessary to produce early and abundant vegetation; in what way this operates is, as to practical purposes, less material;"‡ yet it is always satisfactory to man to be able to give a reason for what he does. To this view I shall add another theory of irrigation, that has been suggested by Professor Rennie, late of King's College, London. It is believed by

* Stephens's Practical Irrigator and Drainer.
† Low's Elements of Practical Agriculture, Edition of 1838.
‡ Stephens's Practical Irrigator and Drainer.

some vegetable physiologists that plants excrete certain matter from their roots, which proves inimical to the health of other plants of the same kind. Hence it is concluded that grasses do not continue permanently in a healthy state in the same site, because they are in time injuriously affected by their own excretions, which, encouraging the growth of plants of a different nature, such as mosses, spring up and extirpate the grasses. It is supposed to be probable that *every species of grass is not alike affected by its own, or the excrementitious matter from other grasses*, and therefore some species withstand the poison longer than others. Now the water of irrigation, in its descent through the soil and subsoil, washes away or carries off in solution the injurious excrementitious matter exuded by the grasses, and thereby cleanses the soil in which they are growing, free of it. Hence the perennial verdure of irrigated meadows.*

(1630.) In order to arrive at a satisfactory explanation of this subject, and believing that both this theory, as well as the one given by Sir Humphry Davy referred to by Professor Low, contain truth, I proposed some time ago a conjunction of the two theories; and the compound theory certainly explains the four great points of irrigation, namely, that it supplies moisture to the soil in dry seasons and in tropical climates; it affords protection to plants against the extremes of heat and cold; it disseminates manure in the most minute manner to plants; and it washes away injurious matter from the roots of plants. The benefits derived from irrigation I therefore maintained are purely mechanical, and doubted the correctness of Sir Humphry Davy's opinion when he says that "in the artificial watering of meadows the beneficial effects depend upon many different causes, some *chemical*, some mechanical,"† because chemical action only commences *after the act* of irrigation has ceased, as the nature of the following particulars attending irrigation will show. No doubt, the effects of the substances, whatever they may be, which are deposited by the water of irrigation, may be chemical, as well as those of manure applied to grass by the hand of man. But the act of the water in depositing fertilizing materials, can be no more chemical than that of the instruments used in spreading dung upon the soil. The truth is, that whenever the water of irrigation, or the substances contained in it, act *chemically* upon the grass or soil, while subjected to the process, that moment irrigation proves injurious to the plants. The chemical action and the injury are both evinced by the same phenomenon, namely, the existence of white scum floating on the water. "If the weather should be mild," observes Mr. Stephens, "and you suffer the water to run over the meadow *too long without intermission*, a white scum is generated, which *is very destructive to the tender grass*."‡ The particulars of irrigation I referred to are these: "The operation of water bringing matter into minute subdivision; the sediment which it contains when used in irrigation being minutely distributed around the stems of the plants; water protecting plants in irrigation against the extremes of heat and cold, by completely covering and embracing every stem and leaf; and the supplying of moisture to the soil and washing excrementitious matter out of it, are all purely mechanical operations." For, "*could the hand of man* distribute manure around the roots and stems of grass as minutely and as incessantly as turbid water; could it place a covering of woolen texture upon each blade and around each stem of grass, as completely as water can embrace each plant and keep it warm; could it water the grass as quietly and constantly as the slow current of irrigation; and could it wash away hurtful matter from the soil as delicately from the fibres of the

* Quarterly Journal of Agriculture, vol. v. † Davy's Agricultural Chemistry.
‡ Stephens's Practical Irrigator and Drainer.

roots of grass as irrigating water, there *would be no need of irrigation*; the husbandman could then command at will verdant pasturage for his flocks and herds, throughout the year, and in the driest season. *His mechanical* agency would be as effective as irrigation; but constituted as the relative state of things at present are between man and the action of physical laws, he employs irrigation as an instrument of his will, and induces Nature to assist him in maintaining his live-stock by an application of her peculiar mode of acting, under his own guidance, but in which she undoubtedly displays her superiority over him, both in perseverance and dexterity."*

SPRING

"Fled now the sullen murmurs of the North,
The splendid raiment of the SPRING peeps forth;
Her universal green, and the clear sky,
Delight still more and more the gazing eye."
BLOOMFIELD.

We have now deliberated upon every topic which the *indoor* operations of the farm, as they may be called, have suggested; and their consideration, to a minute degree, has extended our lucubrations rather beyond their prescribed limits; and yet, when every subject, as it presented itself in succession, was new, and claimed attention, not only on its own account, but as possessing a controlling influence upon those which are to follow, it was requisite to examine particularly into the principles upon which they were based, that the consequent subjects dependent on similar principles may be the more easily understood, and treated according to their nature. I earnestly hope that this may be the result of the deliberations which we have had hitherto together; and I would feel somewhat confident of that issue, if you have bestowed that attention upon the subjects treated of, which they really require.

Upon the whole, we have seen that winter is the season of repose, of passive existence, of dormancy, though not of death. Spring calls forth the opposite emotions; it is the season of revivification, of passing into active exertion, of hope, nay of confidence in what we do will succeed—of hope ripening into fruition as the earnest of prospective plenty is presented in the reproduction of the herds and flocks, and in the world of life which springs into view immediately after the industrious hand has scattered the seed upon the ground. The joy in contemplating such a prospect to the issue of labor is indescribable. I am unequal to the task of describing it, but would not, if I could, in case of giving you an unsuitable idea of the enjoyment. I would rather that you should go and enjoy the pleasure for yourself; because "the chosen draught, of which every lover of Nature may drink, can be had, in its freshness and purity only at the living fountain of Nature; and if we attempt to fetch it away in the clay pitchers of human description, it loses all its spirit, becomes insipid, and acquires an earthy taste from the clay."

The weather in spring, in the zone we inhabit, is exceedingly variable, alternating, at short intervals, from frost to thaw, from rain to snow, from sunshine to cloud, very different from the steady character of the arctic spring, in which the snow melts without rain, and the meads are covered with vernal flowers ere the last traces of winter have disappeared. The sky is very clear when the air is free of clouds. The winds are very sharp when coming from the N. or N. E. direction; and they are frequent, blowing strongly sometimes from an eastern and sometimes from a western direction. In the former they are piercing, even though not inclining to frost; in the latter they are strong, boisterous, squally, and rising at times

into tremendous hurricanes, in which trees only escape being uprooted in consequence of their leafless state; but by which many a hapless mariner is overtaken and consigned to a watery grave, or dashed without mercy on a rocky shore. The air, when dry, evaporates moisture quickly; and the surface of the ground is as easily dried as wetted. Very frequently snow covers the ground for a time in spring. The severest storms and falls have occurred in February. The memorable falls of the 9th February, 1799, and of the 7th February, 1823, are yet fresh in the recollection of many persons alive, when, for weeks together, the internal communication of the country was entirely stopped. Roads opened up in one direction were again blocked up immediately after by a drift from the opposite direction. There is something truly awful among the hills in a storm of snow in spring. Here is a description of one, true to the life. with all its accompanying prognostics. "One evening, after a day of unwonted tranquillity, dense clouds appear like great snowy mountains in the western part of the horizon, while the few clouds which lie in streaks across the setting sun, are intensely deep in their shadows, and equally bright in their lights As the evening closes in, the clouds disappear, the stars are unusually brilliant, and there is not a breath of air stirring. The old experienced farmer goes out to take his wonted nocturnal survey of the heavens, from which long observation on the same spot has enabled him to form a tolerably correct judgment of what will be the state of the weather in the morning. Two or three meteors—brilliant, but of short duration—shoot along a quadrant of the sky, as if they were so many bright lights of the firmament, dropping from their orbits. He returns and directs his men to prepare for what may happen, as there will certainly be a change of the weather. The air is perfectly tranquil when the family retire to their early pillows, to find that repose which healthful labor sweetens and never misses—

'Till rest delicious chase each transient pain,
And new-born vigor swell in every vein.'

But just at the turn of the night the South gives way, the North triumphs, and the whirlwind, herald of victory, lays hold of the four corners of the house, and shakes it with the shaking of an earthquake. But the house, like its inhabitants, is made for the storm, and to stand secure and harmless; while the wind thunders in the fields around, every gust roaring louder than another among the leafless branches of the stately trees. In a little its sound is muffled, without being lessened, and the snow is heard battering at the windows for an entrance—but battering in vain. Morning dawns; but every lea and eddy is wreathed up; the snow still darkens the air, and reeks along the curling wreaths as if each were a furnace. For two days and two nights the storm rages with unabated violence; but on the third day the wind has veered more easterly, blows rather feebly, and though the snow falls as thickly, it falls uniformly over the whole surface. This continues for two or three days more; and on the coming of the last of these days, the sun, which has not been visible for nearly a week, looks out just before setting, as if promising a morning visit. The night remains clear, with keen frost, and the wind steady at north, and blowing very gently. The sun rises bright in the morning, the storm is over, and the weather remains unbroken for four or five weeks.

"When the appointed days of the snow-storm are numbered, a disturbance again takes place in the atmosphere, but it is of a different kind from the former. There are little sheets of lightning playing momentarily in the lower atmosphere, and the lustre of the stars is diminished; but still there is no cloud. The wind, however, dies away to a dead calm toward

evening, and all is ready for the breaking storm. That operation is the first performed by the spring, and we shall borrow the words of the 'British Naturalist' wherein to describe it: 'As the spring gets the mastery, which is aided by the condensation which takes place during the night, it rises to a wind, the sound of which cannot be mistaken. The rigidity of trees, window-frames and other wooden fabrics through which it passes is relaxed; the withered grass and reeds, when these are exposed, moisten; and the rattling and thumping are succeeded by murmuring harmony, in which, compared with the other, there is a good deal of music; and as the morning advances and the animals come abroad, and man begins to be active, the hard metallic sounds are gone, and there is a softness about Nature. There is always a delightful transparency about the atmosphere, because the little *spiculæ* of ice are gone, and the heat of the air is too much occupied in converting the snow and ice into water, for changing much of that into vapor. When the change is accompanied by rain, it is far more pleasant at the time, and there is a danger, almost a certain one, that the spring will be treacherous; and that, in consequence of the great heat required for melting the snow, and the evaporation of the rain together, frosts will return long before the process of thawing, so comparatively slow, is completed. The slow melting of snow by rain, compared by that of a warm atmosphere which is constantly shifting by the wind, can be easily understood, when it is remembered that the water which falls, even if it had the temperature of the greatest summer heat, would be cooled down to the freezing point in melting half its weight in snow. But as the temperature can only be a little above freezing, the water will have the temperature of 32° before it has cooled perhaps $\frac{1}{10}$ of its weight; and as the water is a bad conductor of heat, and great part of the action of the oblique rays of the sun reflected away from its surface, a rainy breaking of a storm is almost sure to be followed by frost, if it do not happen when the season is far advanced.' In such a situation, and under such circumstances, the storm not unfrequently passes away in what is emphatically termed a *gentle* thaw; and when this is the case, the spring comes under the most favorable circumstances. The snow is dissolved by atmospheric influence alone, without any rain from the clouds; although there are generally light clouds hovering about, ready to produce rain if a returning frost should render a contest of the elements necessary. Besides its rare pleasantness, the gentle thaw is attended with several beneficial consequences. In the first place, there is no flooding of the low grounds, and no washing of the soil from the more elevated ones; but the snow forms a trough for the discharge of the water into which it is melted, and thus the coldest of the snow-water does not reach the surface of the land. In the second place, the water produced by the melting of the snow sinks gradually into the earth, and the earth has been opened to receive a greater store than if it had been pelted by rain during winter. This is occasioned by the radiation of the heat from the lower strata of the earth, which is confined by the snow and turned back again to act upon the earth. In the third place, this last circumstance produces a beginning of the spring under the shelter of the snow, which could not have taken place with free exposure to the atmosphere. The blade of the plant is protected, and the roots have heat and moisture, and the air is excluded from them. They are thus placed under the most favorable circumstances, and they are stimulated accordingly. The difference in this respect is very considerable; for if, owing to the action of the wind during the fall, or to any other cause, one portion of a field has been exposed to the air while the frost continued, and another covered by the snow, it will be found that vegeta-

tion upon the part which the snow covered will be fresh, green and vigorous, long before that upon the exposed part shows any decided signs of action. This, by the way, is the real cause why spring is so rapid, and meets with so few reverses, where the winter is firm and decided, but of moderate length, than it does when the winter is variable. In such a place as we are alluding to, the spring wind usually freshens as the snow disappears; and this latter quickens the melting of the snow, and dries the surface of the ground. When the clods begin to dry, the lark soars aloft at the streak of dawn, calling the plowmen to their labors. Nor are they backward to obey; for they and their teams have been rested during the storm, and then return to their labor with fresh vigor."* I have been the more induced to give this long extract, as, besides containing a true description of a spring snow-storm, it indicates its prognostics, and the peculiar states in which the atmosphere presents itself at this season.

Spring is a busy season on the farm. The cattle-man, besides continuing his attendance on the fattening cattle, has now the more delicate task of waiting on the cows at calving, and providing comfortable lairs for new dropped calves. The dairy-maid commences her labors, not, it is true, in the peculiar avocations of the dairy, but in rearing calves—the supply of a future herd—which, for a time, are indulged with every drop of milk the cows can yield. The farrows of pigs now claim a share in her solicitude. The shepherd, too, has his painful watchings, day and night, on the lambing ewes; and his solicitude and tenderness for the simple lambs, until they are able to frisk and gambol upon the new grass, is a scene of peculiar interest, and insensibly lead to higher thoughts. "When we see the attention of a judicious shepherd upon these occasions, we cannot refrain from thinking of the unspeakable condescension and kindness of Him who 'feeds his flock like a shepherd, gathers the lambs into his arms and carries them in his bosom, and gently leads those that are with young.'" The condition of the fields demands attention as well as the reproduction of the stock. The day now affords as many hours for labor as are usually bestowed at any season in the field. The plowmen, therefore, know no rest for at least twelve hours every day, from the time the harrows are yoked for the oat-seed until the potato and turnip crops are sown. The beans first demand the plowman's aid, and then the lea ground, turned over at intervals of fresh weather in winter, is ready, with a due degree of drouth, to receive its allowance of oat-seed. The turnip land, bared as the turnips are consumed by sheep, is now plowed across, or ridged up at once for spring wheat, should the weather be mild and the soil dry enough, or else the ridging is delayed for the barley-seed. The fields containing the fallow land now receive a cross-furrow, in the order of the fallow-crops, the potatoes first, then turnips, and lastly the bare fallow. Grass seeds are now sown among the young autumnal wheat, as well as among the spring wheat and the barley. The field-workers devote their busy hours to carrying seed to the sower, turning dunghills in preparing manure for the potato and turnip crops, and continuing the barn-work to supply litter for the stock yet confined in the steading, and to prepare the seed-corn for the fields. The hedger now resumes his work of water-tabling and scouring ditches, cutting down and breasting old hedges, and taking care to release the sprouting buds of the young quicks from the face of the hedge-bank, fig. 42, which he planted at the commencement and during fresh weather in winter. The steward is now on the alert, sees to the promotion of every operation, and intrusts the sowing of the

* Mudie's Spring. Since I last had occasion to quote Mr. Mudie's sentiments on the influence of Winter, death has seized the hand of him who was so capable of wielding the pen.

crops to none but himself, except a tried hand, such as the skillful hedger. Thus every species of laborer has his work appropriated for him at this busy season; and as the work of every one is individually defined, it is scarcely possible for so great a mistake to be committed as that any piece of work should be neglected by all.

The farmer himself now feels that he must be "up and doing;" his mind becomes stored with plans for future execution; and in order to see them executed at the proper time and in the best manner, he must now forego all visits, and remain at home for the season; or at most undertake an occasional and hasty journey to the market-town to get quit of surplus grain, should the draughts have a leisure day to deliver it. The business of the fields now requiring constant attendance, his mind as well as body becomes fatigued, and, on taking the fireside after the labors of the day are over, seeks for rest and relaxation rather than mental toil. He should at this season pay particular attention to the state of the weather, by observing the barometric and thermometric changes, and make it a point to observe every external phenomenon that has a bearing upon the changes of the atmosphere, and be guided accordingly in giving his instructions to his people.

During a snow-storm in spring, wild-birds, becoming almost famished, resort to the haunts of man. The robin is a constant visitor, and helps himself with confidence to the crumbs cast out for his use. The male partridge calls in the evening within sight of the house in hopes of obtaining a morsel before collecting his covey together to rest for the night upon the snow. In the severe snow-storm of 1823, several covies used to approach my own door at sunset, and oftentimes, ere putting down the sheaf of barley for their nightly meal, at the root of an old beech-tree, the old cocks reminded me of my hospitality, though that was unnecessary in the circumstances, by their loud crisp-like call, before retiring to rest. I believe that, had it not been for this timely supply of nourishing food, they would all have perished in the severity and length of that memorable storm. Hares came to the very door at sunset, and in the moonlight, to receive what food was set down on purpose for them; and so powerful a tamer is hunger of creatures of the most distant habits, that even the wood-pigeons, in large flocks, used daily to frequent an orchard immediately behind the house to pick the curly greens which had grown so tall as to overtop the snow, their favorite food—the Swedish turnip—being then buried out of reach in the snow. The rooks now make desperate attacks upon stacks, and, if allowed, soon make their way through the thatch. Always making their attack at the top, they seem to be aware of the exact place where the corn can be most easily reached. The sparrows even burrow in the thatch, and the lively tom-tits, with a strength and perseverance, one should think, beyond their physical abilities, pull out whole straws from the sides of the stacks, to bring the heads of corn within their reach. Farther on in the season the insect world come into active life in myriads, to serve as food for the feathered tribes. Rooks, with sturdy walk and independent gait, diligently search the ground for them, in the wake of the plow, to feed their young therewith. Tom-tits clamber round every spray of trees which indicate an opening of their floret buds. The swallows at length appear, giving animation to the air, and the stream of migration to the northward betokens the approach of genial weather.

"By the time the season is fairly confirmed, the leisure hours of the cottagers," and of plowmen, who are in fact cottagers of the best condition, are spent, in the evening, "in the pleasing labor, not unaccompanied with amusement, of trimming their little gardens, and getting in their early

crops. There is no sort of village occupation which men, women, and children set about with greater glee and animation than this; for, independently of the hope of the produce, there is a pleasure to the simple and unsophisticated heart in 'seeing things grow,' which perhaps they who feel the most are least able to explain. Certain it is, however, that it would be highly desirable, that not only every country laborer, but every artisan in towns, where these are not so large as to prevent the possibility of it, should have a little bit of garden, and should fulfill the duty which devolved on man in a state of innocence, to 'keep it and to dress it.' It is impossible for any one who has not carefully attended to the subject, to be at all aware how strong the tie is which binds man even to a little spot of his native earth, if so be that he can consider it as his own, and that he himself, and those on whom he loves to bestow it, are to enjoy the fruit. This is the very strongest natural hold which binds a poor man to his country, and to all those institutions established for the well-being of society. Show me the cottage, the roses and the honeysuckles on which are neatly trimmed and trained, and the garden behind is well stocked with culinary herbs and a few choice flowers, and I will speedily find you a cottager who never wastes his time or his money, or debases his mind, and learns the broad road which leadeth to destruction,' in the contamination of an ale-house. If the garden is neat, one may rest assured that the cottage, however humble it is, is the abode of contentment and happiness; and that however simple the fare may be, it is wealth and luxury in full store to the inmates, because they are satisfied with it, and grateful for the possession of it."* I believe that the contentment of the lot of the Scottish married plowmen, and of the attachment to the farm upon which they serve, may be traced to the principles evolved in these remarks. No doubt, much yet remains to be done to inculcate on them and their families the advantages of practicing habits of personal and domestic cleanliness. Hinds' houses, in this respect, might be much improved, and which, if they were, an air of tidiness and comfort would attend their dwellings, which at present is generally wanting. A great deal depends on the example of the farmer himself; for while he keeps his garden and shrubbery and little avenue in a slovenly manner, it is not to be expected in servants to evince a desire to excel their master. A farmer's garden gets a trimming twice or thrice a-year, and in the mean season, weeds may riot in it without molestation, and its produce may be plucked as best suits the convenience or caprice of the kitchen-maid. Doubtless, considerable crops of vegetables are raised in these gardens, but more through strength of manure than skill of culture. It is, I am aware, inconvenient to obtain the assistance of the professional gardener in the country when his services may be most wanted; but on a farm on which a hedger is employed, he should be taught as much of gardening as to be able to keep the garden in decent order in the absence of the gardener, whose principal duty should be to crop the ground. A field-worker now and then would keep the weeds in subjection, and allow both the sun and air a freer access to the growing plants.

Toward the end of spring, the farmer thinks of disposing of his fat cattle; but, should he not be offered the price he considers them to be worth, he keeps them on, and even threatens to put them to grass. The dealer and butcher affect to be shy purchasers at this season, knowing there is plenty of fat stock in the country; but, nevertheless, are unwilling to allow a prime lot to slip through their hands, and therefore keep a sharp look-out on all the best lots for disposal. The ready means of steam conveyance to

* Mudie's Spring.

London for fat stock, gives the farmer a vantage with the butcher, which the latter now knows wel closing a ready bargain on the best conditions he c

8. COWS CALVING AND CALV

"When she has calved, then set the dam aside
And for the tender progeny provide."
DRYDE

(1631.) The first great event in spring, on a farm the *calving of the cows;* not that this event should though most breeders of farm-stock are anxious to ticularly bull calves, (1238,) and on that account c as December and January—but by far the greater p of cows are not desired to begin to calve till Febru calving continues in good time till the middle of

e calves are accounted late, and then seldom retained as a *breeding*-stock, namely, that portion which is specially set aside te its kind. Reluctance to late calves arises from no objection rity of breediug, for earliness or lateness of birth can have no at respect; but chiefly because an early calf possesses the ad- having passed through its period of milking in time to be on grass, as soon as it affords a plentiful supply of food. From eks at this season is a period of great anxiety for the state of and, indeed, till her calving is safely over, the life of the most w is in jeopardy. Every solicitude, therefore, that can conduce sing in safety over this critical period, ought to be cheerfully

You may remember the treatment which I recommended some r cows in winter, in reference to food and exercise, in (1215) When the cow first shows heavy in calf, which is usually ixth month, the litter in the court should not be allowed to be- eep, as over-exertion in walking over soft, loose litter and dung such an excited action of the animal's system, and most prob- womb, as to make her slip calf—or to *slink the calf*, as it termed. The litter in a court which is constantly trampled t freedom, becomes so firm as to afford a good footing; but different in a cows'-court, which is usually filled with loose led from the byre; and as it is walked upon only for a short day by cows, which, when in calf, are not disposed to roam t, it never becomes firm. To render the litter as firm as may he circumstances, the cattle-man should spread each barrowfull ls it out, taking care to mix a due proportion of the straw with

Cows, as they calve, and after it is considered safe for them to he air again, should not be allowed to go into the court at the with those yet to calve; because calved cows soon *come into* he phrase has it, that is, soon become desirous of the bull; and approach this condition there is a very prevalent desire on the e other cows to ride upon them, and, what is remarkable, espe- ose yet uncalved. As may be supposed, such violent exertions, oft litter, are likely to produce injurious results on the uncalved ven causing inversion of the calf in the womb, by bringing on ion, or by causing the slipping of the calf. The time of the day ows in these different conditions should go out, may be left to ion of the cattle-man, who should, however, keep this considera- ew, that as cows, after having calved, become more tender in t than before, they should enjoy the best part of the day; for rom 12 to 2 o'clock.

Cows may be ascertained to be in calf between the fifth and sixth their gestation. The calf quickens at between 4 and 5 months; that period no disagreeable change has been caused in the con- f the cow; but from this period she becomes subject to several The calf may be felt, by thrusting the points of the fingers e flank of the cow, when a hard lump will bound against the and the feeling will be communicated to the fingers. Or when or two of *cold* water is drank by the cow, the calf kicks, when a e sort of motion may be observed in the flank, by looking at it ind, and, if the open hand is then laid upon the space between and udder, this motion may be most distinctly felt. But it is not circumstance that the calf can be felt at so early a period of its

existence; for when it is lying in a natural position in the interior of the womb it cannot be felt at all; and when it lies near the off or right side of the cow, it is not so easily felt as on the opposite side. So that, although the calf cannot be *felt* at that early stage, it is no proof that the cow is not in calf. Some cow-dealers show great acuteness in ascertaining whether a cow is in calf. One, whom I knew, that was bred a tailor, told me that when a resinous-looking substance could be drawn from the teats by stripping them firmly, the cow is sure to be pregnant. After this period the flank in the near side fills up, and the general enlargement of the under part of the abdomen affords an unequivocal symptom of pregnancy.

(1635.) The *womb* of the cow is a bag of irregular form, having a chamber or division attached to each side called the *horns of the womb*, and so called, perhaps, because of the form they present in an unimpregnated state, of the large curved horns of a black-faced tup. The womb consists almost entirely of muscular fibres, with a large proportion of blood-vessels, and of cellular matter, which admits of contraction and extension. Its ordinary size in a large cow is about 2½ feet in length, but when containing a full-grown fœtus it is 7 feet in length. This is an extraordinary adaptation to circumstances which the womb possesses, to bear an expansion of 7 feet from about ⅓ of that length, and yet be capable of performing all its functions. The use of the horns seems to be to form a lair for the calf, and each is occupied by the calf according to its sex. The quey-calf occupies the near, and the bull-calf the off-side horn. So that a quey-calf is more easily felt in the younger stage than the bull-calf; and indeed the latter is frequently not felt at all until the seventh month, when other symptoms afford proofs of pregnancy.

(1636.) The exact time of the cow's calving should be known to the cattle-man as well as by the farmer himself, for the time when she was served by the bull should have been marked down. Although this last circumstance is not a certain proof that the cow is in calf, yet if she passes the period when she should take the bull again without showing symptoms of season, it may be safely inferred that she became in calf at the last serving, from which date should then be calculated the period of gestation, or of *reckoning*, as it is called. A cow generally goes 9 months, or 273 days, with calf, although the calving is not certain to a day. Nay, she sometimes goes as much as 3 weeks, over her time, but far more frequently only 9 or 10 days. When a cow passes her reckoning for a number of days, she will be found most commonly to bear a bull-calf.

(1637.) Cows are most liable to the *coming down of the calf-bed*, to which I formerly referred, (1300,) when near the period of calving, between the eighth and ninth months, and, from whatever cause it may originate, the position of the cow in which she lies in her stall should be attended to, by keeping her hind part as high as the fore, by raising the litter. The immediate cause of the protrusion of a part of the womb, is the pressure of the calf's fore-feet and head against that part of it which is opposite to the vaginal passage, and the protrusion mostly occurs when the calf is in its natural position; so that no great danger is to be apprehended from the protrusion, although it is better to use means to prevent its recurrence, which is an *unnatural* occurrence, than to trust to consequences by over-confidence.

(1638.) Much more care should be bestowed in administering food to cows near the time of their reckoning, than is generally done; and the care should be proportioned to the state of the animal's condition. When in high condition, there is much risk of inflammatory action at the time

of parturition. It should, therefore be the farmer's care to check every tendency to obesity in time. This may be effected by giving fewer turnips and more fodder than the usual quantity; but some cows when in calf, and have been long dry, will fatten on a small allowance of turnips; and there is this disadvantage of administering food in too dry a state, that it tends to aggravate one of the tendencies of the system you are attempting to check, namely, the inflammatory. Other means must therefore be used, along with a limited allowance of food, and, in as far as medical treatment can be applied to the case, there is nothing so safe as bleeding and laxatives. "Every domestic animal like the cow," observes a very sensible writer on this subject, "is to be considered as by no means living in a state of nature. Like man himself she partakes of civilized life, and of course is subjected to similar infirmities with the human race. The time of gestation is with her a state of indisposition, and every manager of cattle should should be aware of this, and treat her with every attention and care during this time. The actual diseases of gestation are not indeed numerous, but they are frequently very severe, and they occasion always a tendency to slinking, or the cow slipping her calf. As the weight of the calf begins to increase, it will then be necessary to take some precautions, and these precautions will consist in an attention to her diet, air and exercise."*

(1639.) It is the 8th and 9th months that constitute the critical period of a cow in calf. The bulk and weight of the fœtus cause disagreeable sensations in the cow, and frequently produce feverish symptoms, the consequence of which is costiveness. The treatment for this is bleeding once or twice, in proportion to the strength and condition of the cow, and the administering of laxative medicine and emollient drinks, such as a dose of 1 lb. of Epsom salts with some cordial mixture of ginger and carraway and treacle, in a quart each of warm gruel and sound ale. Turnips, of course, are given, and they have a laxative tendency. Potatoes, too, are recommended; but I confess I entirely object to giving potatoes to cows at any time, because of their great tendency to produce hoven, of which, if an attack were to overtake a cow far advanced in calf, would either kill the calf in the womb, or cause the cow to slip it. Turnips, though perhaps not of so laxative a nature as potatoes, are yet much safer; though it is quite true that Swedish turnips, at the season of the year when cows calve, are solid in their texture, and have less sap in them, and are therefore more binding in their nature, but on account of these properties they are the better adapted for feeding. In cases of indigestion, consequent on inflammatory action, I have seen the substance of this turnip in the maniplies, or third stomach, squeezed flat like the husks of apples from a cider-press.

(1640.) Having suffered the loss of two or three cows by costiveness, immediately after calving, I was induced to try *oil-cake* as a laxative along with the Swedish turnip. The cake was given to the cows for 2 months, one before and one after calving, and its valuable property of keeping the cows in a fine laxative state, and at the same time in high health, was truly satisfactory; and on continuing the practice every year afterward, a similar mishap never overtook my cows. The quantity given to each cow daily was 4 lbs., at an intermediate time between the feeds of turnips. The time of giving it was as regularly adhered to as that of the turnips, and when the hour arrived, at 10 o'clock in the forenoon, for its distribution, every cow expressed the greatest anxiety for the treat. It was broken to them in

* Skellett on the Parturition of the Cow.

small pieces with a hammer, which is a tedious manner of breaking it when a number of cattle are supplied with it at a time; but the process can be easily and expeditiously performed by the use of the oil-cake breaker, fig. 264.

(1641.) But the opposite state to obesity is also to be avoided in cows in calf, namely, that of weakness and impoverishment of condition. In such a case, bleeding of course is improper, and the cow should rather have good and nourishing food, such as mashes of boiled barley, and turnips and oil-cake, not given in large quantities at a time, but frequently and moderately, with a view of laying on flesh in a gradual manner, and of avoiding the fatal tendency to plethora. I believe he who gives oil-cake to his cows before and after their calving, as I have recommended, need entertain no apprehension of their safety in as far as regards their calving, in whatever condition they may happen to be, because it proves a laxative to the fat, and a nourishing article of food to the lean cow, and in both secures a proper state of all the parts connected with calving.

(1642.) *Slinking*, or slipping calf, is both a vexatious occurrence and a great loss to the breeder of stock. It is not only a loss of the calf itself, but the want of it makes a blank in the number of the lot to be brought up in the season, and which must be made up by purchase. And it is a very vexatious occurrence in a cow that is desired to be kept as a brood cow, inasmuch as she never can again be depended upon to bear a living calf, the probability being that she will slip every calf afterward at one time or another of her gestation. Why this should be, has never been satisfactorily explained, though the fact is undoubted. The only plan for the farmer to avoid a future disappointment by such an untoward event, is to draw the milk from the cow as long as she gives it, and then fatten her for the butcher. I had a very fine Short-Horn cow, bred by myself, that slipped her second calf; and not being disposed to trust her again, fed her off, when she became extraordinary fat, and yielded very superior meat; and this was the only cow I ever had which was a victim to the complaint we are speaking of. This is the same cow that I referred to before, as having yielded so great a quantity of tallow. (1324).

(1643.) The *causes* of this troublesome complaint are various, arising chiefly, however, from violent exercise, the effect of frights, bruises, and knocks; "but," says Skellett, "a more common cause of slinking than any of them, and which is peculiar on the influence of this animal, is a disagreeable *nauseous smell;* the cow is remarked to prepossess a very nice and delicate sense of smelling, to that degree that the slinking of one cow is apt, from this circumstance, to be communicated to a great number of the same herd: it has been often known to spread like an infectious disease, and great losses have been suffered by the cow-feeders from the same."* If there is any truth in the last cause mentioned in producing the complaint, and which I believe to be true, as I know that cows are endowed with a very delicate sense of smell, you will require no arguments to convince you of the necessity of keeping everything in a byre *occupied by breeding-cows* in a clean and wholesome state; to have every particle of filth removed daily from the feeding-troughs before and the urine-gutters behind them; and to have the byre thoroughly ventilated when the cows go out to the court. The same circumstance will show you the propriety of preventing any pig being slaughtered on the litter on which cows are accustomed to walk, and of not allowing any animal to be bled, and of any blood to be spilled near the byre. When any of the cows require bleed

* Skellett on the Parturition of the Cow.

ing, the operation should be performed in a different apartment from the byre.

(1644.) Whenever a cow shows symptoms of slinking, which may be observed in the byre, but not easily in the grass-field, she should be removed immediately from her companions. The *first symptoms are* a sudden filling of the udder before the time of reckoning would warrant, a looseness and flabbiness and redness of, and a yellow glairy discharge from, the vagina, and a giving way of the ligaments or couples on each side of the rump. When any of these symptoms are observed, the cow should be narrowly watched, and means of preventing slinking instantly adopted, one of the chief of which is blood-letting. This should be followed by a laxative dose. But these means may prove ineffective if the symptoms made their appearance suddenly, and went through their course rapidly, and the calf be slipped after all.

(1645.) The risk which the cow runs, after slinking, is *in not getting quit of the cleaning*, or *afterbirth*, or *placenta*, because in such a case it is in an unprepared state to separate from the womb. Should it be retained, a certain degree of corruption is apt soon to take place in it, which will produce a very nauseous smell, that may remain for some time, as the cleaning may only pass away by degrees by putridity. Whenever the cleaning does not come away in the course of a few hours, or at most a day, the assistance of the veterinary surgeon should be obtained. The following cordial drink will promote the cleansing; juniper berries 3 oz., bay berries 2 oz., nitre 1 oz., anise seed 1 oz., gentian ½ oz., gum myrrh ½ oz., asafetida ½ oz., well pounded together, for 1 dose, and given in 1 quart of mild ale made warm in 1 quart of pennyroyal tea. This drink should be given fasting, and repeated every day till the cleansing is evacuated.*

(1646.) After such a mishap the cow should be kindly treated in her diet, by the administration of mashes, gruels, and cordials, and her bowels kept in an open state at the same time, until her system recover its tone.

(1647.) As to the *prevention* of the recurrence of this vexatious complaint, though I believe that the best thing for the farmer is not to attempt any, but just to milk and fatten the cow, yet as a natural desire may be felt to retain a valuable and favorite cow, I shall mention some means which may be used, and which may have the effect of enabling the cow again to bear a living calf; and there is certainly this inducement to try means, that after the womb has again assumed its healthfull tone, so as to retain the fœtus till the proper time, there is a probability of the complaint not returning, provided the following means are used every season during the period of gestation. Skellett mentions these preventive measures: "When a cow has slipped her calf, in the next gestation she should be early bled, her body should be kept open by cooling physic; she should not be forced to take any more exercise than what is absolutely necessary for her health, and her interfering with other cattle guarded against by keeping her very much by herself. At the same time," he adds, "it must be observed that, though it is necessary to preserve a free state of the bowels, a laxity of them will often produce this accident; cows *fed very much upon potatoes*, and such other watery food, *are very apt to slink*, from their laxative effects. In the food of the cow, at this time, a proper medium should be observed, and it should consist of a due proportion of other vegetable matter mixed with the fodder, so as the bowels may be kept regularly open, and no more." Our author, however, does not see that these remedial measures can be very useful. If the cow is in high condition indeed, she should be reduced in

* Skellett on the Parturition of the Cow.

condition; if she is very low, she ought to get nourishing food and strengthening medicines, and if she is much annoyed by nauseous smells, these should either be counteracted, or the cow withdrawn from them. To counteract bad smells, Skellett recommends the following mixture to be formed, and rubbed a little every day on the parts the cows commonly smell each other: Barbadoes tar, 3 oz., balsam of sulphur, 3 oz., rectified oil of amber, 1 oz., fine oil of thyme, 1 oz.; and animal oil, 1 oz. "Of what nature that odor is," continues Skellett, "which gives offence, we cannot altogether be certain; but the author has remarked that its effects occur at one season more than at another, and particularly when the weather has been wet, and the cows have long been kept at grass. From this fact," he concludes, "it will appear that the smell is of a vegetable nature, and connected with their feeding at that time."* It is understood that cows that are fed in the neighborhood of and in woods, and that live on coarse, rank pasture in autumn, are most liable to this complaint. In Switzerland, the complaint increases after the cows are put on rank pastures in autumn.

(1648.) Though slinking is spoken of as an infectious complaint, it has no property in common with any contagious disease; but sympathetic influence being a main cause of it, its result is as fatal as if direct contagion had occasioned it.

(1649.) About a *fortnight before the time of reckoning, symptoms of calving indicate themselves* in the cow. The loose skinny place between the vagina and udder becomes florid; the vagina becomes loose and flabby; the lower part of the abdomen rather contracts; the udder becomes larger, harder, more florid, hotter to the feel, and more tender-looking; the milk-veins along the lower part of the abdomen become larger, and the coupling on each side of the rump-bones looser; and when the couplings feel as if a separation had taken place of the parts there, the cow should be watched day and night, for at any hour afterward the pains of calving may come upon her. From this period the animal becomes easily excited, and, on that account, should not be allowed to go out, or be disturbed in the byre. In some cases, these entire preparatory symptoms succeed each other rapidly, in others they follow slowly; and the latter is particularly the case with heifers with the first calf. These symptoms are called *springing* in England, and the heifers which exhibit them are *springers*.

(1650.) In different parts of the country, different practices exist in regard to attending on cows at calving. In the southern counties of Scotland, the shepherd conceives it to be his duty to attend on the occasion, assisted by the cattle-man, and other men if required. In the northern counties, on the contrary, the calving is left to women to manage. I think this difference in practice must have arisen from the *degree of assistance* required at the operation. In the southern counties, the large class of cows almost always require assistance in parturition, the neglect of which might cause the cow to sink from exhaustion, and the calf to be strangled or drowned at its birth. Powerful assistance is sometimes required and can only be afforded by men, the physical ability of women being unequal to the task. Indeed, I have witnessed the assistance of 8 men, in one way and another, given in the extraction of a calf coming even in a natural position. The calf was the first of twins, was very large, and this was the first labor of the heifer. I shall never forget the distressing cries of the poor creature when racked with pain, nor the patience and sympathy evinced by all the men who were summoned to assist. It was an interesting case, conducted by an experienced shepherd, and lasted altogether

* Skellett on the Parturition of the Cow.

about five hours. The cow and calves were much exhausted; but all recovered in the course of a few days. In the northern counties cows are not only smaller, but their calves are smaller in proportion, so that most cows calve without assistance; and, therefore, women may manage both cow and calf without difficulty. Of the two modes of conducting this delicate and ofttimes tedious operation, I should say that it falls most legitimately under the guidance of the shepherd, who seems to be the natural guardian of all the young stock brought forth on a farm; and where there is no shepherd, the cattle-man should take the charge, the farmer himself, in all cases, giving his sanction to the means about to be used, as it is but fair that he himself should bear the heaviest portion of the responsibility connected with this dangerous procedure.

(1651.) There are a few preparatory requisites that should be at hand when a cow is about to calve. Two or three rein-ropes are useful, to fasten to the calf if necessary—a *flat, soft* rope being the best form, but common rein-ropes will answer. A mat or sheeting, to receive the calf upon in dropping from the cow, should she be inclined to stand on her feet when she calves. The cattle-man should have a calf's crib in R, fig. 3, Plate III, well littered. The shepherd should pare the nails of his hands close, in case he should have to introduce his arms into the cow to adjust parts; and he should supply himself with goose-grease or hog's lard to smear his hands and arms. Goose-grease is best for making the skin smooth, and withstanding evaporation. It may be that a few sacks may have to be put under the cow to elevate her hind-quarter, and even block and tackle may be used to hoist her up by the hind legs, in order to adjust the calf in the womb. These last articles should be ready at hand if wanted. A little straw should be spread on the floor of the byre, to place the new-dropped calf upon.

(1652.) All being thus prepared, and the byre-door closed to keep all quiet, the cow should be attended to every moment. The symptoms of calving are thus exactly described by Skellett, as they occur in an easy and ordinary case. "When the operation of calving actually begins," he says, "then signs of uneasiness and pain appear; a little elevation of the tail is the first mark; the animal shifts about from place to place, frequently getting up and lying down, not knowing what to do with herself. She continues some time in this state, till the natural throes or pains come on; and as these succeed each other in regular progress, the neck of the womb, or *os uteri*, gives way to the action of its bottom and of its other parts. By this action the contents of the womb are pushed forward at every throe; the water-bladder begins to show itself beyond the shape, and to extend itself till it becomes the size of a large bladder, containing several gallons; it then bursts, and its contents are discharged, consisting of the *liquor amnios*, in which, during gestation, the calf floats, and which now serves to lubricate the parts, and render the passage of the calf easier. After the discharge of the water, the body of the womb contracts rapidly upon the calf; in a few succeeding throes or pains, the head and feet of it, the presenting parts. are protruded externally beyond the shape. The body next descends; and in a few pains the delivery of the calf is complete."* The natural and easy calving now described is usually over in 2 hours, though sometimes it is protracted 5 or 6, and even so long as 12 hours, particularly when the water has been easily evacuated, or the water-bladder has broken before being protruded beyond the shape or vagina.

(1653.) But although the calf may present itself as here described in its natural position, with both its fore-feet projecting, its chin lying on both

osition of the calf, especially when it does not present itself in position. In such a case, it is the more necessary to extract ergetically, and remove the uneasiness of the cow, for, till she f it, she will not settle in one position or another. When the near the external air as to enable the operator to get the ropes egs, whether fore or hind, and a gentle pulling commenced, to ntion to the object in view, she will press with great force, the osition giving her additional advantage, so that the extraction in such a case, is generally the most expeditious. As in this the cow the calf will have to fall from a considerable hight to , and may thereby be hurt, it is necessary to be provided with chaff-sheet, which two men hold below the body of the calf, ceive the body upon it when it leaves the cow. I had a Short- that was very troublesome at calving, remaining but a short down, and being the whole time in the greatest state of excite- e always stood to calve, but when the process was actually be- essed with so much vigor that she got quit of it in a few minutes. occasion, after the water had come from her, the shepherd was the ropes to be in readiness in case they should be required; employed at them, and within a couple of yards from the cow , she gave such a powerful press as to project the calf from her, upon the floor, but luckily upon the very straw that had been to receive it. This instance shows the necessity of careful ss on cows after symptoms of actual calving have begun, as in e as I have just narrated, entire neglect might afterward have calf killed or injured by the heavy fall it had received.

Some calves, though extracted with apparent ease, appear as if laid upon the straw after birth. When such a case occurs, the d be placed against the side of the breast, to ascertain if the ; which, if it does, there is of course life, and all that is want- late the lungs. To accomplish this, the mouth and nose should , the mouth opened, and if there still be no breathing, some one w steadily into the open mouth, a device which I have seen an- urpose; as also a hearty slap of the open hand upon the but- e calf, which starts it, as it were, into being. Perhaps a bellows usefully employed in such a case, to inflate the lungs. Should of the heart be felt, and yet consciousness of life seem to be calf should be carried without delay to its crib, and laid down d up with the litter, leaving the mouth free to breathe, and it ve; but even after giving a few gasps, it may die. Most proba- use of its death may be from injury it had received in calving, ng detention in the vaginal passage, or an undue squeeze in pass- h the mouth of the womb, or by some rashness of the operator. of the calf when thus lost should be skinned while warm; it cut in pieces, and buried in compost for manure, and the skin

The difficult cases of presentation which usually occur are with nd the head, and the other foot drawn back, either with the leg k altogether, or the knee doubled and projecting forward. In se states the missing leg should be brought forward. To effect necessary to put round the presented foot a cord to keep it with- wer of the operator when the head is pushed back to get at the , and the greased arm of the operator introduced, and the foot forward into the passage beside the other. A calf may be ex- ith one leg folded entirely back alongside the body, and on feeling

this to be the case, it is perhaps better to extract the calf at once, than to delay the parturition in attempting to bring forward the leg. The presentation may be of the head alone without the feet, which may be knuckled forward at the knees, or folded back along both sides. In the knuckled case both legs may be brought forward by first pushing the head back, but, in case of losing hold of the calf altogether, a loop should be put in the calf's mouth. In the folded case, one leg at least, but both if possible, should be brought forward. A worse case is, when one or both legs are presented and the head folded back into the side. In this case the calf will most likely be dead. The head should be brought forward, and both legs, if possible. It may be beyond the strength of the operator to bring forward the head; then he should put a loop into the calf's mouth, by which his assistants will pull forward the head. Still worse cases may occur, such as a presentation of the shoulder, with the head lying into the side; a presentation of the buttock, with both the hind legs stretched inward. Or the calf may be on its back, and making presentations in all the worst features now enumerated. In whichever of these states the calf may present itself, no extraction can safely take place until it is placed in a position by which the head and one of the legs, with the other folded entirely back, or both the hind legs, with the back turned uppermost, are secured. In no case, however, should a fore or hind leg be left so as not only to obstruct the body in leaving the mouth of the womb, but a foot left so much at liberty as to tear the womb. The *safest* practice, therefore, is to secure both legs as well as the head. This may cause the operator considerable trouble, but by retaining hold of what parts he can with cords, and dexterity in handling the part missing, so as to bring it forward to the passage, while the assistants pull as he desires, his object will in most cases be attained; but it should be borne in mind that none of all these objects can be attained but by the assistance of the cow herself; that is to say, they should only be attempted when seconded by the throes of the animal. If this circumstance is not attended to and patiently watched by the operator, the muscular grasp of the womb will render his arm powerless. Another facility that should be taken advantage of by the operator is, that when the hind-quarters of the cow have an inclination downward she has the power to press the stronger, and of course to counteract his efforts the more easily. What should be done, therefore, is to raise that quarter of the cow with bundles of straw fully higher than the fore-quarter, until he has got the calf in the position he desires, and then, by letting the cow down again, and watching her pressings and assisting her at the same time, but not otherwise, the extraction may be accomplished in a reasonable time. As to block and tackle, the expedient should never be resorted to but to save the life of the cow, and as to *turning* the calf in the womb, there is far more danger in the attempt of injuring the womb than the value of the calf is worth. Much rather destroy it and cut it away in pieces, than run the risk of losing the cow. When the head only of the calf has found its way into the mouth of the womb, and cannot be protruded through the vagina, by reason of the unfavorable and obstructive position of the fore-legs, an inspection should immediately be made of the position of the calf, by first throwing the head back with a loop in the mouth, and bringing the legs forward. When this inspection has been too long delayed, and the head kept confined in the passage, the violent throes of the cow will certainly strangle the calf, and its head will swell to an inordinate degree. In such a case, as the swelling will prevent the calf's head being pushed back to get at the legs, it must be taken off, the legs brought forward, and the body then extracted. One of the

most difficult cases is, when the fore-feet are presented naturally, and the head is thrust down upon the brisket between the legs. The feet must first be pushed back, and then the head brought up and forward, and the extraction will then become natural.

(1660.) A skillful shepherd may be able to manage all these difficult cases within a reasonable time; but unless he is particularly dexterous at cases of parturition, it is much safer to obtain the advice of a veterinary surgeon, even although he should not be required to put a hand to the operation himself. In the case of extracting monstrosities, his assistance is indispensable.

(1661.) In regard to extracting twin calves, before rendering the cow any assistance, it is necessary to ascertain that the calves have made a proper presentation; that they are free of each other; that one member of the one is not interlaced with, or presented at the same time with, that of the other. When they are quite separated, then each can be treated according to its own case.

(1662.) Calving in a byre does not seem to produce any disagreeable sensations in the other cows, as they express no surprise or uneasiness in regard to what is going on beside them. When the cow gives vent to painful cries, which is rarely, the others no doubt express a sympathy; and when the calf is carried away, they may exhibit some restlessness; but any commotion arising from these circumstances soon subsides. But if a difficult labor is apprehended, it is better for the cows, and also for the cow herself, that she be delivered in another apartment, well littered, where the operator and his assistants can have free access to her.

(1663.) A notion exists in some parts of England, that a cow, when seized with the pains of labor, should be made to move about, and not allowed to lie still, though inclined to be quiet. "This proceeds from an erroneous idea," Skellett well remarks, "that she will calve much easier, and with less danger; but so far from this being the case, the author has known a great many instances where the driving has proved the death of the animal by overheating her, and thus producing inflammation, and all its bad consequences. Every rational man will agree in opinion with the author, that the above practice is both cruel and inconsistent in the extreme; and this is confirmed by what he has noticed, that the animal herself, as soon as the pains of calving come on, immediately leaves the rest of the rest of the herd and retires to some corner of the field, or under a hedge, in order to prevent the other cows, or anything else, coming near, that may disturb her in bringing forward her young."* In short, too much gentleness cannot be shown to cows when calving, and they cannot be too strictly guarded against every species of disturbance. The shepherd will not allow even his dog to enter the byre when calving is going on.

(1664.) The *afterbirth*, or placenta, does not come away with the calf, a portion of it being suspended from the cow. It is got quit of by the cow by pressing, and, when the parturition has been natural and easy, it seldom remains with her longer than from 1 to 7 hours. In bad cases of labor it may remain longer, and may only come away in pieces; but when it remains too long and is sound, its separation will be assisted by attaching a small weight to it, say of 2 lbs., which, with its continued force, and occasional pressing from the cow, will cause it to drop. The usual custom is to throw the afterbirth upon the dunghill, or it is covered up with the litter; but it should not be allowed to lie so accessible to every dog and pig that may choose to dig it up. Nay, pigs have been known almost to choke themselves with it. Such a custom is disgusting, and should be put an

* Skellett on the Parturition of the Cow.

end to. Let the substance be buried in a compost-heap, and if there is none such on the farm, let it rather be buried in the earth than exposed to be used in that manner. The umbilical cord or *navel string* breaks in the act of parturition.

(1665.) Should the cow seem *exhausted* by the protracted state of calving, she may be supported with a warm drink of gruel, containing a bottle of sound ale; and should she be too sick or indifferent to drink it herself, it should be administered to her with the drinking-horn, (1407.) After the byre has been cleansed of the impurities of calving, and a supply of fresh litter introduced, the cow, naturally feeling a strong thirst upon her from the exertion, should receive a warm drink. I don't know a better one than warm water, with a few handsfull of oatmeal stirred in it, and seasoned with a handfull of salt, and this she will drink up greedily; but a pailfull is enough at a time, and it may be renewed in a short time after, should she express a desire for it. This drink should be given her for two or three days after calving, in lieu of cold water, and mashes of boiled barley and gruel should be made for her, in lieu of cold turnips; but the oil-cake should not be forgotten, as it acts at this critical period as an excellent emollient. A very common practice is to give a cow barley in the sheaf to eat, and even raw barley, when there is no barley in the straw, and sometimes a few sheaves are kept for the express purpose; and barley-chaff is given where people grudge to part with good barley. Though so very common, the practice is a very objectionable one, for nothing could be proposed that would cause indigestion so readily as raw barley or barley-straw at the time of calving, when the tone of the stomach is impaired by excitement, and it may be by fever. *Boiled* barley, or any other mucilaginous drink, is quite safe, but a substance that can hardly fail to irritate and inflame the stomach is most injudiciously applied in the circumstances. In fact, nothing should be given to a cow at this time of an astringent nature, but rather everything of a laxative quality.

(1666.) It is desirable to milk the new-calved cow, as soon as convenient for her, as, whether the labor has been difficult or easy, the withdrawal of milk affords relief. It not unfrequently happens that an uneasiness is felt in the udder before calving, and should it increase while the symptoms of calving are long delayed, the cow may experience considerable inconvenience, especially if the flush of milk has been sudden. The causes of uneasiness are an unequal hardness in the udder and there is a heat, floridness and tenderness all over it. Fomentation with warm water twice or thrice a day, continued for half an hour at a time, followed by gentle rubbing with a soft hand, and anointing with goose-grease, will tend to allay irritation. In the case of heifers with the first calf, the uneasiness is sometimes so great during the protracted symptoms of calving, as to warrant the withdrawal of milk before calving. Should the above remedial measures fail to give relief, the great heat in the udder may cause direct inflammation, and consequent suppuration. To avert such an issue, the uneasiness should not be neglected from the first moment it is observed, as neglect may allow the complaint to proceed so far as to injure the structure of a portion if not the whole of the udder.

(1667.) *Milking* is performed in two ways, stripping and nievling. *Stripping* consists of seizing the teat firmly near the root between the face of the thumb and the side of the fore-finger, the length of the teat passing through the other fingers, and in milking the hand passes down the entire length of the teat, causing the milk to flow out of its point in a forcible stream. The action is renewed by again quickly elevating the hand to the root of the teat. Both hands are employed at the operation, each having

hold of a different teat, and moved alternately. The two nearest teats are first milked and then the two farthest. *Nievling*, or handling, is done by grasping the teat round at its root with the fore-finger like a hoop, assisted by the thumb, which lies horizontally over the fore-finger, the rest of the teat being also seized by the other fingers. Milk is drawn by pressing upon the entire length of the teat in alternate jerks with the entire palm of the hand. Both hands being thus employed, are made to press alternately, but so quickly following each other that the alternate streams of milk sound to the ear like one forcible, continued stream. This continued stream is also produced by stripping. Stripping, then, is performed by pressing and passing certain fingers along the teat; nievling by the whole hand doubled, or *fist*, pressing the teat steadily at one place. Hence the origin of both names.

(1668.) Of the two modes, I prefer the *nievling*, because it appears to me to be the more natural method, inasmuch as it imitates the sucking of a calf. When a calf takes a teat into its mouth, it makes the tongue and palate, by which it seizes it, play upon the teat by alternate pressures or pulsations, while retaining the teat in the same position. It is thus obvious that nievling is somewhat like sucking, whereas stripping is not at all like it. It is said that stripping is good for agitating the udder, the agitation of which is conducive to the withdrawal of a large quantity of milk; but there is nothing to prevent the dairy-maid agitating the udder as much as she pleases, while holding the teats in nievling. Indeed a more constant agitation could be kept up in that way by the vibrations of the arms than by stripping. Stripping, by using an unconstrained pressure upon two sides of the teat, is much more apt to press it unequally, than by grasping the whole teat in the palm of the hand; while the friction occasioned by passing the finger and thumb firmly over the outside of the teat, is more likely to excite heat and irritation in it than a steady and full grasp of the entire hand. To show that this friction causes an unpleasant feeling even to the dairy-maid, she is obliged to lubricate the teat frequently with milk, and to wet it at first with water; whereas nievling requires no such expedients. And as a farther proof that stripping is a mode of milking which may give pain to the cow, it cannot be employed when the teats are chapped, or when these and the udder are affected with the cow-pox, with so much ease to the cow as nievling. This difference I saw strikingly exemplified one summer, when all my cows were affected with the cow-pox, and when the assistant, who could only milk by stripping, was obliged to relinquish her duty till the cows were so far recovered as to be again able to endure her mode of milking.

(1669.) Milking should be done *fast*, to draw away the milk as quickly as possible, and it should be continued as long as there is a drop of milk to bring away. This is an issue which the dairy-maid cannot too particularly attend to herself, or see it attended to by those who assist her. Old milk left in the receptacle of the teat soon changes into a curdy state, and the caseous matter not being at once removed by the next milking, is apt to irritate the lining membrane of the teat during the operation, especially when the teat is forcibly rubbed down between the finger and thumb in stripping. The consequence of this repeated irritation is the thickening of the lining membrane, which at length becomes so hardened as to close up the small orifice at the point of the teat. The hardened membrane may easily be felt from the outside of the teat, when the teat is said to be *corded*. After this the teat becomes *deaf*, and no more milk can afterward be drawn from the quarter of the udder to which the corded teat is attached.

(1670.) The *milking-pail* is of various forms and of various materials.

The Dutch have brass ones, which are brilliantly scoured every time they are in use. Tin pitchers are used in some parts, while pails of wood in cooper-work are employed in other parts of the country. A pail of oak having thin staves bound together with bright iron hoops, with a handle formed by a stave projecting upward, is convenient for milking in, and may be kept clean and sweet. One nine inches in diameter at the bottom, 11 inches at the top, and ten inches deep, with an upright handle or lug of 5 inches, has a capacious enough mouth to receive the milk as it descends; and a sufficient hight, when standing on the edge of its bottom on the ground, to allow the dairy-maid to grasp it firmly with her knees while sitting on a small three-legged stool. Of course the pail cannot be milked full; but it should be as large as to contain all the milk that a single cow can give at a milking; because it is undesirable to rise from a cow before the milking is finished, or to exchange one dish for another while the milking is unfinished.

(1671.) The cow being a sensitive and capricious creature, is so easily offended that if the dairy-maid rise from her before the milk is all withdrawn, the chances are she will not again stand quietly at that milking; or if the vessel used in milking is taken away and another substituted in its place, before the milking is finished, the probability is that she will *hold* her milk—that is, not allow it to flow. This is a curious property which cows possess, of *holding up* or *keeping back* their milk. How it is effected has, I believe, never been ascertained; but there is no doubt of the fact that when a cow becomes irritated, or frightened by any cause, she can withhold her milk. Of course, all cows are not affected in the same degree, but as a proof how sensitive cows generally are, I believe that very few will be milked so freely by a stranger the first time as by one to whom they have been accustomed.

(1672.) There is one side of a cow which is usually called the *milking side*—that is, the cow's left side—because, somehow, custom has established the practice of milking her from that side. It may have been adopted for two reasons: one, because we are accustomed to approach all the larger domesticated animals by what we call the *near side*—that is, the animal's left side—as being the most convenient one for ourselves; and the other reason may have been, that, as most people are right-handed, and the common use of the right hand has made it the stronger, it is most conveniently employed in milking the hinder teats of the cow, which are often most difficult to reach because of the position of the hind legs, of the length of the hinder teats, or of the breadth of the hinder part of the udder. The near side is most commonly used in Scotland, but in many parts of England the other side is preferred. Whichever side is selected, that should always be used, as cows are very sensitive to changes.

(1673.) It is a rare thing to see a cow milked in Scotland by any other person than a woman, though men are very commonly employed at it in England. For my part, I never see a man milking a cow without being impressed with the idea that he is usurping an office which does not befit him; and this sense seems to be expressed in the terms usually applied to the persons connected with cows—a dairy-*maid* implying one who milks cows, as well as performing the other functions of the dairy—a dairy-*man* meaning one who owns a dairy.

(1674.) Cows are easily rendered troublesome on being milked; and the kicks and knocks which they usually receive for their restlessness, only render them the more fretful. If they cannot be overcome by kindness, thumps will never make them better. But the fact is, restless habits are continued in them by the treatment which they receive when first taken in-

to the byre, when, most probably, they have been dragooned into submission. Their teats are tender at first; but an unfeeling horny hand tugs at them in *stripping*, as if they had been accustomed to the operation for years. Can the creature be otherwise than uneasy? and how can she escape the wincing but by flinging out her heels? Then hopples are placed on the hind fetlocks, to keep her heels down. The tail must then be held by some one while the milking is going on; or the hair of its tuft be converted into a double cord, to tie the tail to the creature's leg. Add to this the many threats and scolds uttered by the dairy-maid, and you will get not a very exaggerated idea how a young heifer is broke into a byre. Some cows, no doubt, are very unaccommodating and provoking; but nevertheless, nothing but a rational course of conduct toward them, administered with gentleness, will ever render them less so. There are cows which are troublesome to milk for a few times after calving, that become quite quiet for the remainder of the season; others will kick pertinaciously at the first milking. In this last case, the safest plan, instead of hoppling, which only irritates, is for the dairy-maid to thrust her head against the flank of the cow, and while standing on her feet, stretch her hands forward, and get a hold of the teats the best way she can, and send the milk on the ground; and in this position, it is out of the power of the cow to hurt her. These ebullitions of feeling at the first milking after calving, arise either from feeling pain in a tender state of the teat, most probably from inflammation in the lining membrane of the receptacle; or they may arise from titillation of the skin of the udder and teat, which become the more sensible to the affection, from a heat which is wearing off. Be the cause of irritation what it may, one thing is certain, that gentle discipline will overcome the most turbulent temper.*

(1675.) Cows, independently of their power to retain their milk in the udder, afford different degrees of pleasure in milking them, even in the quietest mood. Some yield their milk with a copious flow, with the gentlest handling that can be given; others require great exertion to draw the milk from them in streams no larger than threads. The udder of the former will be found to have a soft skin, and the teats short; that of the latter will have a thick skin, with long, tough teats. The one feels like velvet, the other no better than untanned leather.

(1676.) The heifers that are to be transferred to the cow-stock should be taken from the hammels N, fig. 3, Plate III., in which they have been confined all winter, into the byre, about three weeks or a fortnight before their reckoning, at once into the stalls they are to occupy. If they had been accustomed to be tied by the neck when calves, they will not feel much reluctance in going into a stall; but if not, they require some coaxing to do it. When taking them to a byre, it should be remembered that a fright received at this time may not be forgotten for a long time to come. To avoid every chance of that, let them go in quietly of their own accord; let them smell and look at everything they wish; and let them become acquainted with them before driving them on; and having plenty of assistants to prevent any attempt to break away, let the cattle-man, with the shepherd, allow them to move on bit by bit, until they arrive at the stall. Here will be some difficulty; but a little favorite food in the manger will entice them to go up, especially if the time is chosen, which it should be,

[* This caution cannot be too strongly impressed on the mind, as applicable to the breaking in of domestic animals for all purposes. To conciliate and reconcile them to any operation or service, assuredly it is more rational and efficient to have them connect with it agreeable recollections of kind treatment and gentle usage, than anticipations of harshness and violence. *Ed. Farm. Lib.*]

when they are hungry. Another difficulty will be experienced in putting the seal, fig. 11, round the neck. It should hang, when not in use, on a nail upon the stake; and on quietly taking it down, without clanking the chain, and while the creature is eating, let the cattle-man slip one hand below the neck, while the other supports the seal over it, and then bring the loose end of the seal round the neck, and hook it into whatever link he can first get.

(1677.) The milk that first comes from the cow after calving is of a thick consistence and yellow color, and is called *biestings*. It has the same coagulable properties as the yolk and white of an egg beat up. After three or four days the biestings is followed by the milk. That which comes last, the *afterings* or *strippings*, as it is commonly called, is much the richer part of new milk, being not unlike cream. Being naturally thick, it is the more necessary to have it drawn clean away from the udder.

(1678.) The *structure of a cow's udder* is remarkable. It consists of 4 glands, disconnected with each other, but all contained within one bag or cellular membrane; and the glands are uniform in structure. Each gland consists of 3 parts, the *glandular* or secreting part, the *tubular* or conducting part, and the *teat* or receptacle or receiving part. The glandular forms by far the largest portion of the udder. It appears to the naked eye composed of a mass of yellowish grains, but under the microscope these grains are found to consist entirely of minute bloodvessels forming a compact plexus. These vessels secrete the milk from the blood. "Thus, then," says a writer, "we perceive that the milk is abstracted from the blood in the glandular part of the udder; the tubes receive and deposit it in the reservoir or receptacle; and the sphincter* at the end of the teat retains it there till it is wanted for use. But we must not be understood to mean that all the milk drawn from the udder at one milking, or *meal*, as it is termed, is contained in the receptacle. The milk, as it is secreted, is conveyed to the receptacle, and when this is full, the larger tubes begin to be filled, and next the smaller ones, until the whole become gorged. When this takes place, the secretion of the milk ceases, and absorption of the thinner or more watery part commences. Now, as this absorption takes place more readily in the smaller or more distant tubes, we invariably find that the milk from these, which comes the last into the receptacle, is much thicker and richer than what was first drawn off. This milk has been significantly styled *afterings*; and should this gorged state of the tubes be permitted to continue beyond a certain time, serious mischief will sometimes occur; the milk becomes too thick to flow through the tubes, and soon produces, first irritation, then inflammation, and lastly suppuration, and the function of the gland is materially impaired or altogether destroyed. Hence the great importance of emptying these smaller tubes regularly and thoroughly, not merely to prevent the occurrence of disease, but actually to increase the quantity of milk; for so long as the smaller tubes are kept free, milk is constantly forming; but whenever, as we have already mentioned, they become gorged, the secretion of milk ceases until they are emptied. The cow herself has no power over the sphincter at the end of the teat, so as to open it and relieved the overcharged udder; neither has she any power of retaining the milk collected in the reservoirs when the spasm of the sphincter is overcome."†‡

* The teat does not terminate in a true sphincter, there being no muscle in connection with it. A sphincter acts by the power of four muscles, which are contracted or expanded at will, and close or open the orifice around which they are placed. † Blurton's Practical Essay on Milking.

[‡ Observations such as these, on the anatomy and functions of the *udder*, may appear superfluous to some, but not so to him who would desire, for himself or his son, a sort of knowledge which

(1679.) You thus see the necessity of drawing away the last drop of milk at every milking, and the better milker the cow is, this is the more necessary. You also see the impropriety of *hefting* or holding the milk in cows until the udder is distended much beyond its ordinary size, for the sake of showing its utmost capacity for holding milk, a device which all cow-dealers, and indeed every one who has a cow for sale in a market, scrupulously use. It is remarkable that so hackneyed a practice should deceive any one into its being a measure of the milking power of the cow, for every farmer is surely aware, or ought to be aware, that the person who purchases a hefted cow on account of the magnitude of its udder exhibited in the market, gains nothing by the device; because, when the cow comes into his possession, she will never be hefted, and, of course, never show the greatest magnitude of udder, and never, of course, confer the benefit for which she was bought in preference to others with udders in a more natural state. If, then, purchasers derive no benefit from hefting, because they do not allow hefting, why do they encourage so cruel and afterward injurious practice in dealers? Would it not be better to select cows by udders in the state in which it is desired by purchasers they should be in their own possession? Were purchasers to set their face against the barbarous practice, the dealers would soon be obliged to relinquish it.

(1680.) Having spoken of the internal structure of the udder, its external form requires attention, because it indicates different properties. Its form should be spheroidal, large, giving an idea of capaciousness; the bag should have a soft, fine skin, and the hind part upward toward the tail be loose and elastic. There should be fine long hairs scattered plentifully over the surface, to keep it warm. The teats should not seem to be contracted or funnel-shaped at the onset with the bag. In the former state, teats are very apt to become corded or *spindled*, as another phrase expresses it, and in the latter too much milk will constantly be pressing on the lower tubes or receptacle. They should drop naturally from the lower parts of the bag, being neither too short, small, or dumpy, or long, flabby and thick, but perhaps about 3 inches in length, and as thick as just to fill the hand. They should hang as if all the quarters of the udder were equal in size, the front quarters projecting a little forward, and the hind ones a little more dependent. Each quarter should contain about equal quantities of milk, though I have always believed that the hind contain rather the most.*

---

it becomes every man to possess who has leisure to acquire it, and which every farmer should regard as being within the purview of his pursuit and position in society—just as much so as it is befitting in a scholar to be familiar with history, or a diplomatist with living languages and the laws of nations. There is, in fact, not a word in this section, nor in the work to which it belongs, that should not be made a part of the course of instruction for all youths who are to gain their living and maintain their standing in society by the practice of Husbandry and a knowledge of its principles. This Note would apply almost as well anywhere as here; we only seize the occasion to urge an impression which we believe cannot be too often suggested or too widely acted on, as to the variety of knowledge and of studies that ought to embellish the profession of the practical agriculturist, as well as augment its profits. *Ed. Farm. Lib.*]

[* As this number or volume of THE FARMERS' LIBRARY may fall into the hands of persons who do not possess the MONTHLY JOURNAL OF AGRICULTURE in which it was published, it seems proper to refer here to that extraordinary "TREATISE ON MILCH COWS," by M. GUENON. Of the validity of that work the strongest proof has been adduced, not only by the unanimous declaration of Committees of French Societies, but in the testimony of American agriculturists of undisputed judgment, and of the highest respectability. Of these we will take room only for the following statement at a Farmers' Club meeting in Boston: "Mr. Denny fully accorded with Mr. Brooks in his estimate of the treatment of cattle by GUENON. He had tested its value by

(1681.) Largely developed *milk-veins*, as the subcutaneous veins along the under part of the abdomen are commonly called, are regarded as a source of milk. This is a popular error, for the milk-vein has no connection with the udder; but "although the subcutaneous or milk-vein has nothing to do with the udder," says Mr. Youatt, "but conveys the blood from the fore part of the chest and sides to the inguinal vein, yet a large milk-vein certainly indicates a strongly developed vascular system—one favorable to secretion generally, and to that of the milk among the rest."*

(1682.) Let us now attend to the young calf. The navel-string should be examined that no blood be dropping from it, and that it is not in too raw a state. Inattention to this inspection may overlook the cause of the navel-ill, the treatment of which is given below; and insignificant as this complaint is usually regarded, it carries off more calves than most breeders are aware of.

(1683.) The first food which the calf receives consists of what its mother first yields after calving, namely, biestings. Being of the consistence of egg, it seems to be an appropriate food for the fœtus just ushered into the world. On giving the calf its first feed by the hand, in a crib in R, fig. 3, Plate III., it may be found to have gained its feet, or it may be content to lie still. In whichever position it is found, let it remain so, and let the dairy-maid take a little biesting in a small dish—a *handy*, formed like a miniature milk-pail, and of similar materials, will be found a convenient one—and let her put her left arm round the neck of the calf, and support its lower jaw with the palm of the hand, keeping its mouth a little elevated, and open, by introducing the thumb of the same hand into the side of its mouth. Then let her fill the hollow of her right hand with biestings, and pour it into the calf's mouth, introducing a finger or two into it for the calf to suck, when it will drink the liquid. Thus let her supply the calf, in handfull after handfull, as much as it is inclined to take. When it refuses to take more, the creature should be cleaned of the biesting that may have flown over. Sometimes, on a calf being begun to be fed, when lying, it attempts to get upon its feet, and, if able, let it do so, and rather assist it up than prevent it. Some people are afraid to give a calf as much biestings at first as it can take, because it is said to produce the navel-ill. This is nonsense; let the creature take as much as it pleases, for biestings never harmed a calf, and certainly never produced navel-ill, though it has been accused of it; but if the truth were investigated, the illness would be found to have proceeded from neglect of proper inspection in due time, arising from ignorance of the danger. I have minutely detailed the primary and simple process of feeding a new dropped calf by hand, because very absurd ways are adopted in doing it. Nothing is more common than to plunge the calf's head into a large quantity of biestings, and because the liquid bubbles around its mouth with the breath of the nose, and it will not attempt to drink it, its head is the more forcibly thrust and kept down into the tub. How can it drink with its nose immersed among the fluid? And why should a calf be expected at first to *drink with its head*

distributing a number of copies among *intelligent practical farmers*, and their *united report* was in favor of the high value of the work. One of them went so far as to say that 'a farmer keeping twenty cows could well afford to give $100 for this treatise of Guénon, if it could not be obtained at a less cost." According to this treatise, the quality and quantity of milk which any cow will give may be accurately determined by observing natural marks or external indications alone These marks have been fully illustrated by engravings designed to explain the system as already published in THE MONTHLY JOURNAL OF AGRICULTURE, connected with THE FARMERS' LIBRARY. *Ed. Farm. Lib.*]

*Youatt on Cattle.

down, when its natural instinct should lead it to *suck with its head up?* It should always be borne in mind that feeding calves by the hand is an *unnatural* process; nevertheless, it is a convenient, practicable and easy one, provided it is conducted in a proper manner. The creature must be *taught to drink*, and a good mode of teaching it I have described above. In this way it is fed as often as the cow is milked, which is three times a day. After the first two or three days, however, another plan should be adopted, for it should not be *accustomed* to suck the fingers, as then it will not drink without their assistance. The succeeding plan is to put a finger or two of the right hand into its mouth, and holding the small pail of milk with the left under its head, bring the head gradually down into the pail, where the fingers induce it to take a few gluts of the milk; but in doing this, the fingers should be gently withdrawn while the head is kept down in its position with the hand, taking care to keep the nostrils above the milk. In a few days more the fingers will not be required, and in a few days more still you will see the calf *drink* of its own accord.

(1684.) For the first month the calf usually has as much sweet milk warm from the cow as it can drink. It will be able to drink about 3 quarts at each meal, and in three meals a day, in the morning, noon and evening, it will consume 8 quarts. After the first month it gets its quantity of milk at only 2 meals, morning and evening. It is supported 3 months in all on milk, during which time it should have as much sweet-milk as it can drink. Such feeding will be considered expensive, and no doubt it is, but there is no other way of bringing up a *good* calf. Some people grudge sweet-milk after a few days, and take the cream off it, and give the skimmed to the calves. This is considered thrifty management; but its result does not insure immediate gain, because it is not possible to extract double advantage from a given quantity of sweet-milk. If butter is preferred to calves, or good beasts at an after period, the wish is attained, and the farmer has had his preference; but he must know—at least ought to know—that he cannot obtain butter and good beasts from the same milk. Others, more generous, give half sweet and half skimmed milk to their calves; while some provide a substitute for a part of the milk, by making gelatine of boiled linseed or sago, and give it with no milk. When milk is actually scarce, such expedients are permissible; but when it is plentiful, and is used for other purposes than merely to serve the farm-house, the adoption of expedients is a practical avowal that the farmer does not wish to bring up his stock as he might do.

(1685.) The jelly from linseed, or *lythax*, as it is called, is easily made by boiling good linseed in water, and while it is in a hot state to pour it in a vessel to cool, when it becomes a firm jelly, a proportion of which is taken every meal, and bruised down in a tubfull of warm milk, and distributed to the calves. They are very fond of it, and in the third month of the calf's age, when it can drink a large quantity of liquid at a time, and during a day, it is an excellent food for them. Sago may be prepared in the same way. But a better substance for calves than either is, in my opinion, pea-meal. It should not be boiled, but made into *brose*, by pouring hot water upon it, and stirring the mixture till it is *fine*. It becomes gelatinous on cooling; and when cold, a portion of it is put into new warm milk, and mixed so intimately with the hand that not a lump of the meal can be felt; and the mixture is made of a consistence which a calf can easily drink.

(1686.) Another mode of bringing up calves by breeders of stock is to allow them to suck their mothers, and the plan is arranged in this way: Either a large crib is erected at a convenient part or parts of the cow's

byre, to contain a number of calves each, in a loose state, and when the hours arrive at which they are fed, they are let out of the cribs, whence they each proceed forthwith to the cow that supports it; or the calves are tied by the neck in stalls erected for the purpose against the wall of the byre, immediately behind the cows, and when the hours of the respective meals arrive, they are loosened from the tyings, and pass across the byre to the cows. Generally, in both cases, one cow suckles two calves; and a cow that has calved early may suckle two sets, or four calves, or at least three, in the season.

(1687.) With regard to the merits of this plan, I must remark that I am averse to tying calves by the neck. It cramps their motions and deprives them of that freedom of action which is so conducive to health. By preventing motion they will no doubt sooner acquire condition; but for stock-calves, kept for the formation of a herd, this is of less importance than strength acquired by moderate exercise within a limited size of crib. As to having a number of calves within the same crib, though they all have liberty of motion, they are so commixed as to have liberty to suck at one another. The ears, navel, scrotum and teats, suffer by this dirty habit; and there is no preventing it after it has been acquired, so long as two remain together. Upon the whole, therefore, I much prefer the separate crib to each calf, so formed of spars as to allow every calf to see its neighbors, and so sensibly in company, as to remove the idea of loneliness. The separation prevents the abominable habit of sucking being acquired; and the crib is as large and no larger than to allow them to move about for exercise, without fatigue.

(1688.) In regard to *suckling calves*, there is no question it is the best way of bringing them up, provided the calf has free access to its mother or the cow which is supporting it; but I am doubtful of the superiority of suckling over feeding by hand, in the case where the calf is only allowed to go to the cow at stated times. It saves the trouble of milking the cows and giving milk to the calves; but the saving of trouble is not so important a consideration in the rearing of young stock as the promotion of their welfare. There is one objection to suckling where one cow brings up two calves—that the quantity of milk afforded to each is unknown; and the stronger or more cunning calf may steal the larger share. True, they are both brought up; but are they brought up as well as they might be, with the assistance of nourishing food, when the milk becomes scarcer, which it will be to each calf the older it grows. Another objection to suckling is, that a cow which suckles calves at one period of the season does not take kindly afterward to milking with the hand; and a cow will always prefer to be sucked to being milked by the hand. Unless, therefore, cows are kept for the purpose of suckling, they become troublesome to milk after the calves are weaned.

(1689.) At a month old the male calves that are not intended to be kept for bulls are *castrated*. Though the operation is very simple and safe, yet it should not be performed at a time when there is any affection of the navel-string, or indication of costiveness or dysentery; these exciting causes of the system should first be removed ere another is voluntarily superadded. Supposing the calf is in good health, the castration is performed in this manner: An assistant places the calf upon its rump on the litter, and, sitting down himself, takes it between his outstretched limbs on the ground, with its back against his breast. Then seizing a hind-hock of the calf in each hand, he draws a hind leg up to each side of its body, and holds both in that position as firmly as he can. The operator makes the testicles keep the scrotum smooth and stretched with his left hand, and then cuts with a

sharp knife through all the integuments till he reaches one testicle. which he seizes, pulls out as much of the spermatic cord as he can, and there divides it. The same operation is performed on the other testicle, and the castration is finished in a minute or two. The calf feels stiff in the hind quarter for a few days, and the scrotum may swell; and if the swelling appear to become serious, fomentations of warm water should be frequently applied; and should suppuration ensue, the incisions made in the scrotum should be opened to give it vent; but the probability is that the cut will heal by the first intention, and give no farther uneasiness to the calf than a feeling of stiffness in the hind quarter for a few days.

(1690.) When the air becomes mild, as the season advances, and when the older calves attain the age of two months, they should be taken out of the cribs, and put into the court *k*, fig. 3, Plate III., during the day; and after a few days' endurance to the air, should be sheltered under the shed in the court at night, instead of being again put into the cribs. Some sweet hay should be offered them every day, as also a few sheep-slices of Swedish turnips to munch at. Such a change of food may have some effect on the constitution of the calves, causing costiveness in some and looseness in others; but no harm will arise from these symptoms, if remedial measures are employed in time. Large lumps of chalk to lick at will be found serviceable in looseness. The shed of the court should be fitted up with small racks and mangers to contain the hay and turnips, and chalk. Should a very wet, snowy, stormy, or cold day appear after the calves have been put into the court, they should be brought back to their cribs till the storm pass away.

(1691.) At three or four months old, according to the supply of milk and the ready state of the grass to receive them, the calves should be *weaned* in the ordinary seniority, due regard being at the same time had to their constitutional strength. If a calf has been always strong and healthy, it may be the sooner weaned from milk, if there is grass to support it; but should it have ailed, or be naturally puny, it should be remembered that good, sweet milk is the best remedy that can be administered to promote condition or recruit debility, and should be given with an unsparing but judicious hand. Calves, on being weaned, should not be deprived of milk at once; it should be lessened in quantity daily, and given at longer intervals by degrees, so as that they may not be sensible of their loss when it is entirely withheld. I have frequently observed that when calves are stinted of milk preparatory to weaning, means of supplying them with a sufficient quantity of food of an enticing nature are not so well attended to as they ought. Fresh bundles of the most clovery portions of the hay, turnips fresh sliced, pure fresh water at will, a little pounded oil-cake, if presented at times when they used to get their milk, will induce them to eat those substitutes with contentment; whereas, when these are entirely neglected, or the trouble grudged in supplying them, and the creatures left to pick up what they can find for themselves in a court or bare lea, they cannot but suffer from hunger, and vociferate for the loss of what they had enjoyed till then. Thus treated, they evidently fall off in condition; and which if they do at the critical period of weaning, the greater portion of the ensuing summer will elapse ere they regain their former condition, strength, and sleekness of coat. A small paddock near the steading is an excellent place for weaning calves, before turning them out to a pasture field; but then it should afford a full bite of grass to support them as the milk is taken from them, otherwise they will be more injured than benefited in it.

(1692.) When *bull* calves are brought up, they should be early calved,

and receive as much new milk as they can consume; and they should not be weaned till the grass is fully ready to support them. The object of this high keeping is not to fatten them, but to give strength to their *bones* and vigor to their *constitution*, these being much strengthened by the quality and quantity of food given to calves at the earliest period of their existence. The valuable impulse thus given in calfhood to these very essential properties in bulls, is evinced in the vigor of succeeding life, and it is sure to lay a foundation upon which a durable superstructure may be raised, and, what is more, no *durable* structure can be raised on any other. Even in ordinary cases push a calf forward in the first month of its existence, and the probability will be that it will evade every disease incident to its age.

(1693.) The following Table, containing the dates at which cows should calve from those at which they are bulled, will be found useful to you for reference. It is unnecessary to fill up the Table with marking down every day of the year, as within the short period between each fortnight you can easily calculate the particular reckoning of each cow. The period of gestation is taken at 273 days, or 9 calendar months, which is the minimum time, and from which the symptoms of calving should be narrowly watched till the event of calving actually takes place.

A RECKONING-TABLE FOR THE CALVING OF COWS.

(1694.) The usual modes of determining whether the cow is in calf are deceptive: she may not hold when bulled; she may take the bull again in a few days; and she may not show evident symptoms of calving but for a few days only before she actually calves. The most certain sign of pregnancy is the enlargement of the abdomen and filling of the flanks in the third or fourth month. A more philosophical method of determining whether a cow is in calf at all, has been discovered by medical men by the application of the ear to the flank of the cow, suggested by the curious and valuable discoveries brought to light by the *stethescope*. "That greatest of improvements in veterinary practice," observes Mr. Youatt, "the application of the ear to the chest and belly of various animals, (in order to detect by the different sounds—which, after a short time, will be easily recognized—the state of the circulation through most of the internal organs, and consequently the precise seat and degree of inflammation and danger,) has now enabled the breeder to ascertain the *existence of pregnancy* at as early a stage of it as *six or eight weeks*. The beating of the heart of the calf will be distinctly heard, twice or more than twice as frequent as that of the mother; and each pulsation will betray the singular double-beating of the fœtal heart. This will also be accompanied by the audible rushing of the blood through the vessels of the placenta. The ear should be applied to the right flank, beginning on the superior part of it, and gradually shifted downward and backward. These sounds will soon be heard, and cannot be mistaken."*

(1695.) Strathaven in Scotland has long been famed for rearing good *veal* for the Glasgow and Edinburgh markets. There the dairy farmers retain their quey-calves for maintaining the number and vigor of their cow stock, while they feed the male calves for veal. Their plan is simple and efficacious, and therefore may be followed anywhere. They give the calves milk only, and seldom any admixture, and they do not allow them to suck their dams. Some give milk but sparingly at first, to whet their appetite, and all take care not to produce surfeit by giving too much at a time. The young calves get the first drawn milk, or *fore-broads*, as it is termed, and the older, less of the fore-broads and more of the *afterings*, and frequently that of two or three cows, as being the richest portion of the milk. After they are three or four weeks old they get abundance of milk, but only twice a day. They get plenty of dry litter, fresh air, moderate warmth, and are kept nearly in the dark to check sportiveness. They are not bled during the time they are fed, and a lump of chalk is placed within their reach. They are fed from 4 to 6 weeks, when they fetch from £3 to £4 apiece; and it is found more profitable to fatten a number of calves for that time, to succeed each other, than to force them beyond the state of marketable veal, of from 25 lbs. to 30 lbs. per quarter.†

(1696.) *Diseases of Young Calves.*—While speaking of the calf, I may here notice the diseases to which it is subject at this period of its existence, and in this season of the year. The young calf should get quit of the black and glutinous fæces that had been accumulating in its intestines during the latter period of its fœtal existence; and there is no aperient better suited for the purpose than biestings. The farmer, therefore, who throws it away, does not know the jeopardy in which he places the lives of this branch of his young stock. Should there not be enough of biestings to remove the fæces, 2 or 3 oz. of castor-oil, beat up with a yolk of an egg, or in thick gruel,

* Youatt on Cattle.

† Quarterly Journal of Agriculture, vol. v.

should be administered, and a scruple of powdered ginger, to act as a carminative. In cases of costiveness, which young calves are very liable to contract, and inattention to which, at first, is the cause of the loss of many of the best young stock, arising partly from repletion of milk at times when calves are permitted to suck their dams, or when they eat too much hay at one time after the milk has been too suddenly removed from them at weaning, active measures should be adopted to prevent its confirmation, for then the case becomes hopeless, as fever will inevitably ensue and the food harden into a mass in the maniplies. Doses of warm water, containing a solution of 2 or 3 oz. of Epsom salts, should be frequently administered, both to dissolve the matter in the stomach, move the bowels, and wash out the stomach. Calves are liable to a disease of an opposite nature from this, namely, *looseness, scouring* or *diarrhœa*. They are most subject to it when put to grass, though still on milk, at too early an age. I should say that if so treated before attaining 2 months, they are certain of being affected with it. One means of prevention is, to retain the calves in the house or shed till they are at least 2 months old, and if a little older so much the better. Of course, it is only the latest calves that are likely to be thus treated, the earlier having attained mature age for weaning before the grass is ready. In the house, scouring may be brought on by starvation and excess, and on grass by a sudden change of food. So long as the calf is lively and takes its milk, there need be no apprehension from a thin discharge of fæces; but dullness and loathing of food, accompanied by discharge, should create alarm. The first application of a remedy should be a mild purgative, to remove, if possible, the irritation of the bowels, and then should follow anodynes, astringents, and alkalies, with carminatives, the withdrawal of every sort of green food, and the administration of flour or pea-meal gruel. The following mixture the farmer is called to "*rely* on, and it is recommended that he should have it always by him, as it will do for all suckling animals, namely, 4 oz. of prepared chalk, 1 oz. of Winters' bark, powdered, 1 oz. of laudanum, and 1 pint of water. Give 2 or 3 table-spoonsfull, according to the size of the animal, 2 or 3 times a day."* Another recipe is: "Take from ½ oz. to ¾ oz. of tincture of rhubarb, with an equal quantity of water, according to the age and strength of the calf. To be given every alternate day in case one dose is not sufficient. I have used the remedy for several years," says a writer, "and have not lost a calf."† Mr. E. E. Dawson, Ingethorpe, Grantham, recommends this: "For young calves boil ½ oz. of ground black pepper in half a pint of ale; add a tea-spoonfull of ginger; mix together; to be given lukewarm every morning until the calf recovers of its weakness; to have its milk as usual. Older calves will require ½ more for a complete cure. Great care should be used in making use of the above recipe, that the animal does not receive the mixture too fast; for want of attention mischief may be done."‡ I have given all these remedies for the scour in calves, for it would appear that it may be removed by various means, and one may be more efficacious in one locality than in any other. I never experienced among my calves but one instance of serious scouring. It was a Short-Horn quey-calf, and the recipe which effected a cure, after trying many, was very like the first, though I now forget the exact ingredients, with the exception of the pint of water, for which flour-gruel was substituted.

(1697.) *Calf-louse.*—It is not a little singular, in a physiological point of view, that there should be a *peculiar pedicular parasite appropriated to the calf*, yet such appears to be the case, although the creature is by no means common. It is very like the ox-louse. *Hæmatopinus eurysternus*, fig. 268, but comparatively narrower, and having two rows of dusky spots on the abdomen. It is termed *Hæmatopinus vituli*, or louse of the calf.‖

(1698.) "Although parturition is a natural process," as well observed by Mr. Youatt, "it is accompanied by a great deal of febrile excitement. The sudden transferring of powerful and accumulated action from one organ to another—from the womb to the udder—must cause a great deal of constitutional disturbance, as well as liability to local inflammation."§ One consequence of this constitutional disturbance of the system is *milk-fever*. "The cause of this disease," says Skellett, "is whatever obstructs perspiration, and accumulates the blood internally; hence it may be produced by the application of cold air, by lying on the cold ground, or by giving cold water after calving; and these causes will naturally produce this effect from the open state of the pores at this time, and from the external parts being so wide and relaxed after the operation. Cows in high condition are more subject than others to this complaint, and especially if they have been kept up for some weeks before calving."¶ The complaint may seize the cow only a few hours after calving, or it may be days. Its first attack is probably not observed by those who have the charge of the cows, or even by the farmer himself, who is rather chary in looking after the condition of his cows, in case of offending his female friends, to whose special care that portion of his stock is consigned. The symptoms are first known by the cow shifting about in the stall, or from place to place if loose, lifting one leg and then another, being easily startled, and looking wildly about her as if she had lost her calf, and blaring for it. Then the flanks begin to heave, the mouth to open and issue clear water, she staggers in her walk, and at length loses the use of her limbs and lays her head upon her side. The body then swells, the extremities feel cold and clammy. Shivering and cold sweats follow, the pulse becomes irregular and death ensues. The promptest remedy to be used, after the first symptom has been observed, is to bleed to the extent of 3 or 4 quarts; and the next is to open the bowels, which will be found to have a tendency to constipation. From 1 lb. to 1½ lbs. of Epsom salts, according to the strength of the cow, with a little ginger and carraway, should be given as a purge; and if the dose does not operate in due time, ½ lb. of Epsom salts should be given every 6 hours until the bowels are opened. This result will be much expedited by a clyster of warm thin gruel and soap or oil. After the opening medicine has operated, a cordial drink will be necessary, by which time the cow may show symptoms of recovering in expressing an inclination to eat, with which she should be gratified, but with precaution.**

§ Youatt on Cattle. ¶ Skellett on the Parturition of the Cow.

[** The more artificial treatment of cattle in England probably produces diseases and casualties to which they are far less subject in our country, where they are left in a more natural and more-

(1699.) *Red-water.*—The ninth day after a cow has calved, an uterine discharge should take place and continue for a day or two, after which the cow will exhibit all the symptoms of good health. I have observed that when this discharge does not take place the cow will soon after show symptoms of red-water. She will evacuate urine with difficulty, which will come away in small streams, and be highly tinged with blood, and at length appear like dark grounds of coffee. "The nature and cause of the disease are here evident enough," as Mr. Youatt well observes. "During the period of pregnancy there had been considerable determination of blood to the womb. A degree of susceptibility, a tendency to inflammatory action, had been set up, and this had been increased as the period of parturition approached, and was aggravated by the state and general fullness of blood to which she had incautiously been raised. The neighboring organs necessarily participated in this, and the kidneys, to which so much blood is sent for the proper discharge of their function, either quickly shared in the inflammation of the womb, or first took an inflammation, and suffered most by means of it."* The prevention of this disease is recommended in purgative medicine after calving; but as such an administration, in the circumstance, never fails to affect the quantity of milk given by the cow for some time after, a better plan is to administer food which will operate as a laxative at the same time, for some time before as well as after calving, and the substance which possesses these two properties is *oil-cake.* I have proved this from experience. I lost two cows in Forfarshire by red water, one a Short-Horn and the other an Angus, and one of the hinds lost one also—all in different but successive years. By examination of the stomach and bowels after death, I became satisfied that the determination of the blood to the womb during pregnancy had caused a tendency to inflammation in the bowels and stomach, and that indigestion and constipation were the consequences, and these were aggravated by the state of the food, which consisted entirely of Swedish turnips, which, at that season, in April, are fibrous and sweet, by the juice becoming concentrated in the bulb, and which the more readily induce cattle to eat them. The remedy was an obvious one: give laxative diet, and as that cannot readily be effected by turnips, particularly in cows which do not receive so many as they can eat, nor by raw potatoes which incur the risk of hoven (1294), and to the giving of potatoes to cows I have always had an utter aversion—call it prejudice, if you will; and as potatoes boiled have no laxative effects, the only alternative was oil-cake, and, fortunately, from the period I employed it medicinally to the cows, for a month before and a month after calving, to the extent only of 4 lbs. a day to each cow, and which quantity was also given to the hind's cows about the time of their calving, the complaint was never more seen or dreaded.

(1700.) I may here mention an unaccountable fatality which overtook a Short-Horn cow of mine, in Forfarshire, immediately after calving. She was an extraordinary milker, giving not less than 30 quarts a day in summer on grass; but what was more extraordinary, for two calvings the milk never dried up, but continued to flow to the very day of calving, and after that event returned in a flush. In the third year she went naturally dry for about a month previous to the day of reckoning; every precaution, however, was taken that the milk should dry up without giving her any uneasiness. She calved in high health, the milk returned as usual in a great flush after calving, but it proved an impossibility to draw it from the udder; not a teat would pass the milk, *all the four being entirely corded.* Quills were introduced into them at first, and then tubes of larger size were pushed up to the root of each teat. A little milk ran out of one of them—hope revived; but it stopped running, and all the art that could be devised by a skillful shepherd proved of no avail to draw milk from the udder; rubbing and softening the udder with goose-grease, making it warmer with warm water—all to no purpose. To render the case more distressing, there was not a veterinary surgeon in the district. At length, the udder inflamed, mortified, and the cow died in the most excruciating agony on the third day, from being in the highest state of health, though not in high condition; for her milking propensity usually kept her lean, but still she was always spirited. No loss of the kind ever affected my mind so much—to think that nothing *could* be done to relieve the distress of a creature that could not help itself. I was told afterward by a shepherd to whom I related the case, that I should have cut off all the teats by the roots; which horrid operation would, of course, have destroyed her for a milch cow, but, he conceived, would have saved her for feeding. He had never *seen that* operation performed on a *cow*; but it suggested itself to him in consequence of having been obliged at times to cut off a ewe's teat or teats to save her life. The suggestion I think good; and I mention it that it may occur to you in similar circumstances. I purchased this cow when a quey in calf, along with another, from Mr. Currie, then in Brandon, Northumberland.

(1701.) Cows differ very much in the time they continue to give milk, some not continuing to yield it more than 9 months, while others afford it for years. The usual time for cows that bear calves to give milk is 10 months. The cow that died in consequence of the corded teats mentioned above, (1700,) gave milk for 3 years, and bore a calf every year. A cow of mine that slipped her calf, and was not again served by the bull, gave milk for 19 months. But many re-

---

strained condition. Hence with us the parturition of cows is very rarely attended with any difficulty or danger—so rarely as scarcely to make it an object of attention or solicitude; thus all the precautions, descriptions of symptoms and remedies, &c. laid down here, may seem to be almost unnecessary. It is with domestic animals as with the human family—too much care and management seem to beget difficulties. The fine lady is watched with intense solicitude; the family physician is on the *qui vive* for weeks before the event; and she sometimes falls a victim to the contagious sympathy and apprehensions of her friends, and to that delicacy of frame and constitution which is the fruit of too much refinement in her rearing and physical education. The poor laboring man's wife has no such fear, and no such difficulties. The misfortune in his case is that children come too easy and too fast. *Ed. Farm. Lib.*]

* Youatt on Cattle.

markable instances of cows giving milk for a long time are on record. "The immense length of time for which some cows will continue to give milk," says a veterinary writer, 'if favorably treated, is truly astonishing; so much so as to appear absolutely incredible. My own observation on this subject extends to four most remarkable cases: 1. A cow purchased by a Mr. Ball, who resided near Hampstead, that continued to give milk for 7 years, subsequently to having her first and only calf. 2. A large dun Suffolk cow, shown to me as a curiosity by a Yorkshire farmer. This animal, when I saw her, had been giving milk for the preceding 5 years, during which period she had not any calf. The five-years' milking was the result of her second calving. During that period, attempts had been made to breed from her, but ineffectually. 3. A small aged cow, belonging to a *farmier* near Paris, that gave milk for 3 years subsequent to her last calf. 4. A cow in the possession of Mr. Nichols, Postmaster, Lower Merion-street, Dublin. This animal was in Mr. Nichols's possession for 4 years, during the entire of which time she continued to give an uninterrupted supply of milk, which did not diminish in quantity more than 3 pints per diem, and that only in the winter months. . . . . He disposed of her for butchers' meat, she being in excellent condition. The morning of the day on which she was killed, she gave her usual quantity of milk." *

(1702.) The same writer enters fully into a subject with which I was not previously acquainted, namely, the possibility of securing permanency of milk in the cow. This is effected, it seems, by simply *spaying* the cow at a proper time after calving. The operation consists in cutting into the flank of the cow, and in destroying the ovaries of the womb by the introduction of the hand. The cow must have acquired her full stature, so that it may be performed at any age after 4 years.† She should be at the flush of her milk, as the future quantity yielded depends on that which is afforded by her at the time of the operation. The operation may be performed in ten days after calving, but the most proper time appears to be 3 or 4 weeks after. The cow should be in high health, otherwise the operation may kill her or dry up the milk. The only preparation required for the safety of the operation is, that the cow should fast 12 or 14 hours, and the milk taken away immediately before the operation. The wound heals in a fortnight or three weeks. For two or three days after the operation, the milk may diminish in quantity; but it regains its measure in about a week, and continues at that mark for the remainder of the animal's life, or as long as the age of the animal permits the secretion of the fluid; unless, from some accidental circumstance—such as the attack of a severe disease—it is stopped; but even then the animal may be easily fattened.

(1703.) The advantages of spaying milch-cows are thus summed up: "1. Rendering permanent the secretion of milk, and having a much greater quantity within the given time of every year 2. The quality of the milk being improved. 3. The uncertainty of and the dangers incidental to breeding being to a great extent avoided. 4. The increased disposition to fatten, even when giving milk, or when, from excess of age, or from accidental circumstances, the secretion of milk is checked; also, the very short time required for the attainment of marketable condition. 5. The meat of spayed cattle being of a quality superior to that of ordinary cattle."‡ With these advantages, of course, breeders of stock can have nothing to do; but since the operation is said to be quite safe in its results, it may be presented to the notice of cow-feeders in towns.

(1704.) A cow will desire the bull in 4 or 5 weeks after calving. The symptoms of a cow being in season are thus well described by Skellett: "She will suddenly abate of her milk, and be very restless; when in the field with other cows she will be frequently riding on them, and if in the cow-house, she will be constantly shifting about the stall; her tail will be in constant motion; she will be frequently dunging, stalling and blaring; will lose her appetite; her external parts will appear red and inflamed, and a transparent liquor will be discharged from the vagina. In old cows these symptoms are continued 4 or 5 days, but in general not more than 24 hours, and at other times not more than 5 or 6 hours. Therefore, if a cow is intended for procreation, the earliest opportunity should be taken to let her have the bull; for if it be neglected then, it will often be two or three weeks before the above symptoms will return. These instructions," adds Skellett, "are necessary to be given only to the proprietor of a small number of cows, where a bull is not always kept with them. . . . . If a cow, after calving, shows symptoms of season sooner than 4 or 5 weeks, which is sometimes the case, she should *not be permitted to have the bull sooner than 4 or 5 weeks from that period*, for the womb, before that time, is generally in so relaxed a state as not to be capable of retaining the seed; consequently she seldom proves with calf, if she is suffered to take him sooner."‖ This last remark I consider of great value, for I am persuaded that most cases of cows not holding in calf the first serving after calving, arises from the want of consideration on the part of breeders, whether the cow is in that recovered state from the effects of calving as to afford a reasonable hope that she will conceive; and this is a point more to be considered than the mere lapse of time after calving, for a cow after a severe labor, may be in a much worse state for conception, even at double that length of time, than another which has

[† It is not, of course, meant to say that cattle may not be spayed earlier. On the contrary, it is quite common, especially in our western country, to spay heifers, and where the operator has some experience there is little danger. Should the system of M. GUENON, by which it may at a very early age be pronounced whether a calf will make a good or a very indifferent milker, be fully established, it will undoubtedly become expedient for farmers to sell to the butcher for veal, or to have spayed all that are found to be *devoid of the marks or escutcheons*. Being spayed, they have a greater tendency to fat, and cases might happen we should think, where the farmer has few cattle that it might be economical to bring such condemned and spayed heifers *under the yoke*. *Ed. Farm. Lib.*]

* Ferguson on Distemper among Cattle.

‡ Ferguson on Distemper among Cattle.

‖ Skellett on the Parturition of the Cow

passed the calving with ease, though the former may come as regularly into season as the latter. The state of the body, therefore, as well as the length of time, should be taken into consideration in determining this point.

(1705.) There are still other considerations connected with the serving of cows which deserve your attention. The usual practice, in places where there is no bull, is to take the cow to the bull at a convenient time for the cattle-man to go with her; and should she have passed the bloom of the season before her arrival at the bull the issue is of course doubtful. The cow may have traveled a long distance and become weary, and yet no rest is allowed her, and she must undergo the still farther fatigue of being served. Some people cannot be satisfied with the service which their cows receive, until both cow and bull are wearied out. Others will force either the cow or bull, or both together, against their inclination, she being held by the nose, and he goaded on with threats and thumps. In all such cases the chances are much against conception. There is, to be sure, the difficulty of not having the bull on the spot, but, when he is reached, he may have been worn out for the day by previous service. No such difficulty is felt when there is a bull at home; but even then, when the cow has to be taken to him out of the byre, for example, some judgment is requisite of the proper time at which she should be taken out; and this can only be ascertained by studying the idiosyncracy of every cow, and remembering each case. It appears to me to be as essential a matter to keep a record of the characteristics of each cow, in regard to her state of season, as of her reckoning to calve; and this remark is strengthened by the great differences, in this respect, evinced by different cows under the same treatment. For example, one arrives soon at mature season after the symptoms are exhibited; another requires a few hours to arrive at the same point, and the season continues for some time longer in a languid state. A third runs through the course of season in a few hours, while a fourth is only prepared to receive the bull at the last part of her season. A fifth may exhibit great fire in her desire, which induces her keeper to have her served at once, when too soon; while another shows comparative indifference, and in waiting for an exhibition of increased desire on her part, the season is allowed to pass off; and when this is the case, some cattle-men, conscious of neglect, and afraid of detection, will persist in the bull serving her, though she may be very much disinclined for the embrace, and does everything in her power to avoid it. There is no way so natural for a bull serving a cow, as when both are in the field together, and understand one another. The most proper time is wisely chosen by both, and failure of conception will be rare in the circumstance. But it is possible that the bull may be unable to obtain possession of the cow in the field, by reason of disparity in hight and of corporeal conformation; in which case he will require to be taken to a part of the ground which will favor his purpose. Two or three *thorough* skips are quite sufficient for the purposes of conception. The cow should be put into and kept quiet in the byre, after being served until the desire leave her, and she should get no food or water for some hours after, as any encouragement of discharges from the body at this time, by food and drink, is inimical to the retention of the semen.

(1706.) "When nature is satisfied," says Mr. Skellett, who is a great authority in the vaccine department of veterinary practice, "or the symptoms of season disappear in the animal, conception has taken place. The neck of the womb becomes then completely closed by a glutinous substance which Nature has provided for that purpose, being perfectly transparent, and with difficulty separated from the parts. This matter is for the purpose of excluding all external air from the mouth of the womb during gestation, which, if admitted to the fœtus, would corrupt the membranes and the pellucid liquor in which the fœtus floats, and would undoubtedly cause the cow to slink. This glutinous substance also prevents the lips of the mouth of the womb from growing together; and when the cow comes into season it becomes fluid—in the act of copulation serving to lubricate the parts and prevent inflammation."*

9. THE ADVANTAGES OF HAVING FIELD-WORK ALWAYS IN A FORWARD STATE.

"Who breakesh timely his fallow or ley,
Sets forward his husbandrie many a waye.
This, timely well ended, doth forwardly bring
Not only thy tillage, but all other thing."

Tusser.

(1707.) The season—*early spring*—having arrived when the laboring and sowing land for the various crops cultivated on a farm of mixed husbandry are about to occupy all hands for several months to come, the injunction of old Tusser to undertake them in time that each may be finished in its proper season, should be regarded as a sound advice; for whenever your field labor is advanced ever so little at every opportunity of

* Skellett on the Parturition of the Cow.

weather and leisure, no premature approach of the ensuing season can come upon you unawares; and should the season, on the other hand, be delayed beyond its usual period by natural causes, you will be *ready* to proceed with your work whenever the weather proves favorable. When work advances little by little, there is time to do it effectually; or, if it be not then executed in an effectual manner, you have yourself to blame for not looking after it. When I say, however, that work may be advanced little by little, I do not mean that it should be done in a slow, careless manner, as if the work-people were unimpressed with the importance of what they were doing. The advantage of doing even a little is that whatever is done is not to do afterward; and that a little may be done as *well*, and in as short a time, as if it had been done as a part of a great operation. In this way, even if only one man is kept constantly at the plow, he would turn over, in the course of a time considered short when looked back upon, an extent of ground almost incredible. He will turn over an imperial acre a day, that is, 6 acres a week, 24 acres in a month, and 72 acres in the course of the dark and short days of the winter quarter. All this he will accomplish on the supposition that he has been enabled to go at his plow every working day; but as that cannot probably happen in the winter quarter, suppose he turns over 50 acres instead of 72, these will still comprehend the plowing of the whole extent of ground allotted to be worked every year by each pair of horses when the farm was taken. In fact, here is a large proportion of a whole year's plowing done in a single, and in the shortest quarter of the year.

(1708.) Now, a week or two may quickly pass in winter in doing things of little moment, and which, in fact, amount to time being thrown away; such as sending away a rake of all the draughts to a stock corn-market, on a day when there is little prospect of disposing of the grain, and when they would have been better employed at home at the plow; or driving some material on the farm which would better and easier be done when the plows are laid idle at any rate by frost; or in setting men to the corn-barn to thresh or clean corn, and laying the horses idle for the time; or in contriving some unimportant work to fill up the time for half a day, until the frost thaws a little on the lea, because it would give too much trouble to take the plows from the lea to the stubble field, if there be any such at the time. Sharpening and setting irons differently may form a reasonable excuse for shifting the plows from a stubble to a lea field, but no such excuse is available in neglecting to make the opposite transference. Such omissions and instances of misdirected labor are too much regarded as trifles *in winter*; but is undeniable that they occupy as much *time* as more important work; and in a season, too, when every operation of the field is preparatory to one at a more busy season. Occasionally the state of the work will force the consideration on the farmer, that it is not so far advanced as it should be, or even as he could wish; still, instead of pursuing a different course from that which has given rise to the reflection occasioned by the delay, his unsatisfied mind consoles itself with the assurance that when the season for active work actually arrives, the people will be able to make up for the lost time. This is, however, mere delusion; for if work can be made up, so can *time*, the two being inseparable; and yet how can lost time be made up, when every moment of the year has its work to perform, and when that period, long as it is, is usually found too short in which to do *everything* as it *ought to be done?* "There's the rub." For time eludes pursuit, and brooks no interruption; but neglected *work*, though *attempted* to be overtaken—and *it* may be overtaken before its issue—still the race will never terminate *in a satisfactory manner*. The

neglected work may, no doubt, be done in a short time—in an unprecedentedly short time; but in that case, it is the time in which the work is done that is boasted of, not the work itself—the measure, and not the thing measured, which is held up to view; and yet, time being the standard by which all well-executed labor is measured, it cannot be deprived of that property, whatever devices may be used to make it go beyond its steady pace. You should remember that *its* pace is the same in winter as in summer, and the extent of labor, measured by the length of its tread, ought to be as great in winter as in summer, otherwise an irreclaimable error is assuredly committed in that season.

(1709.) Convinced that *field*-labor should be perseveringly advanced in winter, whenever practicable, I am of opinion that plan is good which appoints plowmen to different departments of labor; some to work constantly on the farm, others occasionally to go from home; some to be constantly, or nearly so, at the plow, others frequently at the cart. Thus the benefits of the subdivision of labor may be extended to the farm. When a certain proportion of the draughts are thus set aside for plowing, *that most* important of all operations will not only be well done by those whose special duty it is to do it, but perseveringly and judiciously done. This proportion is only legitimately employed at any other work when there is no plowing for them to execute. Plowing being a steady occupation, not subject to the irregular action of the cart, can be performed by the older men and horses, who cannot so well bear the shocks of carting as younger men and horses.

(1710.) It may be proper to give some familiar examples of what I mean when I say that *field*-labor should be advanced at every opportunity. The order of work in spring is well understood; it should therefore be the study of the farmer to conduct the operations of winter so as to suit those of spring in their natural order. If the weather seems tempting to sow spring wheat, then a portion of the land cleared of turnips by the sheep, best suited to that species of crop, should be so plowed as to answer wheat instead of barley. If beans are desiderated as a crop, and there is land suitable for their culture, then, in autumn or in early winter, the stubble land, in its particular state should be so plowed as to suit their growth; and in whatever mode beans are to be afterward cultivated, care should be taken to have the land particularly dry, by letting off water in winter by additional gaw-cuts, where necessary, or by deepening those already existing, where they seem to require that amendment. Beans being an early crop, such precautions to render land dry on the surface are requisite. If common oats are to be sown in spring, they being sown earlier than other sorts, the lea intended for them should be plowed first, and means taken to keep it dry in winter, so that the most unpropitious weather in spring may not find the land in an unprepared state. What land is intended for potatoes, what for turnips, or tares, or bare fallow, should be prepared in their respective order; and when every one of all these objects have been promoted, and there is found little or nothing to do till the burst of spring-work comes, both horses and men may enjoy a day's rest now and then, without incurring the risk of throwing work back; but before such recreations are indulged in, it should be ascertained that all the implements, great and small, have been repaired for work—the plow-irons all new laid—the harrow-tines new laid and sharpened, and fastened firmly into the bulls of the harrows—the harness all tight and strong—the sacks new patched and mended, that no seed-corn be spilled upon the road—the seed-corn threshed, measured up, and sacked, and what is last wanted put into the granary—the horses new shod, that no

casting or breaking of a single shoe may throw a pair of horses out of work for even one single hour—in short, to have everything prepared to start for work when the first notice of spring shall be heralded in the sky.

(1711.) But suppose the contrary of all this to happen; suppose that the plow-irons and harrow-tines have to be laid and sharpened, when perhaps to-morrow they may be wanted in the field—a stack to be threshed for seed-corn or for horses'-corn in the midst of a sowing of a field—suppose, too, that only a week's work has been lost, in winter, of a single pair of horses, and the consequence is that 6 acres of land have to be plowed when they should be sown, that is, a loss of a whole day of 6 pair of horses, or of 2 days of 3 pair—suppose all these inconveniences to happen in the busy season and the provoking reflection occurs that the loss incurred now was occasioned by trifling offputs in winter. Compare the value of these trifles with the risk of finding you unprepared for sowing beans or spring wheat. Suppose, once more, that instead of having turnips in store for the cattle, when the oat-seed is begun in the fields, and that, instead of being able to prosecute that indispensable piece of work without interruption, you are obliged to send away a portion of the draughts to bring in turnips, which *must be brought in*, and brought in, too, from hand to mouth, it being impossible, in the circumstances, to store them. In short, suppose that the season of incessant labor arrives and finds you unprepared to go along with it—and what are the consequences? Every creature about you, man, woman, and beast, is then toiled beyond endurance every day, not to *keep up* work, which is a lightsome task, but to *make up* work, which is a toilsome task, but which you said you could easily do, when you were idling your time in a season you consider of little value; and, after all, this toil is bestowed in vain to obtain the end you wish, namely, to prepare your crop *in due season*. You who are inexperienced in the evils of procrastination may fancy this to be an overdrawn picture—even an impossible case; but unfortunately for that supposition, it is drawn from the life. I have seen every incident occur which I have mentioned, both as to work being in a forward and in a backward state, not, it is true, in any one year; but some instances in one, and some in another year, but what may occur in different years may all occur in one, and such a result may easily be realized by indulgence in increased negligence.

10. CROSS-PLOWING, DRILLING, AND RIBBING LAND.

"The new-gained field laid down in seemly drills."
GRAHAM.

(1712.) I have already described the various modes of plowing land at the commencement and during winter. It remains for me to describe other modes of plowing, which were deferred from that time until the season in which they are usually begun to be executed, namely, spring. These modes are cross-plowing, drilling, and ribbing.

(1713.) And, first, as to *cross-plowing*. I have alluded to this mode of plowing, not so much to describe it minutely, as to deprecate its practice before winter. "Its object is to cut across the existing furrow-slices into small pieces, that the land may be the more easily pulverized and prepared for the future crop." Fig. 312 represents a field to be cross-

plowed, and it is purposely formed of an *irregular* shape, as most fields are, to show the side from which the cross-furrows should be feered, and the mode of plowing the last, or irregular feering, according to the circumstances of the case.

(1714.) The first thing to be done in preparing any field for cross-plowing is to render its surface as free of large clods as possible; and this is effected by *harrowing*, an operation which is executed by an implement that will be particularly described when it comes to be spoken of in seed-time. The winter's frost may have softened the clods of the most obdurate clay-soil, and the mould-board of the plow may be able to pulverize them fine enough, and the lighter soils may have no clods on them at all; from all which circumstances it may be regarded as a loss of time to harrow the ground before cross-plowing it in spring; and, for these reasons, I believe, some farmers do not practice harrowing; but it appears to me to be always the surest plan of pulverizing the soil to harrow it before cross-plowing the winter furrow; because you cannot be sure that, in the strongest land, all the clods have been softened to the heart by frost; and should they happen still to be hard there, and become buried by the cross-furrow, they will not be so easily pulverized as when lying exposed upon the surface of the ground to the action of the harrow; and even in the lightest soils, the harrows not only make a smoother surface, but assist in intermixing the dry frost-pulverized soil of the surface with the moister and firmer soil below, at least as far as the tines of the harrows reach.

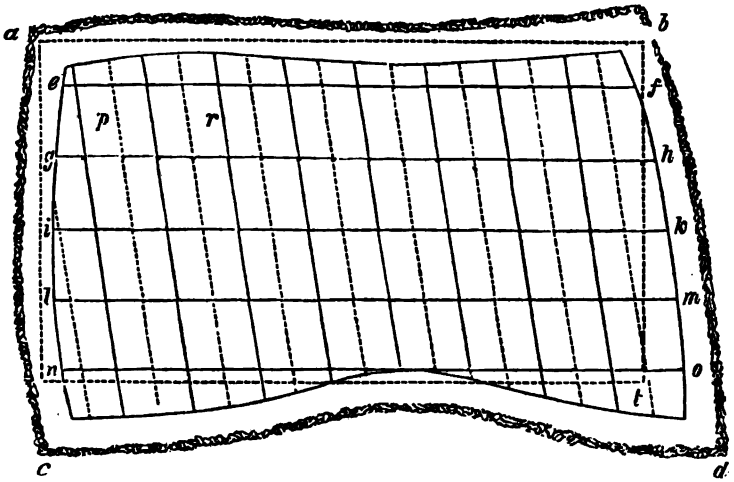
(1715.) There is not much time lost in harrowing before cross-plowing; for although the harrowing should be given a *double-tine*, that is, backward and forward upon the same ground, to pulverize the clods, or equalize the texture of the ground; and although it should be given *across* instead of along *the ridges*, that the open furrows may be filled up with soil as much as possible, whether the land had been plowed with gore-furrows, fig. 136, or not—that which has been cloven down with gore-furrows, fig. 141, or twice gathered up, fig. 139, being the most difficult to cross-harrow, not only on account of the numerous open furrows of the former method, and the inequality of the ground, occasioned by the latter, but because both these methods are adopted for winter furrows on *strong* land, which is the most difficult to be labored even in the most favorable forms—yet the worst form of plowed land can be harrowed in a short time.

(1716.) Two pairs of harrows should be set to cross-harrow together, as being the best mode of accomplishing effective harrowing in all cases, as will be shown afterward; and that number of harrows, when unconfined by ridges, will cover at least 16 feet in breadth, and proceeding at the rate of 2 miles per hour for 9 working hours, will give 19 acres of ground a double tine, on the supposition there have been no interruptions; but as time must be lost in turnings, as you have already seen in plowing (930), and a breathing occasionally given to the horses, that quantity of land cannot be harrowed a double tine at that rate of traveling, in the ordinary mode of conducting labor; but say that 16 acres are thus cross-harrowed in the course of a day, a half day's harrowing will make room for a number of plows.

(1717.) If time presses, the feerings for cross-plowing can be commenced almost immediately after the harrows have started; and if these cannot get way before the plow, it can either take a bout or two in each feering, till the harrows have passed the space for the next feering, or the harrows can pass along the lines of each feering before the plow, and return and finish the harrowing of the ground between the feerings. Thus in fig. 312, after the line of feering *e f* has been harrowed, the plow can either take a bout

or two around it, till the harrows have passed the next line of feering *g h*; or the harrows can go along each line of feering, first *e f*, then *g h*, then *i k*, and so along *l m* and *n o*, in succession, to prepare the ground for feering, and then return and harrow out the ground between *e* and *g*, *g* and *i*, *i* and *l*, and *l* and *n*. In this way the harrowing, and feering, and the plowing of the different feerings can be proceeded with at the same time. But if time is not urgent, the systematic mode is to harrow the field

Fig. 312.



A FIELD FEERED FOR BEING CROSS-PLOWED

in a continuous manner, beginning along the fence *a b* from the gate at *b* and proceeding by breadths of the harrows across the field till the other side of it, *c d*, is reached; or another equally effective mode is to step off feerings from *a b*, in breadths of 30 yards in succession, along the field, in the manner I am about to describe, for cross-plowing; and this mode has the advantage of giving an easier turning to the horses at the landings.

(1718.) Suppose, then, that all or as much of the field to be cross-plowed has been harrowed as will give scope to a single plow to make the feerings without interruption. In choosing the side of the field at which the feerings should commence, it is a convenient rule to begin at the side farthest from the gate, and approach gradually toward it, and its convenience consists in not having to pass the finished feerings, and so to avoid the risk of trampling on the plowed to get at the unplowed land. The convenience of this rule is felt not only in cross-plowing, but in prosecuting every species of field-work; and besides avoiding the risk of damage to finished work, it is gratifying to the minds of laborers to think that, as their work proceeds, they approach the nearer home; while it conveys to others the idea of a well-laid plan, to witness the operations of a field which have commenced at its farthest end, and are finished at the gate, where all the implements employed meet, ready to be conveyed to another field. The gate in this instance is like home, and in most instances it is placed on that side or corner of the field nearest the steading. In the particular case of the field represented by fig. 312, these conveniences are not all available, owing to its form, which is a very common one; and peculiarities of form involve considerations in regard to conducting field operations of more importance than mere convenience, and one of these is the most

important one of loss of time. It is always desirable to commence a feering at a *straight* side of a field, whence there is little risk of error in ing off the feerings to include parallel spaces of ground; and wher estrik- this particular is not attended to, much time is needlessly spent in plowing a number of irregular pieces of ground. It is better to leave any irregularities in plowing to the last; and, as an irregularity must occur, at all events, along the side of a crooked fence, it is saving of time to throw any irregular plowing to that side. In fig. 314 it so happens that the straightest side of the field is nearest the gate at *b*, and the crooked fence, *c* to *d*, farthest from it. In pursuance of the rule just announced, the feering should begin along the side of the straight fence *a b*, and terminate in an irregular feering, along the crooked fence *c d*. A straight feering could, no doubt, be made at first along *c d*, leaving any irregularity between it and the fence; but the setting off of that feering *parallel* with the straight fence *a b*, in order to avoid making an irregularity there also, would im pose considerable labor, and take up more time than the advantage would compensate of avoiding the inconvenience of having to pass plowed ground.

(1719.) Let the first feering, then, be made about 7 or 8 yards from the fence *a b*, or from the ditch-lip of that fence, if there be a ditch there. Some farmers neglect the head-ridge in the cross-plowing, and measure the feering from the open furrow between it and the ends of the ridges. I maintain that the head-ridges should be plowed at this time, as well as the rest of the field, for if they are neglected now, the busy seasons of spring and of early summer will prevent attention being paid to them till, what with the trampling of horses in working the land for green crop, and the probable drouth of the weather in those seasons, will render them so very hard that it will be found impracticable to plow them, and they will thus be deprived of the ameliorating effects of the sun and air during the pest part of the year. Let them, therefore, be included in the cross-plowing, although they cannot be *cross*-plowed themselves. But if it is desired to plow them with the side-ridges, which form the head-ridges to the cross-plowing, and which side-ridges must be plowed before the crop, whatever it may be, can be sown upon them, then the head-ridges may be left out of the feering, and the first feering be struck at 7 or 8 yards from the head-ridge open furrow. Suppose that this line of feering is *e f;* and as it is executed in the same way as that already described in feering ridges in (646), I refer you to that paragraph, as well as to fig. 132, where the furrow-slices *m n* are shown to be thrown out right and left from the line of feering *k l*. The next line of feering is *g h*, at 30 yards' distance from *e f*, and so there is a feering at every 30 yards' distance, to the last feering, *n o*.

(1720.) After as many feerings are struck as there are plows to be employed in cross-plowing, each plow enters a feering, and first lays the furrow-slices of the feering together, to form the crown of the future cross-plowed break of land. The horses are *hupped* around each feering, *e f*, *g h*, &c., till about $\frac{1}{4}$ of each break of land is plowed, that is, $\frac{1}{4}$ from *e* toward *g*, and $\frac{1}{4}$ from *g* toward *e*, thus plowing $\frac{1}{2}$ the break between *e* and *g* by *hupping* the horses. The remaining $\frac{1}{2}$ of the break, between *e* and *g*, is then plowed by *hieing* the horses (901) from *e* to *g*, and from *h* to *f*, till the middle, between *e* and *g*, is gained by an open furrow. No open furrows, however, are left in cross-plowing, these being plowed together again by 2 or 3 bouts, lessening the size of each furrow in every bout, till the last one is closed up by the mould-board of the plow, which is laid over on its side, and dragged forward while the plowman holds

only by the large stilt. The obliteration of the open-furrow is necessary to avoid any hollow that would be left there across the ridges, when they are again plowed into form. I have alluded to this subject before in (667.)

(1721.) The plowing of the complete feerings is all plain work, and, indeed, the only difficulty encountered in cross-plowing is when the last or irregular feering, such as *n o*, is reached. This feering is begun to be plowed like any of the rest, till the nearest point to the open furrow of the head-ridge is attained, and if the head-ridges have been included in the feerings, then the plowing proceeds till the ditch-lip or hedge-root stops the plow; but if left to be plowed with the side-ridges, a small feering should be made at the lowest points of the ridges at the head-ridge furrow, and the break included between these points and the feering should be plowed out by *hieing* the horses with a long furrow on the one side and a short one on the other, till the middle is gained, where the open furrow is closed up like the others. This feering will take longer time to plow than any of the rest, in proportion to the quantity of the ground turned over in it, on account of the plow having to go empty from the bend of the fence to the points on both sides.

(1722.) Had the field been a true rectangle, like the space included within the dotted lines *a n b t*, the feering might have been struck from either fence, and there would have been no loss of time in plowing alternate long and short furrows. Scarcely a more striking comparison can be made of the loss of time in plowing land of the same extent than between a field of regular and irregular form at a busy season. The letters *p* and *r* indicate single and double ridges.

(1723.) The furrow given at cross-plowing is always a deep one, deeper than the one given at the commencement of winter; and this is easily accomplished, as the land, not having had time to consolidate, nor any labor executed upon it to consolidate it, the plow passes easily under the old furrow, and not only turns it over again, but raises a portion of the land below it. Indeed, it is requisite to make the plow take hold of this firm substratum in order to keep it steady, otherwise the formerly turned-over furrows, which are still cloddy, or the unrotted stubble which has been buried by the plow, may form obstacles under and on both sides of the plow, so as to throw it out of operation altogether, or at least so affect its motion as to prevent its maintaining an equal depth of furrow. Perhaps 9 inches may be considered a good average depth in cross-plowing with a pair of horses.

(1724.) But means are frequently used at this season to cross-plow with a deeper furrow than can be reached by a plow drawn by a pair of horses, 3 or 4 horses being employed for the purpose. The *third* horse is very commonly yoked in front of the furrow-horse of the plow, and harnessed in cart-traces, as represented in the trace-horse of the cart in Plate XVIII., the hooks of the trace-chain being passed into a link of the plow-chains, behind the haims, of the rear horse. A simpler plan still is adopted by only using the plow-harness, and lengthening the plow-chains by *short-ends*, that is, short pieces of chain, which are hooked in a similar manner to that just described. Neither of these methods, however, will bear a comparison, in point of draught, with the yoking of 3 horses, as represented in fig. 201, and described in (909). I have an objection, however, to this mode of yoking, which is founded, not on its principles, which are faultless, but on account of an inconvenience to one of the horses. When so yoked, the three horses work nearly abreast, the middle one being only a little in advance of those on either side; and the objection is, that the

middle horse will become more heated in the work, in that position, than either of the other two. This inconvenience may not be much felt in early spring-work, but at the time when the largest proportion of cross-plowing is usually executed, or in summer, the middle horse must suffer considerably more than the others, and this result I have frequently witnessed in places where three horses are still yoked abreast to the harrows. There are various modifications of yoking three horses practiced in different parts of the country, to which reference has already been made in (910), (911) and (912), and where will also be found methods of compensating the labor of any individual horse by an alteration of the swing-tree, when unequally yoked, which one of the horses is, when three are made to work together, as they are usually yoked in tandem fashion. Three horses will take a depth of furrow of 11 or 12 inches, according to the texture and depth of the soil.

(1725.) A still greater depth may be attained, and is frequently desirable in cross-plowing, and there is no other sort of plowing which affords such facilities for obtaining a deep furrow. This greater depth is attained by yoking four horses to a plow, 2 leading and 2 following, the 2 off ones walking in the furrow, and the 2 near ones on the firm land. Two very convenient and efficient modes of yoking 4 horses may be seen in figs. 202 and 203, and a description of them is given in (913) and (914). Yoked as in fig. 202, the leading horses are best harnessed, as in the traces of the cart, Plate XVIII; but, as in fig. 203, they may be in their usual plow-harness, with the exception of the chains, which are made for this particular mode of yoking. The depth reached by a 4-horse plow is, on an average of soils, 14 inches. I have used the 4-horse plow much, and with *stout*, well-matched horses have never reached less than 14 inches in obdurate subsoils; while in freer soil and substratum, not properly a subsoil, but rather an undisturbed soil, the plow went to 16 inches of perpendicular depth, and the work was most satisfactory,

(1726.) An ordinary stout plow will answer for 3 horses, and so it may for 4, where there are no bowlder-stones in the land; but where a considerable quantity of 4-horse plowing is desired to be executed, it is better to have a plow made for the purpose a little stronger than the ordinary 2-horse plow.

(1727.) In a 3-horse yoke, one man may drive all the horses by means of reins or by the voice, though a boy to assist at the turnings will save as much time in that matter as will compensate for his wages. Where 3 horses are yoked abreast, one man may as easily manage them as 2 horses. In the case of 4 horses, however, there should be a man to drive the horses, and this is usually done with the whip instead of reins, though the near leader should have a rein. The second man, in this case, is no loss, as the 4 horses just constitute 2 pairs of the ordinary draughts. Even if the second man were taken away from his horses—which should never be the case—and set to other work, he would be of little service, as his mind would be constantly occupied with the desire to know how his horses are getting on under the guidance of another man. But the fact is, that no man can manage 4 horses at the plow with advantage to the work. Fig. 206 shows how a 4-horse plow may be yoked and driven.

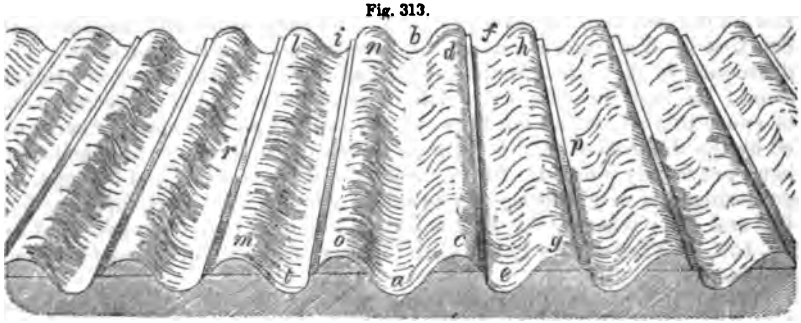
(1728.) This deep cross-plowing with a 3 or 4-horse plow should not be confounded with trench-plowing, which is best and usually performed as represented in fig. 206. Trench-plowing only deserves the name when a common plow goes before and turns over a furrow-slice, and in the bottom of which the 4-horse plow follows and goes as deep as it can. In deep-plowing, the 4-horse plow goes as deep as it can of itself, and it is rare that

it meddles with the subsoil, which it is the special object of trench-plowing to disturb. Deep-plowing will be very well executed by one common plow following another in the same furrow; and when the substratum is free, this is a very good way of stirring up the soil to the moderate depth of 10 or even 12 inches.

(1729.) The 3 and 4-horse plows should not be inconsiderately employed in cross-plowing in spring, because, either mode of plowing occupying a considerably longer time with the same number of draughts, and employing more horses than ordinary plowing, it cannot be prudently employed on land that is immediately to be occupied by an early spring crop, such as beans, though the time in which potatoes, turnips, and fallow are respectively finished, will afford plenty of leisure to have the land appropriated to them deeply cross-plowed in the best manner.

(1730.) Next as to *drilling*. This is a form of plowing very different from the ordinary, but it is not unlike that mode of plowing stubble in some

Fig. 313.



THE MODE OF PLOWING SINGLE DRILLS.

parts of the country which is represented by fig. 142, and which I alluded to only to condemn. The principal reason for my condemnation of it was that, while it professed to turn up the soil to the action of the atmosphere, it buried more than half of it untouched by the plow, thus in a great measure running counter to its own avowed object. On comparing fig. 313, with fig. 142, the *form* of the two modes of plowing are somewhat similar, but their structure, that is, the state of the soil within and without, they are very different. In fig. 142, the ground *b* is quite solid and unmoved from the state in which it had borne crops, and the moved parts *a* are full of stubble and weeds. The lines of the drills *c* are quite irregular, having no reference to the quarters of the compass, the direction of the ridges, or in parallelism with themselves. The regular drill, on the other hand, is formed of deep loosened soil, plowed and harrowed on purpose, and made as clear of weeds as the time allotted to prepare the soil will allow. Drilling is a finished piece of work, the other only confessedly a preparatory one. Drilling is essential to the proper cleaning of the land at a future period of the season, the other a very questionable mode of attaining any good object.

(1731.) I have said that before land is drilled it should be well pulverized, well cleaned, at least as well as the time when it should be drilled will allow; and the ground should be in a soft state by labor when drilling is to be executed, otherwise the drills will not have their proper form and structure. Drills should not be formed on hard land, nor ought they to be attempted to be formed on hard land, as the object of making them at all is, in the first place, to afford a sufficient quantity of loose soil to

cover the manure deposited in them; in the next place, to afford the roots of plants sufficient freedom to roam in search of food; and, in the last place, to afford opportunity, notwithstanding the presence of a crop, to free the land of weeds, by stirring it occasionally with proper implements. There is no way of effecting all these objects so effectually as by drilling. Accordingly, all crops intended to meliorate and clean the ground are cultivated in drills, and these are what are called green crops, namely, potatoes, turnips, mangel-wurzel, beans, &c.

(1732.) After land has been much plowed and harrowed, and even rolled to render it friable, it is usually in a flat state, whatever may have been the form in which it had been before plowed; and when flat, it is in the best state for being plowed into drills. Yet strong land that is constantly retained in ridges of a rounded form, that is, twice gathered up, fig. 139 and (656), will exhibit the form of ridges, even after it has been well pulverized by plowings, harrowings, and rollings; it will still appear as if gathered up from the flat, fig. 133, and it had been harrowed and rolled fine on the surface. Lighter soil with the same work will appear quite flat, that is, of a uniform surface throughout, not as if it were level. This distinction in the appearance of the ground of being ridged or not ridged, should be kept in view, as it will in great measure determine the width of space that should be left between the drills: and it is entirely occasioned by the difference of the form in which the different sorts of soils had been previously plowed. Strong soil is always kept round by repeated gatherings up, or gatherings-up based on casting with gore-furrows, figs. 135 and 136; whereas the lighter soils are usually only once gathered up, fig. 133, cast together without gore-furrows, fig. 135, or plowed two-out-and-two-in, fig. 138.

(1733.) In whichever of these states the land may be, whether completely flat or exhibiting a slight indication of rounded ridges, the drills are made of the same form; and they are formed in the following various ways. They are made by one landing of the plow, when they are said to be *single*, or they are made with a bout of the plow when they are called *double;* and both single and double drills are made either *toward* or *from* the *feering*. The ultimate forms of the two different modes are apparently the same, but that which makes them *from* the feering is nevertheless the best, as I shall show in the sequel.

(1734.) In beginning to make drills, let us take one of the simplest cases that present themselves, namely, a field having a straight side at its farthest end, and having the forms of ridges still visible; and as it is requisite in strong land to preserve a form that will keep it as dry as possible, the drills should be so formed upon the ridges as to be accommodated between their open furrows. If the ridges are 15 feet in width, 6 drills of 30 inches apart will fill up that space between the open furrows; and if 18 feet wide, 8 drills of 27 inches will answer the same end. When the ground is flat, any width of drills previously determined on may be executed. have seen it stated in cases of drilling land for turnips in England, that only 18 inches was a good distance to be preserved between drills; but what object is gained by adopting a distance which is too narrow for the free operation of the implements required to keep the ground clean, I cannot imagine.

(1735.) Suppose, then, that the ridges present a form of 15 feet in width on strong land, they should be made 30 inches wide, and they are made in this way: Begin at the end of the field farthest from the gate, and where the fence runs in a straight line; and set up 3 feering-poles (446) in a straight line upon the nearest furrow-brow of the third ridge from the

fence, and 15 inches from the middle of its open furrow. Split out the feering along the line of the poles, turning over the furrow-slices first to one side and then to the other, like the furrow-slices *m* and *n*, along the feering *k l*, fig. 132. The reason that the first feering is made on the furrow-brow is, that when the drills are split to cover the dung, or whatever else is put in them, the place which the hollow now occupies will then be filled up by the drill, and the open furrow will then be the hollow between the drills upon the furrow-brow of both ridges. In fig. 313, suppose *a b* to be the feering in the furrow-brow of the ridge. On passing up from *a* to *b*, the plow lays over the furrow-slice *c d*, and the soil having been pulverized, it crumbles down in a continuous heap upon the firmer land under it. On gaining the head-ridge at the other end of the feering, the horses are *hied*, and the plow comes down from *b* to *a*, laying over a similar furrow *n o* upon the firm land. A similar feering is made in the furrow-brow of the 6th ridge from the last, and so on upon every 6th ridge across the field; but ere the field is all feered for drilling, some of the drills are formed between the feerings, that the land may be proceeded with for the purpose it has been drilled, while the feering and the drilling of the remainder are proceeded with. To proceed, then, with the drilling at the first feering, at a distance of 30 inches, this previously determined width of the drills is measured off from *a* to *e*, and this the plowman does with his plow-staff, or shaft of his plow-spade, as that implement is call in some parts of the country, upon which the various breadths of drills executed on the farm are notched off. The plow then proceeds from *e* to *f*, preserving a parallelism with the feered furrow *a b*, laying over the furrow-slice *g h* upon the firm ground, upon which it crumbles down in a continuous heap. On *hieing* the horses at the other end of the drills, a similar distance of 30 inches is marked off from *b* to *i*, the plow passes down from *i* to *t*, laying over the furrow-slice *l m* upon the firm ground. *Hieing* the horses again, the plow passes on to *p*, and goes by *p*, forming another drill like the others. The plowman does not measure off the width of every drill he makes in this manner, his eye being able to keep him right for a number of drills, across which he then lays his plow-staff, to ascertain how he has been proceeding, whether the drills he has made be too narrow, or too wide, or quite the proper breadth, and then again proceeds with his work. It will be observed, from the description of this process, that one drill has been formed every time the plow has gone up in the direction of *e f*, and another every time in coming down in the direction of *i t*, with the exception at striking the feering, when the plow both went up and came down *a b*. In this way the horses are made to *hie* round *a b*, and the plow to make 2 drills every bout till 2 ridges on each side of the feering *a b* are drilled up, and the last drill will be made close behind the fence. When this takes place, the plowman goes to the next feering, when two furrows were split out as at *a b*, and forms drills around it in the same manner till 2 ridges also on each side are drilled. Two ridges having thus been drilled to the right of the first feering and two to the left of the second, and six ridges intervening between the feerings, two ridges of the six have yet to be drilled, upon which the drills are formed by *hupping* the horses from the one set of drills to the other; but in doing this, caution is requisite to make all the drills of the exact width of 30 inches, and particularly the last two formed at the junction of the two feerings. The caution is exercised by the plowman applying his plow-staff frequently to ascertain the breadth of the ground to be drilled, and the width of the drills themselves; and should he find that he has more or less ground than he should have for the number of drills he has yet to make, he must modify the width of each

drill, so as the whole number may be very near the width, and not reserve any surplus or deficient ground to be added to, or substracted from, the last drill alone. Another caution of not less importance is to ascertain if the ground to be last drilled is of the same breadth at both ends at the head-ridges, for if this point is not attended to, the last drill may run out to a point at one end, and be too broad at the other. In closing every feering, therefore, the greatest caution is required to preserve the breadth of the drills.

(1736.) This is one way of forming *single* drills, and the following is another. Instead of splitting out the feering *a b*, fig. 313, as just described, the plow lays two furrows together, and forms a finished drill with an elevated ridge, in the place of the hollow furrow *a b*; and this is done by *hupping* the horses instead of *hieing* them, as in the other case. Still *hupping* the horses and measuring off the width of the drills as formerly, the next drill is made in the direction of *f e*, laying the furrow-slice upon the firm ground, toward the open track of the plow left in making the previous drill in the same direction. The next drill is made in the direction of *t i*, again laying the furrow-slice toward the plow-track left open in forming the previous drill. The drills are thus formed around the first feering over the 2 ridges on each side, then over the 2 ridges on each side of the second feering, and the drills are closed up between them, with the precautions noticed above (1735), by *hieing* the horses.

(1737.) The essential difference betwixt these two methods is this. In the first, the furrow-slices are all laid over *from* the feerings toward the *unplowed* land, and the horses are first *hied* and then *hupped* in finishing the feerings. In the second method, the furrow-slices are all laid over *toward* the feerings and the *plowed* land, and the horses are first *hupped* and then *hied*. As to the treatment of the horses, there is no difference in regard to them, being *hupped* and *hied* in both cases, but there is a considerable difference in regard to the treatment of the land. In the *second* method, the furrow-slice being laid over toward the open track which the plow has made in making the previous drill, should the land be at all cloddy, and it is impossible to reduce every clod on strong land at all times, clods or stones may roll down the crumbling furrow-slice, acquiring an impetus by the action of the ear of the mould-board, into the hollows between the drills; and this is no imaginary inconvenience, for clods and stones actually roll down into the said hollows, when they happen to be numerous, or when the soil is so firm as to acquire a considerable force of the plow to elevate it into drills, and when it is apt to rise in large masses before crumbling down in its fall from the mould-board. When the width of the drills is as much as 30 inches, this inconvenience is less likely to happen, but when the more usual width of 27 inches is adopted, I have seen it occur to a considerable degree. The immediate inconvenience occasioned by these clods is, that they interrupt the progress of the bean-barrow when the land is drilled up in this way for the bean-crop; and when the land is dunged, they occupy the best part of the drill, and being there covered up with the dung, they remain among it, and form obstructions to those roots of plants that may be pushing through the manure in search of farther sustenance. At all events, they can do no good.

(1738.) In the first method, on the other hand, this inconvenience is entirely avoided, and no other is substituted in its stead; for should clods and stones roll away from the furrow-slice when the drill is making, and which they will inevitably do when present, upon the open and firm land, they remain there only to the next passage of the plow, which sweeps *them*

away, and at the same time leaves a small space of ground between the former furrow-slice and its track, as from *t* to *o*, &c., and which track is clear and open, ready for the bean-barrow, or the dung that may be deposited in it. The advantage possessed by the first over the second method of drilling in these respects is so obvious, that any argument in support of it appears unnecessary, and being so obvious, you should not fail to adopt this method as your invariable practice.

(1739.) When the ground is flat, that is, when the ridges are not remarkably prominent, the drills are made the common width of 27 inches, some make them 28 inches, and the feering is conducted in the same way; but in setting off any feering from the last one, when there is no such guide as the breadth of ridges to measure the proper distances, care should be taken to set off such distances as will contain a determinate number of drills of the fixed width, otherwise an error will inevitably occur at the closings of the feerings. Thus, if the drills are 27 inches in width, in a feering of 30 yards broad, 6 ridges of 15 feet, each making a very convenient breadth of feering, the number of drills will be exactly 40.

(1740.) So much for single drilling; now for *double*. For this mode the feering is made in a different manner from that for the single mode of drilling. Supposing, again, that the ridges are visibly marked in the ground, the feering is taken from the furrow-brow of the ridge nearest the fence, at 15 inches from its extreme outer edge, and there setting up a straight line of poles, split out the feering as before by the plowing passing up and down in the same furrow. Suppose this furrow to be represented by the line in *e f* in fig. 132, then set up a square table at *d*, and mark off therefrom a line with poles at right angles in the direction of the arrow through *s* to *t*. Removing the square table to *g*, set off a similar and a parallel line in the direction of the other arrow through *u* to *v*. Split out both these lines with the plow as straight as the plowman can, and the bottom of the furrow in them will form a guide to set off the requisite widths of drills at right angles to the feering, at least they will serve to check the plowman in his making the drills correct. Plowmen expert at drilling are apt to contemn such guides in forming double drills, because they conceive they can preserve the widths sufficiently well by the eye, and no doubt plowmen are to be found who drill with precision, and I have met with such, though very few in number, but the generality of them cannot be intrusted in this delicate task without a guide of some sort, and there is none more simple and more effective than the one I have described and recommended. And where *single* drilling is to be executed on land on which no vestige of a ridge is seen, it is quite impossible for the most expert driller to set off the feerings with sufficient accuracy. Plowmen, I know, try to do it, and I have seen good ones nearly succeed in it, but never witnessed one who was not obliged to modify the widths of the drills at the closings. Strict accuracy in regard to drills is not required in some crops, such as in the bean and potato; but with regard to the turnip, which is sown with a machine set to a given width, unless the drills are very nearly alike in breadth at both ends, the sowing will be very imperfectly performed. The means, too, of attaining accuracy are so simple—merely drawing two or three furrows across the field—that it is culpable to neglect it. There will be, I am certain, more time spent by the plowman in measuring the widths of drills with his plow-staff at every closing, than he would spend in drawing a few cross-furrows at first; and after all his adjustments, his mind is not satisfied that he has done the work in the most accurate manner. It is true that with all the assistance cross-furrows can afford him, he will still have to measure the widths of drills with his plow-staff at every closing,

but he is much less likely to err in his measurements while having the cross-furrows to guide him at right angles to the direction of the drills, than in measuring at random in a supposed right direction. This is so self-evident that your mind must assent to the facilites afforded by cross-furrows.

(1741.) The double drills are formed in this way, on the supposition that ridges are visible at 15 feet asunder; and this method is analogous to the first method of feering single drills. After the furrow-slice *c d*, fig. 313, is laid over at the feering of *a b* along the furrow-brow of the ridge nearest the fence, the horses are *hupped*, and the plow is made to come down at the prescribed width of the drills, namely, 30 inches, along the line *f e*, and to put a furrow-slice against the other furrow-slice *c d*, which had just been turned over upon the firm ground, and in doing this the drill receives a somewhat sharp-pointed crest. At 30 inches this crest is never very sharp, but at 27 inches it may be made as sharp as you please, by making the plow go a little deeper. Then *hieing* the horses, the plow again goes along *e f*, but in the opposite direction, and lays over the furrow-slice *g h* on the open ground. *Hupping* again, the horses come down *p*, and form the other side of the drill *h g*; and so on, one drill after another. No breaks of feerings are required in this mode of drilling, as every drill is finished as it is formed, and the precautions required are, that the proper widths of the drills are preserved throughout their lengths, in which they may be easily checked by the assistance of the cross-furrows.

(1742.) The other mode of double drilling is analogous to the second mode of single drilling. After the feering-poles are set up, as in the former case, the plowing is commenced from the other head-ridge, and the first furrow-slice *n o* is laid over while coming down *b a*. The horses are then *hied*, and the plow is passed up the same furrow in the opposite direction *a b*, and having little earth to lay over, but a small furrow-slice is laid toward *c d*. *Hupping* the horses, the plow is then brought down *f e*, which being a fresh furrow, the furrow-slice *d c* is large, and completes the drill *d c*. *Hieing* the horses, the plow again passes along the last furrow in the opposite direction *e f*, and having little earth to take lays over the small furrow-slice *g h*; and then *hupping* again, a large furrow-slice is laid over from *q* and completes the drill *h g*, and so on, one drill after another, at the requisite width.

(1743.) The same difference exists in the two modes of making these double drills, or in making the single. Thus, in the first method the large furrow-slice is laid over upon the open and firm ground, and the drill is finished by the second and smaller furrow-slice; whereas in the second method the larger furrow-slice is laid toward the already drilled land, and upon the smaller furrow-slice which was first turned over.

(1744.) On considering carefully both modes of drilling, it will be observed that the two sides of a double drill are not equal, that side which receives the furrow-slice raised from the firm land receives a larger quantity of earth than the side which receives the small furrow-slice derived from the same track out of which the former large slice had been taken. The immediate consequence of this inequality of earth upon the two sides of a drill is to give it the form of an unequal triangle, and its effect on the growth of any seed deposited within the drill, is to cause the germ of the plant to grow out of the side at the upper part instead of the top of the drill. This effect is particularly shown by the sloping direction which a strong growing stem of beans or potatoes takes, and to obviate which the tops of the drills are always, in practice, harrowed down as much as to allow the stems to grow upright.

(1745.) This inconvenience of the unequal form of the double drill attends both modes of making them; but, of the two modes, that which lays the large furrow-slice upon the open side of the firm land possesses two advantages over the other; the first of which is that no clods, large or small, can roll from the top of the drill into the hollow; and the other advantage is still greater, that of the finished drills being less trampled by the horses in making the succeeding ones. This last circumstance may be explained by referring to fig. 313. When the plow, for instance, goes up *e f* to commence a new drill, it cuts the firm ground along that line, laying the furrow-slice *g h* upon the open unoccupied ground to the right, and leaving on the left a small space of firm ground *c e* and *d f*, between the line of the plow *f e* and the crumblings of the previous large furrow or unfinished drill *c d*. In doing this, the furrow-horse walks up the hollow of the former made drill *a b* to guide him in the exact line he should go, and the other goes on the firm ground by the side of *e f*. On returning, the furrow-horse comes down *f e*, while the other comes down *p*, while the plow is making up the small side of the drill *d c*; but in doing this the footsteps of the horse that went up the finished drill *a b* are left untouched. This may be considered a matter of little importance, and from the generality of the practice, one would be led to conclude it of little importance; and in case of some horses which walk neatly and narrowly in a drill, the impressions of their footsteps may be almost unobserved in its bottom; but in the case of a horse which walks wide behind, and in that of all weak horses which stagger under their draught, both sides of the drills are frequently much trampled; and in the case of drilling strong land, footprints injure the soil by holding water. These may be obliterated in this way: instead of perfecting the drills one by one in succession, let an intermediate drill remain unfinished between one that is finishing and another that is forming. For example: instead of finishing the second side of the drill *h g* by returning down the hollow *b a*, let the drill remain unfinished until the new drill *p* is formed so far as to lay over its furrow-slice on the firm ground. Then let the plow come down *b a*, having the furrow-horse before it, and it will obliterate its footmarks, and let the other horse come down the intermediate open furrow *f e*, because in going up and down, it is necessary in drilling that one of the horses shall go in a hollow of a drill formerly made to guide it in the proper line. With regard to the mode which lays the large furrow-slice toward the drilled land, it seems impossible but to leave the finished drills trampled. For example: on finishing the drill *h g*, on the plow coming down *b a*, the furrow-horse walks down the finished drill *i t*, and the other walks on the firm ground down *d c*; and the same ground is gone over by the horses on the plow laying over the small furrow toward *c d* on passing up the hollow *a b*. When the plow comes down *f e* to lay over the large furrow toward and to finish the drill *d c*, the furrow-horse comes down *b a*, and the other upon the firm land alongside *f e*; and thus the finished hollow *a b* is twice trampled, first in guiding the furrow-horse while the plow is forming the drill *d c* when coming down *f e*, and again on the plow passing up *e f* to lay the small furrow toward *h g* for the next drill, which is completed in its turn when the plow comes down *p*, and the furrow-horse tramples the finished hollow *f e*.

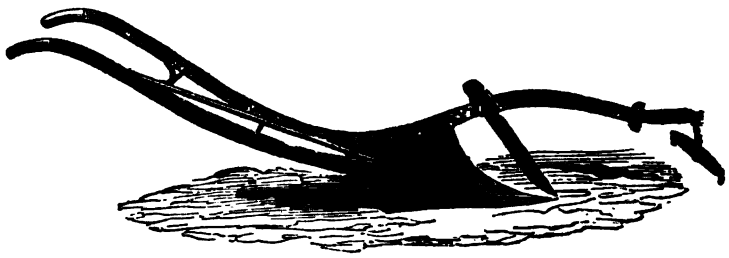
(1746.) When the ground is quite flat, double drills may be made 27 inches wide, and the same width may be adopted when ridges of 18 feet are visible, for 8 drills of 27 inches just cover an 18-feet ridge. A feering of 6 ridges of 18 feet just includes 64 drills of 27 inches, so that where drills are desired of 27 inches in width, and no more, the land should be

in 18-feet ridges, if ridged, or it should be flat—otherwise some of the 27-inch drills on 15-feet ridges will be left in the open furrow, a position which in strong land cannot fail to prove injurious to that part of the turnip crop in winter. When the soil is thorough-drained, it is of no importance where the drills are situated; but till that operation is performed, it is necessary to attend to the safety of the crop in the most unfavorable circumstance of soil by judicious management.

(1747.) It may have occurred to you to inquire that, if a perfect drill is formed by a bout of the common plow, why it is that perfect drills are not formed by one landing with a double mould-board plow? The inquiry is a natural one, and it can receive a satisfactory answer. Were a drill perfectly formed, a vertical section would give a triangle whose hight is equal to half the length of the base. The hight to which a common plow can elevate the crest of a drill is that of the ear of its mould-board, which, in the common (Small's) plow, Plate X., is 12 inches; and this hight is conformable to a drill of only 24 inches in width. Such a plow, therefore, to make a drill of the usual width of 27 inches, will either leave a flat space on its tops of 3 inches in breadth, or it will leave a sharp crested ridglet of 3 inches in breadth at the bottom of the hollow of the drill. A common plow varies in width from the ear of the mould-board to the land-side from 18 inches (Wilkie's) to 20 inches (Small's). A bout of Wilkie's plow could thus make a drill 36 inches, and that of Small's 40 inches in width in a bout, were it plowed to the full breadth either was capable of; but as drills are only made 27 inches in width, the second furrow is taken by the plow going nearer the side of a drill than in the middle of the hollow between two drills, and it is this expedient which gives to drills one sloping and another more perpendicular side. A double mould-board plow, constructed of similar dimensions of an ordinary one, would make drills much wider than are required; but even if its mould-boards were set as narrow as to make a 27-inch drill, it is found that on account of the width of double mould-board plows below, they cannot go so deep as to give drills their proper elevation of 13½ inches, required to bury the requisite quantity of manure deposited in them.

(1748.) There is a species of drilling executed by the small plow, fig. 314, which has received the appellation of *ribbing*. In executing this mode

Fig. 314.



THE SMALL, OR RIBBING OR PARING PLOW.

of plowing, it exactly follows the mode of making single drills; and of the two modes of making these, it is necessarily restricted to that which lays the furrow-slices toward the unplowed ground, because the ribs being necessarily narrow, were clods and stones to fall into the hollows, which the other method would infallibly cause, the purposes of the ribs forming a kindly seed-bed would in a great measure be frustrated. The ribs, with

great pains, can be formed as narrow as 9 inches, and by careless plowmen they are made as wide as 14 inches, so that 12 inches may be considered a good medium width. They are always formed on ridges, never on a flat, and only used in seed-furrowing. The best width of feering for making them is 2 ridges, beginning on the furrow-brow of the ridges, and laying the furrow-slices into the middle of the open furrows between the two ridges; by *hupping* the horses the seed is kept out of the open furrow, and retained upon the best land of the ridges. Ribs are formed in the length of the ridges. Supposing them to be 12 inches asunder, there will just be 30 ribs in every feering of 2 ridges of 15 feet each. Another implement which makes a number of ribs at once is described below.

11. SOWING SPRING WHEAT AND GRASS-SEEDS.

"When winter frosts constrain the field with cold,
The flinty root can take no steady hold."
DRYDEN'S VIRGIL.

(1749.) Wheat cannot be sown in spring in every sort of weather, and upon every variety of soil. Unless soil possess a certain degree of firmness, that is, contains some clay, it is not considered adapted for the growth of wheat, at least it is more profitable to sow barley upon it; and unless the weather is as dry as to allow strong soil to be plowed in the proper season, it is also more profitable to defer the wheat, and sow barley in due season. The general climate of a place affects the question of sowing wheat there in spring, and it is a curious problem in climate why wheat sown in autumn should thrive at a place where spring wheat will not. Elevation of position, even in a favorable latitude, produces the same effects. Experience in these well-known circumstances renders the farmers of Scotland chary of sowing wheat in spring, unless the soil is in excellent condition, and the weather very favorable for the purpose.

(1750.) When wheat is sown in spring, it is usually after turnips, whether these have been entirely stripped from the land, or partly consumed on the ground by sheep. In whichever of these states of the turnip crop may be chosen to be followed by wheat, it is not sufficient merely to raise a crop of turnips by dint of a plentiful supply of manure at one time upon an otherwise exhausted soil that will insure a good crop of spring-wheat; the land itself should be and have been for some time in good heart, otherwise the attempt will inevitably end in disappointment.

(1751.) On a farm possessing the advantages of favorable soil and climate, and on which it is the custom to sow spring wheat every year, the turnip-land is plowed with that view up to a certain period of the season, not later than the beginning of March; and even on a farm on which spring wheat can only be sown occasionally, when a favorable field comes in the course of rotation, or the weather proves tempting, the land should be so plowed as that the advantage may be taken to sow wheat. Should circumstances warrant the attempt, or matters take an unfavorable turn for the purpose, there will be no harm, as the soil can afterward be worked for barley.

(1752.) Land should only receive one furrow, the seed-furrow, for spring wheat, for if it is plowed oftener after a manured green crop, and in spring,

when it has become tender by the winter frost, it would want that firmness which is essential for the growth of wheat. The nature of this seed-furrow depends upon circumstances. If the land presents a visible form of ridge, and if it soon becomes wet, the best way to plow it is to gather it up, and then it will have the appearance of being twice gathered up, as in fig. 139. If it is flat, and the subsoil somewhat moist, gathering up from the flat will answer best, as in fig. 133. If the soil has a dry subsoil, though of a pretty strong clay itself, it may be cast with gore-furrows, (663). And should it be fine loam resting on an open bottom, the ridges may be cast together without gore-furrows, as in fig. 135. It is probable that a whole field may not be obtained at once to plow up in either of these ways, and indeed such an event rarely happens in regard to preparing land for spring wheat; but when it is determined to sow it, a few ridges should be plowed up as convenience offers, and then a number of acres sown at one time. In this way a whole field may be sown by degrees, whereas to wait until the sowing of the whole field at once can be obtained, may prevent the sowing of any part of it in proper season. Nay, bad weather may set in and prevent the sowing after the land has been plowed; still a favorable week may occur, and at the worst, at the latter end of the season the land may be ribbed with the small plow, in the manner I have described in (1758), and which will move as much of the tender part of the soil on the surface as sufficiently to bury the seed, and the greater part of the former furrow will still remain in a firm state to support the wheat plant.

(1753.) The land being plowed, it should be *sown* as quickly as possible; for which purpose the seed-wheat should be measured up in the sacks, or ready to be measured up in the corn-barn or granary, and the means of pickling it also ready when wanted. Wheat should be sown thick in spring, because there is no time for the plant to *stool* or *tiller*, that is, to throw out young shoots from the roots, as in the case of autumnal-sown wheat. About 3 bushels per imperial acre will suffice for seed.

(1754.) Seed-wheat should be *pickled*, that is, subjected to a preparation in a certain kind of liquor, before it is sown, in order to insure it against the attack of a certain disease in the ensuing summer called *smut*, which renders the crop comparatively worthless. Some farmers affect to laugh at this precaution, as originating in a nonsensical faith in an imaginary specific: but the existence of smut and its baneful effects upon the wheat crop are no imaginary inventions, and when experience has proved, in numberless instances, that the application of a steep has the effect of warding off the evils of smut, the little trouble which pickling imposes may surely be undertaken, rather than the whole crop be put in jeopardy. *Why* pickling *now* should have the effect of preventing the smut at a *future* period is a different question; and it is perhaps because this question has not hitherto been satisfactorily answered, that pickling is thought lightly of by some farmers, rather than because any valid objection can be urged against its practice. Indeed there cannot, for the palpable fact stands obvious to conviction, that one field sown with pickled wheat, and managed in the usual way, will escape the smut, while an adjoining one, managed in exactly a similar manner, but sown with plain wheat, will be almost destroyed with the disease. I have seen this identical case tried by two neighboring farmers, the Messrs. Fenton, late tenants of Nevay and Eassie, in Forfarshire. It is true that, on some farms, wheat sown in a plain state escapes the disease, as I have heard Mr. Oliver, Lochend, near Edinburgh, state is the case with his farm; and it is also true that pickling does not *entirely* prevent the recurrence of the disease on other farms; but such cases are ex-

ceptions to the rule, which is, if wheat is not pickled it *may* be smutted; at least no one can aver beforehand that it *shall not* be so; and while uncertainty exists in the recurrence of a serious disease, the *safer* practice is to bestow the trouble of pickling, the expense being very trifling, rather than incur the risk of disease. It is now a well-ascertained fact that inoculation will not insure immunity from small-pox, yet it will certainly modify the attack when it occurs, and so it is with the case of pickling wheat; and as long as means are used to ward off small-pox, so long also, from analogy, ought wheat to be pickled.

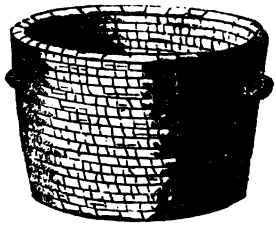
(1755.) Wheat is pickled in this way. For some days, say 2 or 3 weeks, let one of the tubs referred to in (1229) be placed to receive a quantity of chamber lye, and whenever ammonia is felt to be disengaging itself freely from the lye, it is ready for use. It is better that the effluvium be so strong as to smart the eyes, and water added to dilute the liquor, than that the lye be used fresh. This tub should be removed to the straw-barn, as also the wheat to be pickled, and part of the floor swept *clean*, to be ready for the reception of the wheat. Let 2 baskets be provided, capable of holding easily about ½ a bushel of wheat each, having handles raised upright on their rims. Pour the wheat into the baskets from the sacks, and dip each basketfull of wheat into the tub of lye as far down as completely to cover the wheat, the upright handles of the baskets preventing the hands of the operator being immersed in the lye. After remaining in the liquor for two or three seconds, lift the basket up to drip the surplus lye again into the tub, and then place it upon two sticks over an empty tub, to drip still more till another basketfull is ready to be dripped. Then empty the dripped basket of its wheat on the floor, and as every basketfull is emptied, let a person spread by riddling through a barn wheat-riddle, a little slaked caustic lime upon the wheat. Thus basketfull after basketfull of the wheat is pickled till it is all emptied on the floor, when the pickled and limed heap is turned over and over again till the whole mass appears uniform. The mixing by turning is most surely managed in this way. Let two men be each provided with a barn shovel, and let one stand on each side of the heap, one with his shovel in the right and the other with his in the left hand; let both make their shovels meet in their edges upon the floor, under one end of the heap of wheat, and each, on lifting his shovelfull, turn it over behind him, and thus proceed, shovelfull after shovelfull, to the other end of the heap. Let them return in a similar manner in the opposite direction, and aye till the heap of wheat is completely mixed with the lime and lye. The pickled wheat is then sacked up and carried to the field in carts. Other substances beside chamber lye are used for pickling wheat, such as brine of salt, sufficiently strong to float an egg; solution of blue vitriol—all good enough, I dare say, but when so simple and efficient and easily-obtained an article as lye can be had, it appears to me unnecessary to employ anything else. It is a powerful ingredient, destroying vegetable life in the course of a few hours, and it is perhaps to this property that is to be ascribed its efficacy as a protection against the attack of that vegetable enemy of the wheat-crop —the smut. The wheat pickled with it should therefore be used immediately after the process; and as danger may be apprehended to pickled wheat being kept over night, the quantity pickled should be sown at once, and no more should be pickled at one time than can immediately be sown. The use of the quicklime seems to be to dry the lye quickly, so that the grains may be easily separated from one another in the act of sowing; but there may some chemical change arise between them in the circumstances, which may be serviceable to the purpose for which both are em-

ployed. Can it be that the lime fixes the ammonia of the lye, and preserves it for use until wanted by the plant or seed?

(1756.) There is some art in setting down sacks of seed-corn on the field. It should be ascertained how many ridges of the field to be sown are contained in an acre, so that the sacks may be set down at so many ridges as each sack contains seed to sow the ground, allowing the specified quantity of seed to the acre. This instruction should be given to the plowman before he proceeds to the field with the sacks, otherwise he may set them down either too close or too wide. When one row of sacks is sufficient, and the ridges just long enough for the sower to carry as much seed as will bring him back again to the sack, the sacks should be set down in the middle; when the ridges are short they may be set down on the head-ridge, and when of such a length as to require two rows of sacks, each row should be set on the same ridges, and the distance between them made to suit the circumstances of the case. The setting down of the sacks should be begun from the side at which the sowing commences, and this again depends on the nature of the surface of the field. If the surface is level, it matters not which side is selected for commencing operations; but if it has an inclination, then that side which lies to the left while looking down, or to the right on looking up the inclination, should be begun to be sown. The reason for this preference is that *breaking* in the surface with the harrows—that is, the first stroke of them over the ground, along the ridge—is most difficult for the horse to draw; and to ease their draught the *breaking should be executed down hill.* The sacks are always placed on the furrow-brow of a ridge, that the hollowness of the open furrow beside it may give advantage to the person who carries the seed to take it out more quickly and easily when it sinks near to the bottom of the sack.

(1757.) The *carrier of the seed* is a field-worker, and the instant the first sack of seed is set down, she proceeds to untie and fold back its mouth, and fill the *rusky*, fig. 315, with seed, and carries the first quantity to the sower, who should be ready sheeted awaiting her arrival on the head-ridge at the side of the field. Her endeavor should be to supply him with such quantities of seed as will bring him in a line with the sack when he wants more; and as the sacks are placed about half-way down the ridges when only one row is wanted, this may easily be arranged; or should there be two rows, she must go from row to row on the same ridge, and endeavor to form the same arrangement. This regular plan will give her the least trouble, and supply the sower always with the requisite quantities of seed; and it should be borne in mind that nothing can be more annoying to a sower than to have his sheet brimfull at one time and at another stinted; and it is also very annoying to him to be obliged to wait the arrival of the seed-carrier, whereas she should rather wait on him. If the sacks of seed are conveniently placed, one active seed-carrier will serve two sowers, at *e*, fig. 322; but where the sacks are set down in more than one row, and there are more than one sower, there should be a carrier at each row.

Fig. 315.



THE SEED-CORN RUSKY.

(1758.) The *rusky*, fig. 315, or seed-basket, is usually made of twisted straw laid in rows above each other, and fastened together by means of withes of willow. It is provided with a couple of handles of the same material, sufficient to admit the points of the fingers, and also a rim around the bottom, upon which it stands. In the Border counties it is carried on the head or the seed-carrier

when full, in other parts it is carried in the arms with the bottom rim supported by the haunch. It should be filled each time with just the quantity of seed, and no more, which the sower requires at one time. The mouth of the sack should be rolled round upon itself, that the seed may be easily and quickly taken out, for there is usually no time to lose when seed is sowing. As one sack becomes empty it should be taken by the carrier to the nearest sack, and as they accumulate they should be put into one, and thus taken forward out of the way of the harrows. It is not unusual to see the sacks lying upon the ground where they are emptied, and only removed when the harrows come upon them, and not unfrequently tear them, and they are then cast away to be in the road again when the field is harrowed in another direction. The carrier should be careful not to spill the seed upon the ground on taking it out of the sack.

(1759.) The *sower* is habited in a peculiar manner; he puts on a sowing-sheet. The most convenient form of *sowing-sheet* is that of a semi-spheroid, having an opening at one side of its mouth large enough to allow the head and right arm to pass through, and by which it is suspended over the left shoulder. On distending its mouth with both hands, and on receiving the seed into it, the superfluous portion of the sheet is wound over the left arm and gathered into the left hand, by which it is held tightly, while the load of corn is securely supported by that part of it which passes over the left shoulder, across the back and under the right arm. The right arm, which throws the seed, finds easy access to the corn from the comparatively loose side of the mouth of the sheet, between the left hand and the body of the sower. A square sheet, knotted together in three of its corners, and put on in a similar manner, is sometimes used as a sowing-sheet; but one formed and sewed of the proper shape, and kept for the purpose, is a much better article. Linen sheeting makes an excellent material for a sowing-sheet, and when washed at the end of the sowing season will last many years. The difficult point is to make the sowing-sheet fit the sower on the top of the left shoulder, where the greater part of the weight of corn is felt; and, in attempting this, the principal thing to be considered is to make the plain part which goes over the shoulder broad enough, and to slope with the shape of the shoulder. The gatherings of the cloth on each side of the shoulder-top should be neatly executed, and a couple of tapes drawn tight in a slot-hem in front of the sheet across the breast.

(1760.) A *basket* of wicker-work, such as in fig. 321, is very commonly used in England for sowing seed. It is suspended by girthing, fastened to the two loops shown on the rim of the basket, and passed either over the left shoulder and under the right arm, or round the back of the neck; and the left hand holds it steady by the head of the wooden stave shown on the other side of the basket.* No doubt such an instrument answers the purpose of the sower, or it would not have been so long in use; but, for my part, I much prefer the comfortable feel of the linen sheet to the hard rubbing of the willow basket.

Fig. 321.

THE ENGLISH SOWING BASKET.

[* Wilkinson says the handle ought to be at the bottom instead of top, projecting forward. *Ed. Farm. Lib.*]

(1761.) Both these forms of utensils for sowing seed are intended for the use of one hand only; but some sowers throw the seed with both hands, and then the instrument must be made to suit the practice. In this case a linen sheet will not answer; a basket or box, made of thin deal, having a curved form to suit the front of the body, should be used It is fastened round the body by a strap and buckle, and is suspended besides by girthing fastened to loops on the side next the sower, and passed round the back of his neck; and the further side is suspended by a strap passing upward toward the chin of the sower, where it divides into two, and passes over both shoulders, and is made fast to the strap buckled round the body. A more simple form of sowing-sheet for both hands, is a linen bag attached to a hoop of wood or iron-rod, made to suit the form of the body, buckled round it, and suspended in front in the manner just described. Both hands are thus at liberty to cast the seed.

(1762.) In sowing with one hand, the sower walks on the third and fourth furrow-slices from the open-furrow, which he keeps on his right hand. Taking always as much seed as he can grasp in his right hand, he stretches his arm out and back, with the clenched fingers looking forward, while the left foot is making an advance of a moderate step, as represented by *a*, fig. 322. When the arm has attained this position, the seed is begun to

Fig. 322.

THE SOWING OF CORN BY HAND

be cast, which is done with a quick and forcible thrust of the hand forward. At the first instant of the forward motion, the fore-finger and thumb are a little relaxed, by which some of the seed drops upon the furrow-brow and in the open furrow, and while relaxing the fingers gradually, the back of the hand is turning upward till the arm is stretched forward, when the fingers are all thrown open, with the back of the hand uppermost. The forward motion of the hand is accompanied by a corresponding forward advance of the right foot,* which is planted on the ground the moment the hand has cast forward the most of the seed. This position is attempted to be represented by the figure at *b*. The figure which the seed describes on the ground, in being thus cast forward, is something like the area of a section of the extreme end of the larger axis of a very eccentric ellipse, having one corner of the section at the open furrow, and

[* Mr. Wilkinson, of Dutchess County, says this is unnatural; that it should be the left foot in concert with the right hand. *Ed. Farm. Lib.*]

the other stretching 2 or 3 feet beyond the crown of the ridge, and its broadest part spread over that side of the ridge on which the sower walks; this figure is attempted to be shown by *b c d*. The moment the seed is got quit of, the hand is brought back to the sowing-sheet and, thence replenished, is stretched back for a fresh cast, while the left foot is made to advance simultaneously. Thus the right hand and right foot play into each other with a regular *simultaneous* motion, while the same hand and the left foot play with an *alternate* motion.

(1763.) Many points require consideration to enable the sower to cast the seed *equally over the ground*. If the hand and feet do not correspond in their motions, the ground will not be equally covered, but a strip between the casts left almost bare. When the braird comes up, the omission shows itself like the steps of a ladder, and hence it is named, in some parts of the country, *laddering*, in others, *happergain'*, as if the seed had been cast in hopping. This error is most apt to be committed by a sower with a stiff elbow. The arm should always be thrown well back and completely stretched out, though in continuing this action it will become painful in the inner fold of the elbow-joint. If the hand is opened too soon, a larger portion of the seed than necessary will fall upon the furrow-brow, and the crown will receive less than its proportion. This fault young sowers are very apt to commit, from the apprehension that they will retain the seed too long in the hand. If the hand is brought too high in front, the seed will be apt to be acted on by the wind, and tossed to a different direction to that intended by the hand. High casting is a very common error with sowers, and is an unsafe practice in windy weather. In strong wind the sower is sometimes obliged to walk on the adjoining ridge to the windward, to sow the one he wishes; and a sower who casts high will never make good work in such a case. In casting high, the hand is sure to be elevated above the level of the elbow, whereas it should always be below it. The hand should be kept low, the arm stretched out, and the seed made to fly in a curve in front, by a sharp turn of the hand, and a free opening of the fingers near the end of the action, the nearest edge of the cast falling within two paces of the sower. Seed when so cast will be little affected by even a strong wind. Some sowers take long steps, and fill their hand with the seed as if in a shovel, and of course make long casts, reaching across the ridge from open furrow to open furrow. Such a sower will spill the seed behind the hand, and make bad work in wind. The step should be short, the casts frequent, and the seed held firmly in the hand, when a complete command of the whole work will be obtained.

(1764.) A sower with both hands must make high casts, otherwise the seed will not reach the furrows as he walks along the crown of the ridge, which he must do. I can see no advantage attending this mode of sowing over the other, but, on the contrary, a considerable risk of scattering the seed unequally, for however dexterous an ambidexter sower may become, his left arm will not make so perfect a cast as his right, if he is a right-handed person. In calm weather he may get on tolerably well, as also with the wind direct in his face or in his back; but a side-wind would puzzle him, for while adjusting himself to it for one of the hands, the other is immediately placed in a disadvantageous position. In short, he should not sow with both hands in wind. An Irish sower usually makes a step, stands still, and scatters one handfull of seed with two short and one long cast of the arm. This is slow work.

(1765.) A single-handed sower makes a bout to sow a ridge. When the ridge is single, fig. 133, he always keeps the open furrow on his right

hand; when it is double, that is, cast together, fig. 135, he must go a boat round the crown, as well as by the open furrows; and where the land is plowed two-out-and-two-in, fig. 138, a mark of some sort will be required to keep him in the proper place between the crown and open furrows.

(1766.) It is obvious that in sowing with the hand the corn is scattered promiscuously, and, in whatever arrangement it may come up, depends on the form of the ground, whether it had been plowed in common furrows or in ribs; for, in the latter case, the corn comes up in rows or drills, the corn having fallen into the hollows of the ribs when sown; and in the former, broadcast, that is, equally over the surface of the ground.

(1767.) The *harrows* follow the sowers, each sower keeping 2 pair of harrows employed when the land receives a *double tine*, that is, backward and forward on the same ground, which a *breaking in of the seed* should always be. To draw harrows as they should be drawn is not so light a work for horses as in appearance it is; and, indeed, when the tines are new sharpened and long, and take a deep hold on the ground, the labor is considerable. To harrow the ground well, that is, to stir the soil over the seed, and bring to the surface and pulverize all the larger clods, requires the horses to go at a smart pace; and, indeed, harrows should always be employed with a quick motion. If the men owe the steward a grudge for his sharp discipline, spring-wheat sowing is a favorable time to take advantage of him, when the land is naturally friable and easily pulverized, and the horses are quite fresh, and when, on the other hand, the lime of the pickle annoys the sower's face, and the land is rather soft for quick walking. If they keep the harrows hard at his heels, for very shame he must sow hard to keep out before them; and if he is a slow sower, he must get a good heating. I never see a man sowing with his coat on below the sowing-sheet, than a wish arises to see the harrows close at his heels to punish him for the lazy-looking trick.

(1768.) After the appointed piece of ground, whether a whole field or part of one, has been sown and broken in, the land is cross-harrowed a double tine, but as, in this, the ground is not confined within the breadths of ridges, the harrows cover as much of the ground as they can, and get over it in less time than in breaking in; and, besides, the second harrowing being easier for the horses, they can walk faster.

(1769.) In regard to harrowing ribbed land, a double tine of breaking in is all that it receives to place it in the same position as the common mode of seed-furrowing is placed after the cross-harrowing—ribbed land never being cross-harrowed, as that would derange the drilled-like state of the seed, and bring a large proportion of it again to the surface.

(1770.) To judge of the harrowing of land, the sense of feeling is required as well as that of sight. When well done, the friable portion of the soil seems uniformly smooth, and any clods that are seen should lie free upon the surface. The ground, too, should feel uniformly soft under foot. When the land is not enough harrowed, the surface appears rough, and the clods are still half immersed in the soil, and the ground feels unequally soft under foot, in some parts resisting pressure, in others giving way too easily.

(1771.) The well harrowing of land is a point of more importance than seems generally to be imagined. Its object is not merely to cover the seed, but to pulverize the ground, and render it of a uniform texture. Uniformity of texture keeps the soil in a more equal state of temperature, not absorbing rain so fast, nor admitting drouth so easily, as when the soil is rough and the clods keeping it open. Whenever the texture is made uniform, the harrowing should cease, for it is a fact, especially in light,

soft soils, that more harrowing than necessary brings part of the seed up again to the surface.

(1772.) Spring wheat following a green crop is always sown down with grass-seeds, and the land is in a fit state to receive them when it is in the above condition of its harrowing; but as grass-seeds are also sown at this time among the wheat that was sown in autumn, it is requisite to consider, in the first place, the state of that crop before proceeding to sow them among the spring wheat, especially when both kinds of crop are in the same field. The state of the *winter wheat* depends entirely on the sort of weather it had to encounter in winter and early spring. If the winter has been open and mild, the autumn wheat plant will have grown luxuriantly, indeed so much so that it may have become *proud*, that is, in a precocious state of forwardness for the season. When it is in this state in spring, which is rarely the case in Scotland, though not unfrequent in England, a heavy fall of snow in spring, that happens to lie for some weeks, will rot a great many of the plants; and, instead of the rest retaining their green color under the snow, they will become blanched at the roots, pressed flat to the ground, and will probably never rise again. Blanks will in consequence be formed where this catastrophe has happened; but unless these be of large extent, or the season be far advanced before the wheat has been liberated from its snowy covering, the plants will tiller out with new runners from the roots of the surviving old plants, and occupy the blank spaces. When snow falls upon wheat in the early part of winter, and covers it for a considerable time, it protects the crop from injury from the atmosphere, and prevents the earth from cooling below 40° Fahr. In this position the young plant retains its healthy green color, though it does not grow much; and whenever it is relieved from the snow, it grows rapidly, unless it happen to encounter black frost, which changes its greenness into a brown, and may kill some of the plants; but should there be no black frost, there is no state of the young wheat plant in spring in which it tillers so closely, and afterward grows so equally, as after emerging in favorable circumstances from snow. The most trying time, however, for winter wheat is in March, when sharp frosts frequently occur at night, and bright sunshine in the day. The frost draws the moisture of the ground to the surface, and there freezes it; when the sun shines upon the ice it melts, and most frequently very rapidly, and the consequent evaporation produces such an intense degree of cold as even to kill the plants suddenly; and if they escape destruction in this way, the damp ground that had been raised up by means of the expanded condition of the ice suddenly contracts by its melting, leaving the plants with their roots half drawn out of the earth, in which state many perish. It must be owned, however, that this particular effect is most commonly produced on loamy soils which rest on impervious clay subsoil and not on a dry subsoil, so that draining may be reasonably expected to prevent this injury. Continued rains upon winter wheat make it change its color to a bluish hue, and if the air is temperate the plant becomes tender, and at length sets up with red-pointed leaves, as if it would grow no more. Continued drouth in spring, on the other hand, makes winter wheat of a vivid green, especially in fresh weather; but should it be cold and inclined to frost, the points of the leaves become brown, which latter effect is invariably induced by the cold east winds so prevalent in spring in this country. Drouth and heat combined always promote the vigor of the wheat plant.

(1773.) Although I have said that double harrowing across prepares the land on which spring wheat has been sown for grass-seeds, it should not be imagined these are sown whenever wheat-seed is sown, because the lat-

ter may be sown at any time during winter or early spring that the state of the weather and soil will allow; but when spring wheat is sown at the latest period of the season, then grass-seeds may not only be sown among this, but among all the spring wheat that had been previously sown: and at the same time among the winter wheat, if the land that has stood all winter is dry enough to bear harrowing at the time. Frost injures clover-seeds, and will even kill them when exposed to it, so that they cannot safely be sown very early in the season; but there is not much risk of frost being so powerful in March as to injure seed that is harrowed in. Many farmers used to sow grass-seeds without harrowing, trusting to so small seeds finding their way into the soil among the clods, and of being covered by their mouldering, and this practice is, I believe, not yet relinquished; but the safer and more correct practice is to cover every kind of seed when it is sown by harrowing. It may happen that in the same field in which the latest spring wheat has been sown, may be found some that had been sown at a former period, and even winter wheat may occupy another part of it. When this is the case, and especially if the last sown completes the cropping of the field, then the grass-seeds should be sown over the whole field at one time, beginning with that part which has just been sown, continuing it over that which was the next last, and finishing upon the winter wheat; because it is desirable first to finish the land that has been most recently worked, in case the weather should change, and prevent the finishing of the whole field. Should barley, however, have still to be sown on that field, it will be better to defer the sowing of the grass-seeds upon the wheat until the whole field is sown at one time; and in this case the new-sown spring wheat can be water-furrowed and put past danger for the time. If the winter wheat in the same field is, on the other hand, far advanced, and the weather still favorable to its growth, the grass-seeds should be sown among *it*, for, if delayed too long among strong plants, part of the seed may not find its way to the soil, and the subsequent harrowing may injure the progress of the already forward plant. In such a case the spring wheat should be sown with the grass-seeds at the same time, and the barley-land can be sown by itself, when the barley-seed is finishing.

(1774.) The grass-sowing machine is a most perfect instrument for the sowing of grass-seeds, distributing the seeds with the utmost precision, and to any amount, and scattering them so near the ground as to render their sowing a matter independent of windy weather. This machine will be found in Plate XXVI., fig. 316, and a detailed description of it by Mr. Slight will be found below. Its management is easy, when the ground is plowed in individual ridges; the horse which draws it walking in the open furrow, as in *a*, fig. 133, and the machine reaching in length to the crown of the ridge on each side, to *b* and *b*, sows the width of a ridge at once, the length of the machine being made to suit the breadth of the ridges adopted on the farm. The gearing is put out of action till the horse enters the open furrow from the head-ridge, when it is put on and it is again taken off when the machine reaches the opposite head-ridge. The seed is supplied at one of the head-ridges, and the head-ridges are sown by themselves. When ridges are coupled together, the horse walks down in the middle between the crown and the open furrow, taking the furrow-brow as a guide for the line he should keep. Where ridges are plowed in breaks, as two-out-and-two-in, fig. 138, it is necessary to use some marks on the spaces of the ridges between the crown and open furrows, to guide the line of the machine. The driver ought to be provided with double-reins. Were this machine to proceed onward, sowing without interruption for 10 hours at

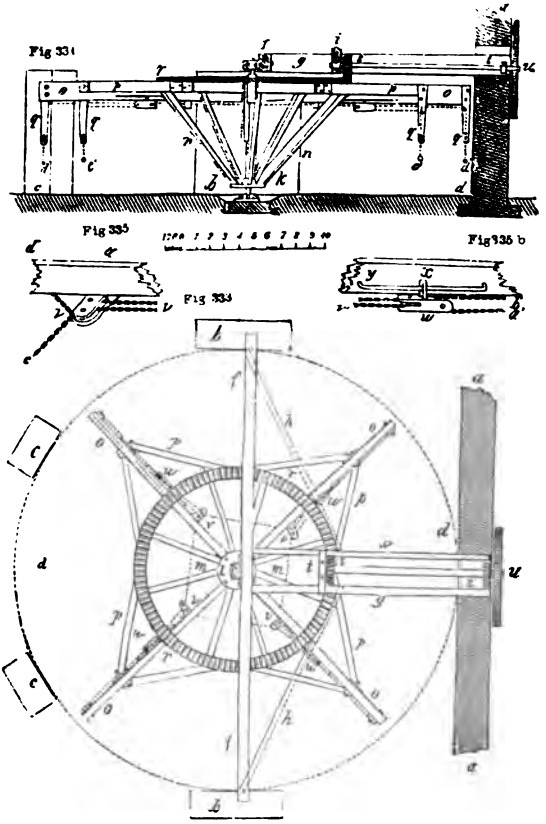


Fig 334
Fig 335
Fig 335 b
Fig 333

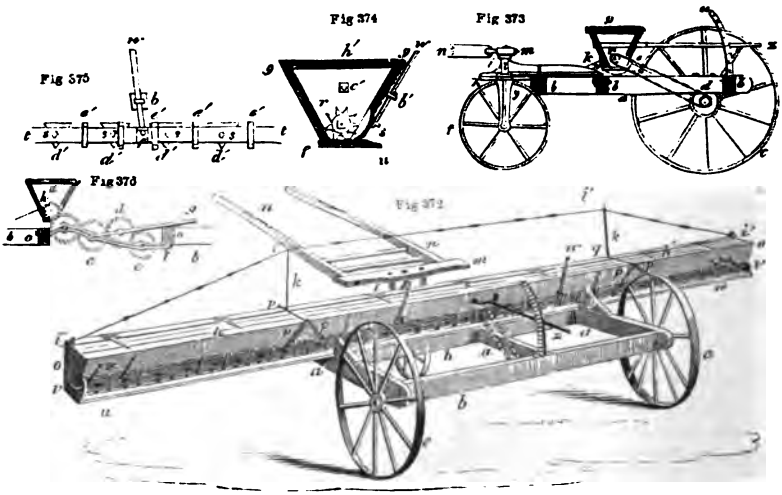

Fig 374
Fig 373
Fig 375
Fig 376
Fig 372

the rate of 2½ miles per hour, it would sow 54 acres of ground; but, of course, the turnings of the landings, and the time spent in filling the machine occasionally with seed, cause a considerable deduction from that quantity. The machine is also used to sow corn in broadcast, and it answers the purpose very well, but not perhaps in so superior a manner to the hand as it does the grass-seeds, nor is it so generally employed to sow corn as grass-seeds, but for what reason I cannot say. There was a reason for this before the introduction of the third or front wheel, the weight of the box when full of corn being too heavy for the horse's back, especially in going down hill. I cannot refrain from pointing out the superior construction of this machine, as represented in Plate XXVI., in putting it in the power of the person who drives it to contract its length, so as to admit the machine easily into a field-gate, and thereby to dispense with removing it, at any time, from its carriage.

(1775.) After the grass-seeds are sown, the ground is harrowed to cover them in; and for this purpose lighter harrows are used than those for ordinary harrowing; and being light, are not unfrequently provided with wings, to cover a whole ridge at a time, so that in following the sowing-machine, the process connected with the grass-seed sowing may be finished at once. There is some dexterity required in driving winged grass-seed harrows. It is not convenient to move them from one ridge to another immediately adjoining, as a part of the implement will have to turn almost upon a pivot; in doing which, unless conducted with great care injury is apt to be done to it. And, besides, it is a particularly awkward movement to *hup* the horses with these harrows. The plan to avoid the inconvenience alluded to, is to *hie* the horses at the end of all the landings, and leave an intermediate unharrowed ridge at every turning, which will be greatly facilitated if the plowman lifts up the near wing from the ground with a hooked stick when the turning is to commence, and lets it drop down again when it is finished.

(1776.) The land may be rolled or not, according to circumstances, before the grass-seeds are sown. If it is dry, even strong land would be the better, at this season, to be rolled, to reduce the clods before they become very hard, and to form a kindlier bed for the small seeds. Should it, however, be in a waxy state, between the wet and the dry, the rolling had better be deferred until afterward. When it is in a proper state for rolling at the time of sowing the grass-seeds, it should be rolled before the sowing, and, of course, before the harrowing of the grass-seeds; because, were the land left with the smooth rolled surface, and rain come after, and this succeeded by drouth, which is not an unfrequent state of the weather at this season, the smooth ground would become so battered and hardened as to curb the wheat braid considerably; whereas, were it rolled before it was sown, and then harrowed, the harrowing would again raise a small, round clod, which would prevent the battering by rain, and consequent incrustation of the land, while the smooth ground would offer a fine surface for the small grass-seeds to spread themselves upon. On lighter soils, such as hazel loams and turnip soils, it is better not to roll until the land has been sown and harrowed, because the smooth rolled surface assists in repelling the drouth for a considerable time, and rain cannot injure such a soil in any way.

(1777.) The roller is represented below, where it is particularly described by Mr. Slight in its principles and action. It is most conveniently formed of cast-iron, and in two pieces, and mounted with shafts and framing. The cast-iron gives weight, which a roller should always have, and being in two pieces, gives a facility to turn on little space. In driving it, the plowman

may sit on the front of the framing, if he wishes, and urge the horses with whip and reins. The framing sometimes supports a box, into which stones are placed to render the roller heavier, and this device may be necessary when reducing hard clods of clay, in summer. Whether used for this purpose or not, the box is useful in carrying any stones that may be found on the land to either side of the field. It has often seemed to me ridiculous to see a small stone-roller, or one lightly constructed of wood, used to crush clods on new plowed heavy land. Instead of breaking them, a light roller only presses them into the softer soil upon which they are lying. The roller is found to do its work in the best manner when drawn *across* the ridges, at right angles to the open furrows, which are thus easily passed over.

(1778.) The finishing process consists of *water-furrowing*, that is, making a plow-furrow in the open furrows, for the purpose of affording facilities to rain-water to flow off the surface of the land. It is executed with a common plow and one horse, or with a small double mould-board plow and one horse; and in the execution, the plow obliterates the horse's foot-marks. When the land is harrowed after the rolling, as in the case of heavy land, the water-furrowing is done after the harrowing, and finishes the work of the field; but when rolling is the finishing operation, as in the case of light soils, the water-furrowing is executed immediately after the harrowing and before the rolling. Water-furrowing *after* rolling gives a very harsh-looking finish to a field.

(1779.) The presser-roller, used to give consistency to light soils, is seen below, where Mr. Slight's description of it will be found. Like the best of our agricultural implements, it is of English origin, where it has long been employed to compress light soils. It is used in this manner in compressing the soil. Driven by one horse, it follows the last of 2 plows, after they have laid over their furrow-slices; and on passing along these furrow-slices, not only compresses them into less bulk, but leaves a groove on each of them to receive the seed when the land is sown. With 1 presser, 2 acres of ground can only thus be compressed in the course of a day; and, where a considerable extent of spring wheat may be sown, this rate of sowing would be too slow. Either the number of pressers should be increased, or a considerable extent of land be pressed before it is sown; for it would be tiresome work to sow only 2 acres a day of a large field, which might require a fortnight of 2 plows to plow. Perhaps the most convenient plan for most farmers would be to have 2 pressers in operation, and sow the ground compressed every two days, that is, 8 acres, which would be a large enough sowing of spring-wheat in one day upon a farm that worked 4 pair of horses; and this plan may be followed, with perfect safety to the wheat crop, for a double tine along of the harrows is quite sufficient to cover pressed spring wheat; and, indeed, it should receive no more, unless perhaps a single tine along, in case the surface is considered not sufficiently fine, for cross-harrowing would discompose the seed that had fallen in rows into the grooves made by the pressers. Another plan is to plow and press the lea early in winter, allow it to consolidate still more, and then sow an entire field with wheat in spring, if the weather be favorable, and if not, it will be ready for oats. This, I conceive, would be an excellent plan to follow on light soils, that are in a rich enough state for spring wheat.

(1780.) This same instrument may be beneficially employed in compressing light turnip-land as it is plowed into ridges, and rendering it more fit for spring wheat; and in effecting this purpose it is employed in the same manner as on lea.

(1781.) But the presser may be employed on even strong lea, and the crop of wheat consequent thereon increased to a sensible degree, as the

following case will testify: "A very striking instance of the utility of this machine," says Mr. Hugh Watson, a gentleman whose name is well known in this country as an eminent farmer, "was exhibited on a field belonging to my friend Captain Barclay Allardyce of Ury, who last season (1832) broke up a piece of grass land near his mansion-house, supposed to have lain out about one hundred years. It was a strong soil, and required 4 horses to work the plow, and it was followed by the presser, leaving the work in such a finished state that, although Captain Barclay's intention was to sow the field with oats after the preparation of a winter's exposure, he was induced to try a crop of wheat, and succeeded beyond his expectation, having reaped 50 bushels per imperial acre, while the probability is that if the field had been sown in spring with oats they would all have rotted." "I have used the presser," continues Mr. Watson, "for two seasons, and can with confidence recommend it on *all light soils with every sort of corn crop*."* It would thus appear that the use of the presser is almost of general application, and that the ground may be plowed a considerable time before it is sown, which renders it of use even on a winter furrow. Several farmers in Forfar and Fife shires, I am aware, have used this instrument for several years, but I have not learned with what success.

(1782.) With regard to the varieties of wheat which you should sow in spring in preference to others, is a subject in which I feel I cannot advise with confidence. The erroneous classification of wheat by botanists, in as far as it affects Agriculture, into beardless or winter and bearded or spring wheat, is apt to mislead the farmer; and were he so far to rely on the opinions of botanists as to try these two distinctions of wheat in the season said to be suitable to each, he would certainly be disappointed, for the results would probably be the very opposite anticipated. For this reason I quite agree with Mr. Lawson in what he has said on the subject. "Botanists," he states, "generally divide the common beardless and bearded wheats into two distinct species, terming the former *Triticum hybernum*, or winter wheat, and the latter *Triticum æstivum*, or summer wheat. But the propriety of the distinction may well be questioned, more particularly as the chief distinguishing character between them consists in the varieties of the former being beardless, or nearly so, while the awns of the latter are generally 2, 3 or more inches in length; and it being an established fact that the awns or beards in grasses form by no means a permanent specific distinction, and that in many cases they do not even constitute a variety, so much does their presence or absence depend upon the effects of climate, culture, soil, &c. . . . . But the principal objection to the names commonly used is that they make no proper distinction between the two great classes—*winter* and *spring* wheats; for instance, under *Triticum hybernum* are included several of the earlier, and, without doubt, the best sorts of spring wheat; and under *Triticum æstivum* are included several bearded wheats, equally hardy, and requiring as long time to arrive at maturity as our common winter sorts."† Colonel Le Couteur falls into the same error when treating of the classification of wheat, by dividing all wheats into the two distinctions of "beardless or winter wheats," and "bearded, or spring wheats."‡

(1783.) Although the subject is thus rendered by botanists and writers on the cultivated varieties of wheat sufficiently puzzling to the farmer, yet there are a few considerations which may direct you in the choice of your spring wheat. I may premise that you cannot make a mistake in regard to a winter wheat; for however early may be the habit of the variety

* Quarterly Journal of Agriculture, vol. iv.
† Lawson's Agriculturist's Manual. ‡ Le Couteur on Wheat.

sown, the very circumstance of having sown it in autumn, when there is not sufficient time to mature the plant before winter will convert it for a time into a winter variety. The wheat plant is a true annual, but when sown late, and the progress of its growth retarded by depression of temperature, it is converted for a time into a biennial. It is therefore highly probable that as the nature of all wheats is to bring their seed to maturity in the course of one season, that any variety sown in spring would mature its seed in the course of the ensuing summer and autumn. I suppose there is no doubt of this being a fact; nevertheless, circumstances concur to render the fact of doubtful application *in this climate*. A variety of wheat, for instance, that has long been cultivated in winter in the same latitude, on being sown in spring will not mature its seed that season in the same latitude, should the temperature fall below its usual average, or should it be cultivated on very inferior soil to what it has been accustomed; so that in practice it is not safe, in a precarious climate, to sow *every variety* of wheat in spring. One criterion, however, may safely be applied to any variety of wheat in order to ascertain its character, provided its history is known, which is, that a wheat brought from a warmer to a colder climate will prove earlier in the latter locality than the native varieties, and, in so far, is better suited for sowing in spring in that latitude than the native varieties, and if you can ascertain, besides, that the same variety is an early one in the warmer latitude—bringing its seed to maturity in a short period, perhaps not exceeding 4 months—then you may safely sow it as a spring wheat, whether it be a red or white colored variety.

(1784.) In my own experience of spring wheat the old Lammas red, and another old variety which I have not heard of for many years, the Cobham red, were at one time considered excellent varieties of spring wheat. Of the Lammas red, I have seen a field of 35 imperial acres sown on the 8th March, and cut down, an excellent crop, on 26th August. This was, however, in the memorable year for all kinds of good crops, 1815. The variety, I believe, exists to the present day, and is still a favorite with may farmers, and in my opinion deservedly so.

(1785.) [*The harrow*, considering the operation it has to perform, in covering the seeds that have been cast upon the surface of the soil, is an implement of no small importance; and yet its effects are apparently rude and uncertain, while its construction is of the simplest order. So simple, indeed, is this construction, that at a very remote period it appears to have taken that form which, in so far as the simple principles of the action are concerned, is almost incapable of farther improvement. Variations in size, in weight, in materials, and slight changes of form, have from time to time been proposed and effected; but yet no important change has been made in the action of the implement, though among these changes a more uniform distribution of its effects over the surface of the soil has been attained. The only important improvement on the harrow of which we have any historical data, was achieved about fifty years ago by, I believe, the late Mr. Low, Gordonbank, Berwickshire, father of Professor Low, of the University of Edinburgh; and this improvement lay chiefly in the *form*, but which also afforded a more uniform distribution of effect. Previous to the period just alluded to, the seed harrow was always constructed in the form of a rectangular frame of wood, consisting, as it still does, of four longitudinal bars, known, in the language of the agricultural mechanic, by the term *bulls*, which are framed together by mortising, with four lighter transverse bars, or *slots*. The dimensions of the rectangular harrows are, on an average, 3 feet 9 inches in breadth, measuring over the bulls, and 3 feet 10 inches in length over the slots. The bulls are generally about 4 feet 6 inches of extreme length, 3 inches in breadth, and 3 to 3½ inches in depth; the slots are 3 inches in breadth, and ¼ to 1 inch in depth. Each bull is armed with 5 tines or teeth of malleable iron, about 10 inches in length. They are fixed in the bull by being driven into an auger-hole bored through it, and project downward from 6 to 7 inches.

(1786.) The *improved form* given to the harrow, as above alluded to, changes the rectangle into a rhomboid, and this, when duly proportioned, gives to the implement as has been supposed, as high a degree of perfection, in point of form, as it appears capable of attaining. Fig. 323 represents a pair of the rhomboidal harrows in the working position. The frame of these harrows consists of the same number of parts as the common sort already alluded to. Four bulls *a a a a*, and four slots *b b b b*, the breadth of the frame over the bulls, at right angles to them, is 3 feet 6 inches; and in the same manner, over the slots the length is the same, but the bulls extend at each end 4 inches beyond the slots, making their entire length, including the obliquity, about 4 feet 6 inches. The dimensions of the parts vary a little, according to the quality of the material employed, from 2½ to 3 inches in breadth by 3 to 3½ inches in depth, for the bull. The slots are from 2½ to 3 inches in

breadth, and from ¾ to 1 inch in depth, the bulls being mortised, and, when the slots have been inserted, are fixed with wooden pegs driven through the bulls. In each harrow an iron bar *c c*, having a number of holes punched in it, is likewise fixed into mortises in the two outer bulls on the left side, for the attachment of the yoke. Each bull is divided into four equal parts, the extreme division being about 1 inch clear of the mortise of the slot, and at each division the

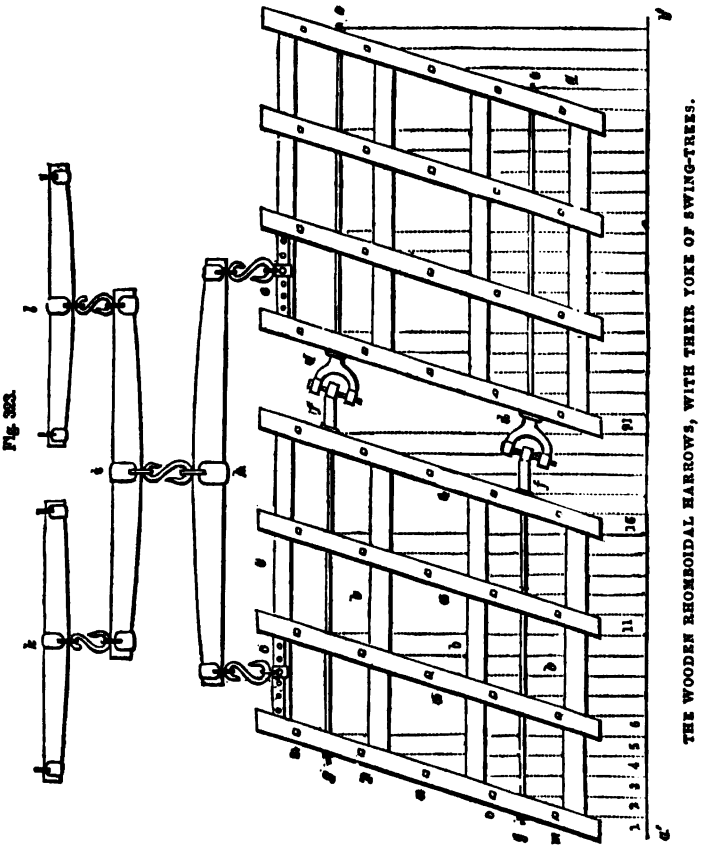

Fig. 323.

THE WOODEN RHOMBOIDAL HARROWS, WITH THEIR YOKE OF SWING-TREES.

bulls are bored with an auger for the reception of the tines, and in thus boring, a slight inclination forward below is given to the tines, though this, it must be admitted, is not of very great importance. The length of the tine is about 10 inches, of which 6 or 7 inches project below the bulls; and it has been recommended that the front row should be 7 inches, the succeeding rows diminishing gradually to 6 inches, to compensate for the effect of draught of the horses tending to elevate the fore-parts of the harrows. This tendency to rise in front is not so great as has been supposed, for the weight of the swing-trees and whole yoke will nearly compensate for the effect of the angle of draught. In all cases of this kind, the yoke, consisting of chains, hooks and swing-trees, of which the latter, in the harrows-yoke, forms a portion of considerable weight, the system resolves itself into a catenarian curve, more or less perfect, of which the point *c*, where the yoke is attached to the harrow, will approximate to the apex of the curve, and consequently to a horizontal line, thereby neutralizing the tendency to rise in the front of the harrows.

(1787.) There is one point in the improvement of this harrow that appears to me of even more importance than the rhomboidal shape; it is the joints or hinges *d d*. In the one harrow, fig. 323, the tail of the double joints of the hinge is prolonged into a bolt *d e*, *d e*, passing through all the bulls, and secured with screw-nuts at *e e*. The single joints are in like manner prolonged into the bolts *f g*, *f g*, thus serving to add greatly to the strength as well as to the efficiency of the harrows. The loose joints *d f*, *d f* have been found to answer their purposes much better than the well-fitted joints originally given to them, by their allowing of a great freedom of action, and the double joints *d d* are therefore now usually made as in the figure, the span of the bow *d* being about 6 inches, with a small eye at each end to fit the joint-bolt. The eye of the single joint *f* is about 1¼ or 2 inches diameter, having thus great freedom to play upon the joint-bolt.

(1788.) From the figure of the rhomboidal harrow, when duly constructed, it can only perform its maximum of effect when drawn forward with its slots at right angles to the direction of its mo-

tion, and this is effected by the master swing-tree *h*. This tree, fo
described, requires to be 4 feet 8 inches in length between the poi
nected to the harrows by means of the S hooks and shackles at *c*
the harrows is adjusted by shifting the shackles into the different

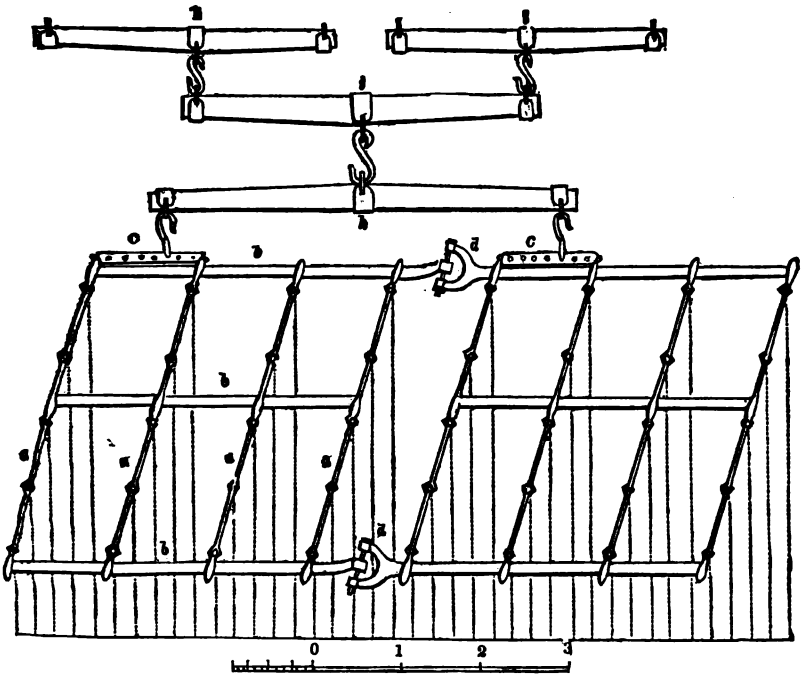
(1789.) The objects to be attained on the construction of the rhom
formity and equal distribution of effect from the tines, and to cover
with such effects. In these respects, it has been supposed that the
over the rectangular form, but such advantages seem to fall only wi
tangular harrow, if due attention is paid to its construction and posi
with the hinge-joints, will perform all the functions ascribed to the
effect. Though the rectangular form presents no advantage in poin
this advantage in construction, that, by keeping simply to one dim
could occur with the maker to mar the attainment of the objects in
boidal harrows made at all angles of obliquity, though the length an
all; and such being the case, many of them must be defective in
sought for. To exhibit this more clearly, and to render the basis of
plement practically intelligible, let us suppose that a pair of harrow
be so constructed as to cover 9 feet in breadth, we shall have 39
tines, which are to form equal intervals. Draw a base-line *a' b'*, fi
scale, or at full size, a distance *a' b'* equal to 9 feet; divide this into
points of division draw the dotted lines at right angles to *a' b'*, the di
will be 2·76 inches, or say 2¾ inches, which represents the distance
through the ground. Having determined, also, the distance between
bulls to be 9¼ inches: set off, on the first dotted line 1, any distance
be the place of the first tine. With a length of 38 inches, or 4 tine s
from the point *m* a distance *m n*, cutting the fifth dotted line in *n*,
place of the 5th tine, or the foremost in the first bull. If a line is the
m n, it will cut the divisions 2, 3, 4, in the points *o a p*, indicating the
the first bull, and the line *m n* is the true position of the central line
of 73° nearly with the base-line. A line drawn through *m* to *q*, and
mine the position of the first tine on each succeeding bull, where the
16th, 21st, &c., of the dotted lines of division, and lines drawn throu
section parallel to the first line *m n*, will determine the central line of
harrows. It is then only necessary to extend the length of the bull re
for the slot, with a sufficient extent beyond to prevent the bursting of th
ted, may be about 4 inches, or the bulls will be about 4¼ feet in length

(1790.) Were it desired to have the tines so placed as to follow
tances of 2¼ inches instead of 2¾ inches, in this case the distance
would be 39 times 2¼ inches, or 8 feet 1¼ inches. The line *a' b'*, fig. 3
feet 1¼ inches, and being divided into 39 equal parts, and the lines of
repetition of the process described in (1789) will give the true form of
lar breadth, and so of any others; and it should be particularly observ
the rhomb has been correctly laid down, the harrows should progress
at right angles to the line of direction in which they are drawn forwa
insure the best possible effects from the harrow, and at the same time
of surface that it is capable of harrowing, to the best advantage.

(1791.) I have said that the common rectangular harrow is capable
with those of the rhomboidal; and though this cannot be said of all
struction of such as will do this is not more difficult, while it is, perhap
The chief difference lies in the mode of applying this harrow, for, wh
only necessary, in order to produce equal intervals of the tines, to yoke
tion as will make the bulls lie upon the ridge with the same degree of
rhomboidal shape occupy when they are drawn in the position due to th
rhomb. It is necessary, however, in order to secure the due performan
row, to pay attention to its construction as regards the distance between
simply this: Whatever breadth the pair of harrows are intended to
breadth into a number of divisions, one less than the whole number of
distance from center to center of the bulls must be made equal to as m
there are tines in each bull. Thus, taking the first case of the rhomboidal
times 2¾ inches nearly, or 13¾ inches for the distance between the centers
ches in breadth overall. To complete the arrangement, the harrows must b
boidal form, and mounted with iron draught-bars, as at *c c*, fig. 323, so t
can be adjusted to bring the harrows to their proper position; and here it
they should never be drawn by the extreme angle; but if not hinge-join
second bull, and the fore-slot, will be tolerably near to the true point of dr
a very useful practice has long existed, of coupling two harrows togethe
iron, called a rider. This bar falls loosely at each end upon a stud proje
second bull of each harrow, and the bar being adjusted to that length whi
rows at their proper distance, serves to prevent them from riding over on
them cover their full extent of surface. The introduction of the rider wa
to the more perfect modern improvement of the hinge-joints.

(1792.) **The extensive** application of iron has of late years brought the use of that material to the **ormation of the harrow** as well as of the plow, and iron harrows are now coming very generally **nto use, both in the** rectangular and the rhomboidal form. Fig. 324 represents the malleable-iron **homboidal harrow,** as commonly constructed, and its dimensions are the same as already given **or those of wood.** The arrangement of the parts are somewhat different, and, from the nature of **he materials, the** dimensions of the parts differ also more materially. Thus, the bulls *a a a a* are **inch in breadth** and 1 inch in depth, swelled out where the mortises for the slots are formed, and **lso for the tines,** their ends projecting only 2 inches beyond the slot. The slots *b b b* are 2 inches

Fig. 324.



THE IRON RHOMBOIDAL HARROWS, WITH THEIR YOKE OF SWING-TREES.

in breadth. ⅜ inch in depth, and there being only three of them, the middle one is so placed as to be free of the middle row of tines; while the end slots are elongated toward the meeting sides of the pair, and are there formed into the hinge-joints *d d*, as formerly described for the wooden harrows. The draught-bars *c c* are inserted in the projecting ends of the first and second bulls, and retained in round pivot-holes; the swing-trees *h i k l* are the same as described for the wooden harrows. The construction of the iron harrow is so similar to the others that it is unnecessary to enter into farther details regarding it; but it may be remarked that, from the almost imperishable nature of the materials, as compared with wood, there seems every reason to expect the iron implement will entirely supersede the wooden; and though the price of the iron harrows is considerably above that of wood, the additional first cost is more than repaid by the greater durability of the iron. There is good reason also to believe that by a construction more adapted than the present to the nature of the material, the price may yet be considerably reduced.

(1793.) The *form of the tines* of the harrow, as regards their effects in stirring the soil and covering the seed, is deserving of inquiry. In the wooden implement, we are, from the nature of the material, confined to one form of tine; that which has for its horizontal section an oblong square; the tines in these cases being ¾ inch broad by ½ inch thick, must, for the safety of the wood, have the greatest dimension lying in the direction of the fibres of the wood. Another and a better form, for the purpose of stirring the soil, is that which has its cross-section forming an exact square of ¾ inch on each side, and inserted in the bull with its diagonal pointing in the direction of the progressive motion. This form and position of the tine, however well adapted to the soil, cannot, with propriety or safety to the implement, be used in the wooden harrow, from the powerful tendency it has to split the wood. In the iron implement this difficulty does not exist; and as this form of tine is in every respect best adapted to the intended purpose, it should never be omitted in the iron harrow. Whatever be the cross-section of the tine, in that part which passes through the bull, the projecting part is tapered toward the point, not uniformly, but a little barreled, and terminates in an obtuse point. In all wooden harrows the tines are simply driven firmly into the

wood after it has been bored. In most iron harrows they are fixed in the same manner; but as the tines are sometimes liable to become loose, when simply inserted and driven down by the hammer, they are, when a more perfect construction is followed, fixed by being driven from below, and secured by a screw-nut above.

(1794.) *Grass-seed Harrows*, or those that are employed for giving a light covering to grass-seeds when sown, differ from the common harrow in no respect except in dimensions and weight. They have generally the same number of tines, bulls and slots. The breadth over all is about 3 feet, or from that down to 33 inches, and the distance between the tines about 7 inches, giving a length of bull 3¼ feet, and the tines vary from 5 to 6 inches in length. Harrows of this description are frequently used by English farmers to give the last turn of harrowing in grain, and a fine finish to the surface. Grass-seed harrows are made of iron as well as of wood, but withal it is not held as an essential implement, the common harrows being more frequently used for the purpose to which the grass-seed harrow is more especially and almost exclusively adapted.

(1795.) Various other forms of harrows are adapted for special purposes, such as the *bush-harrow*, which is a frame of wood interwoven with the smaller branches or croppings of trees, and in this manner employed instead of the grass-seed harrow described above, and it is also employed for harrowing in top-dressing upon grass.

(1796.) The *Iron-web Harrow* is a late invention by the ingenious and indefatigable Mr. Smith, late of Deanston, for the same purpose. It is formed of an assemblage of annular disks of cast-iron, of the size and shape of the common playing-quoit; and these are interwoven with iron wire of about ¼ inch diameter, in a certain regular form, until the whole forms a flexible web, in which the disks have liberty to play and roll about within small limits. The web may be 2 yards in length by 1 in breadth, and is simply dragged over the ground, when it is said to give the surface a finish superior to anything hitherto proposed or introduced.

(1797.) *The Brake-harrow* is only an enlargement of the common implement, wherein every part is increased in size and weight for the purpose of breaking down and pulverizing rough and stubborn land. Brakes are made of various forms, such as rectangular, rhomboidal, and triangular; and every form has its advocates, the preference being given frequently to that which accident had thrown in the way of the experimenter; and without taking measures to compare its effects with those of other forms, the implement is marked as the most perfect of its kind. There appears no good reason for concluding that any one of the above forms is better than another, provided proper weight is put in the implement, and the tines of proper length and number, and disposed in a manner that, with a duly applied draught, will make an equal distribution of its pulverizing effects over the surface which it covers. The extended application of draining, and the increasing employment of the grubber, which I shall shortly have to notice, appear in some measure to be superseding the brake-harrow.

(1798.) *The Broadcast Sowing-machine* has now come into pretty general use, especially in those districts where the arable system is under the best management, and on large farms is nearly superseding the process of hand-sowing. It not only sows all the white grains, wheat, barley, oats, when sown broadcast, in a very uniform manner, and with any desired allowance per acre; but it serves in a superior manner for grass-seeds, in point of distribution, and, in the case of windy weather, is greatly superior to hand-sowing. This last advantage arises chiefly from the low position of the discharging orifices, as compared with the hight of the *hand* in sowing; but partly also from the more direct discharge of the seed from the machine; its velocity of discharge, likewise, and the distance it has to fall, being always uniform. The nice gradation of the discharge is one of its chief qualifications, for it may be adjusted to sow any required quantity per acre, between the lowest and the highest, that may be judged expedient, and in all cases, from the uniformity of the distribution, a considerable saving in seed may be effected.

(1799.) I have on previous occasions had to notice the rather curious facts of the introduction of certain practices from England into the Scottish system of farming. Such practices have remained either stationary in the former country, or have been but partially extended, whereas the practices thus borrowed by the latter have been improved on and widely extended. The machine now under consideration is another example of this; for though it appears to have been originally brought into Scotland from Yorkshire, I believe it is even now but sparingly used in England, while here it is in extensive use in the best arable districts, and still rapidly extending. In the course of some inquiries as to the period when this machine was first adopted in Scotland, I have been enabled, through the kindness of Mr. Scouler, Haddington, to fix the time of its introduction to the year 1817, and the first machine so made appears to have been by Mr. Robert Lowrie, Edington, who makes the following statement: "The first broadcast sowing-machine that came into this county (Berwickshire) was ordered by myself from England from Mr. Short of Chiverton by Hackhill; it was a smart thing, wheeled by a man, and was about 8 feet long; it is still in the possession of Mr. Wilson of Edington Mains. I got that machine in 1816, and in the following year I made one from it for Mr. Wright, late tenant in Prenderguest, which was 15 feet long, and was drawn by one horse. So far as I know, this was the first sowing-machine made in Scotland; and after it had sown Mr. Wright's crop of that season, I exhibited the machine at the Agricultural Shows of Coldstream and Kelso, and received premiums for it at both places; this was in 1817; and in the following year I made one of the same dimensions for Mr. Wilson's father, the late Mr. Abraham Wilson." From Berwickshire the machine made its way immediately into East-Lothian, where the manufacture of it was taken up by the late Mr. Adam Scouler after the machines of Mr. Lowrie above referred to, and has been successfully carried on by his successors, Messrs. Scouler and Company of Haddington. The machine here referred to as having been brought from Chiverton, is the same as are yet to be found in the northern and eastern counties, and used chiefly for sowing grass-seeds; its application to the sowing of grain having made little progress, or it may rather be considered as having been superseded by the drill system of sowing, so much practiced in these counties of England.

(1800.) In the early application of the broadcast machine, it was mounted on two wheels: but a few years' experience pointed out the advantages of a third wheel, which was applied to it by

Messrs. Scouler about the year 1830, the third wheel being applied as a swivel or fore-carriage. The carriage is still subject to considerable variety of construction, but these varieties are not of a nature to alter its general character. A carriage of a nearly triangular form is very generally adopted, the apex being in front over the swivel-bar. A rectangular carriage is also very much employed, and this is the most workmanlike construction, though perhaps not the cheapest, but it is withal the most convenient and useful form. As regards the general construction, an important improvement has been introduced within the last six years; this is the cutting of the seed-chest into sections. The chest is usually made 18 feet long, which being far beyond the width of any field-gate, produced a necessity for changing the position of the chest when passing through a gateway. It was therefore the practice to lift the chest from its working position parallel to the axle of the machine, and deposit it parallel to the horse-shafts until it had passed through the gate. This was clearly both imperfect and inconvenient, and these defects gave rise to the cutting into sections, the middle part being 9 feet, and the extremes each 4½ feet, so that when the latter are folded up, the extreme length of chest is 9 feet.

(1801.) The illustrations of this machine which I have here given in Plate XXVI. are taken from those manufactured by James Slight and Co., Edinburgh, and they exhibit the machine in its most complete state, embracing the chest in sections, with the mode of supporting the same; this last improvement having, it is believed, been first introduced by the above-named house. In Plate XXVI., fig. 316, is a view in perspective of the entire machine, as it appears when in work, and fig. 317 a section, on a scale of ½ inch to a foot, taking the chest transversely through its center, the carriage being cut in the same line, or parallel to the horse-shafts. In these two figures the same letters mark corresponding parts. The carriage is marked *a b a*, fig. 316, and is a frame of hard wood, the bars of which are from 4 to 5 inches in depth, and 2½ inches in thickness; the dimensions of the frame being 7 feet in breadth over all, and 4 feet in length over the rails, of which there are three, as seen at *b b*. The hind wheels *c c* are 34 inches in hight, generally formed with cast-iron naves, wooden spokes and felloes; or, as in the figure, the felloes are superseded by a simple hoop of malleable iron 2½ inches by ¾ inch, which, for light carriages of this description that never travel on hard roads, is found sufficiently serviceable. The axle of these wheels is 1½ inches diameter, seen at *d*, in fig. 317, and is in two lengths supported in pillow-blocks bolted to the lower edge of the bars *a a a* of the frame, and meeting in the middle bearing. The nigh-side wheel is fixed dead upon the axle, carrying the axle round with it to give motion to the pitch-chain *d e* of fig. 317, and which is seen also at *a*, in fig. 316, where it is seen as entering the chest. The off-side wheel may in this case be also fixed dead upon the other half of the axle, or it may run loose. But the axle may also be made in one piece, the off-side wheel being left loose, which is necessary for the convenience of turning round, this wheel being disengaged from turning with the other. The front wheel *f*, fig. 317, and seen also partially in fig. 316, is 24 inches diameter, usually of cast-iron, and is supported on the cast-iron sheers *g*, which are 4 inches wide between the arms, and terminates upward in the lower half of the swivel-plate *h*, and this, again, is furnished with a strong pivot, passing upward through the head *i* of the cast-iron fore-beam *i k*. The head of the fore-beam is formed into a swivel-plate corresponding to that of the sheers *g*, and is bolted to the two foremost bars *b b* of the carriage. Two small pillars *l* are cast upon projecting ears of the swivel-plate of the sheers *g*, and bolts passing through these pillars and the splinter-bar *m*, bind these parts firmly together, producing an effective swivel-carriage. The horse shafts *n n*, broken off in fig. 317, are attached to the splinter-bar *m* by means of a long draft-bolt passing through the ends of the shafts, and through eyes fixed in the splinter-bar.

(1802.) The seed-chest *o o* is 18 feet in length, formed of ¾-inch deal. The breadth of the bottom board is 6½ inches, projecting on one side 2½ inches, forming an apron, on which the seed falls from the orifices. The sides of the chest are 10½ inches in depth, and the cover 14 inches in breadth, 9 inches of which form a hinged flap, as seen in the figure. The chest is bound together upon ends and partitions of hard-wood 1½ inches thick; when in sections as here described, each section has two such ends, and the middle section has two partitions in the middle, set at 2½ inches apart. When the chest is in one length, two ends and the two middle partitions only are required. The joints or hinges of the sections are formed of the iron straps *p p*, two of which are securely riveted on each side of the chest, having eyes formed at the apex *q q*, and through these eyes a small bolt, *q*, passes from side to side, which completes the hinge; and by withdrawing the bolt the parts of the chest are at once disengaged. For the better connection of the segments, however, when the machine is in action, the contiguous ends are held in contact by a bolt and nut, as seen at *c'* in fig. 318, which, together with fig. 319, are on a scale of 1 inch to a foot. The two extreme segments, also, are supported by the light tension chain *i'' i' i' i''*, which passes over the two upright iron stanchions, *k k'* the tops of which, *i' i'* form the suspending fulcra for the chain, while its extremities are secured at the points *i'' i''* with adjusting nuts.

(1803.) The *sowing-geer* of the machine consists of the following parts: The main axle of the carriage is mounted with a pitch chain-wheel 4 inches diameter, placed upon the axle close to the middle bar *a* of fig. 316, and seen in full at *d e*, fig. 317; a corresponding wheel *r* is placed upon a short axle within the seed-chest, and between the two middle partitions of the chest. In this way motion is communicated from the carriage-wheels *c*, and their axle, to the axle of the small wheel *r*, fig. 317. A light shaft, ¼ inch square, is coupled to the ends of the axle of the wheel *r*, extending to each end of the chest; when the chest is entire, each of these shafts is also entire; but in the present case each shaft is in two pieces, coupled at the junction of the segments of the chest by means of small clutch couplings attached to the ends of the shaft, and these engage or disengage of themselves when the segments of the chest are let down or folded up. These last-mentioned shafts are supported in bearings of hard-wood laid in the bottom of the chest, at distances of from 2 to 2½ feet, and the journals, which are 1½ inches long, covered with straps of stout hoop-iron. The shafts are armed with the seed-wheels of the form as shown at *r* in fig. 318, which are placed upon it at distances of 6½ inches, 32 wheels being required for an 18-feet chest. The seed-wheels have suffered a variety of changes: originally circular brushes were employed, then came wooden naves, of about 3 inches in length and 2½ inches in diameter; and into these

were inserted leaves or teeth of hoop-iron, about 1 inch broad and 1 inch long, and this form of wheel is still much employed. In the progressive stages of the machine it was furnished with one set of these small shafts, carrying brushes, and another set carrying wheels, as above described; the former being then thought necessary for sowing grass-seeds, and the latter were employed for grains: observation shortly pointed out that the toothed wheels were equally well adapted for either grass-seeds or grain, and the brushes have consequently been laid aside. The wheels represented by *r*, fig. 318, are of cast-iron, of very light fabric; they are ten-toothed, and are 4¼ inches in diameter, measuring to the extreme points in the cross-section; the points of the teeth are slightly rounded, to adapt them to the concave groove or cup that is formed in the back of the chest around each discharging orifice; the wheels are cast with a square eye, and fixed upon the shaft by barbing the angles of the shaft round the eye of the wheel.

(1804.) Corresponding to each seed-wheel, a discharging orifice *s* is formed in the back of the chest; these are ¾ inch diameter, and their center is 1½ inches above the apron-board *f w*. On the inside of the back-board oval excavations are made in the wood around the orifices, leaving the bottom of the cups or edges of the orifice not exceeding 1-16 inch thick; and in this oval cup the seed-wheel sinks until the points of the teeth are only ¼ inch clear of the bottom of the cup or the edges of the orifice as seen at *s*. The position of the seed-wheels in relation to the bottom *f u* of the chest is such as to make the teeth turn at about ¼ inch clear of the bottom. The seed orifices are defended by the iron plates *d'*, fig. 319, of a triangular form, the apices *d'* are driven into the apron, which secures that point of the plates, and the other two points are fixed by nailing. The fixing of the plates requires some attention, in order that the orifices may exactly coincide with those of the slide *t t*; without perfect coincidence in these two parts the sowing will be unequal.

(1805.) The slide is a bar of hoop-iron 2 inches in breadth, and about 1-12 inch in thickness; it is perforated at the regular distance by means of a punching instrument, and gauged to determine the precise intervals. In the entire chest the slide is in two lengths, but in that now described each half is again cut in two at the junction of the sections, and connected by a slip hinge-joint. The slide is held in its place by the small clasps *e' e'*, and a clamp *f* is riveted upon it at any convenient point; the short arm of the lever *w* enters an opening in this clamp, while its fulcrum lies in the plate *b*, which carries a perforated stud, and is fixed on the back of the chest as in fig. 318, forming the fulcrum of the lever, by means of which the slide is moved over the seed-orifices. To effect the precise adjustment of the orifices, the slide is made in two halves, and at each end of the chest an adjusting-screw *v* acts in a nut attached to the end of the chest, the point of each screw being brought to bear against the end of the slide, which is here thickened to meet the point of the screw. The adjustment will be understood by reference to fig. 319, which represents a portion of the slide of the left-hand half of the chest. The slide is here supposed to have been pushed toward the right hand by means of the adjusting-screw *v*, fig. 316, till the orifices have been reduced to the desired size, as here shown in fig. 319 about half shut; in this state the machine is supposed to be fit for sowing, and that it has reached the end of the field, when it becomes necessary to shut while turning; the shutting is effected by moving the slide still farther, to the right hand, by means of the lever, until the orifices are entirely closed. Both ends of the chest having undergone this operation, which is done in an instant, but in reverse directions, the machine may go to any distance without discharging a grain; but whenever it has been turned into the next ridge, the levers *w* are thrown in the opposite direction, moving the slide toward the adjusting-screw *v*, and this being done at both ends, the orifices will have attained precisely the same area as before, and thus the shutting and opening again to the same area: and of course the same discharge is effected for any number of turns without the smallest variation, so long as the screw *v* remains unaltered.

(1806.) For the purpose of equalizing the distribution of the seed over the surface of the ground after it has left the discharging orifice, the bottom-board *f w* of the seed-chest is made to project beyond the back of the chest about 2½ inches, as at *w*, fig. 318, forming an *apron* on which the seed is first received from the orifice, and being thus checked in its descent, is thereby more uniformly scattered over the surface. Another precaution is taken, the better to secure a uniform discharge in the case of sowing on ground that has a high inclination. In sowing up-hill, in such situations the weight of the basket is thrown more upon that side of the chest from which it is discharged, tending thereby to increase the discharge. On sowing down-hill, on the other hand, the effect of pressure is reversed, and the discharge will be less. To avoid these inconveniences, Messrs. Scouler, among their other improvements in this machine, introduced a tilting motion to the seed-chest in the following manner: on the two outward bearers *a a* of the carriage-bolsters *y y*, having a semi-circular seat of about 8 inches diameter, and corresponding to these, on the bottom of the chest, are formed two circular bearing or journals *y y e* on the bottom of the chest and concentric with the shaft of the seed-wheels *r*, figs. 317 and 318. Upon these journals the chest can be tilted to a certain extent backward or forward, and this is effected by the lever *z*, which may be variously attached to the chest. In the present case it is a fork thrust into two apertures in the chest, forming a lever, whose arm is retained in the sheers of the quadrant *a'*, and by raising or depressing the lever *z* the chest is tilted backward or forward as the sower sees it necessary; the lever being retained in the required position by a bolt passed through the lever and the then corresponding hole in the quadrant.

(1807.) As the seed-chest is 18 feet in length, and it may sometimes be desirable to reduce its breadth of sowing to 16 or to 15 feet, suiting ridges of these breadths, the reduction is effected by stopping two, three, or more of the seed-orifices at each end. For this purpose the orifices intended to be stopped are provided with a flat swing-clasp, turning upon a pin to which it is riveted, and having a flat tail which is brought over the orifice that is to be stopped. Two of these clasps are seen at each end of fig. 316, under *x*, where they are in the position that leaves the orifice open.

(1808.) The *sowing-geer* of this machine has undergone a variety of changes. In the example before us, the pitch-chain is employed to communicate motion from the first mover—the carriage

axle—to the seed-wheels. It has the property of great simplicity, but has been objected to on the score of its keeping the seed-wheels constantly in motion, whether sowing or not, which has been supposed to have a tendency to injure the grain which lies in contact with the wheels. Perhaps there may be grounds for this supposition; but if it do exist, the deterioration must be very trifling. Be these surmises what they may, they have given rise to the means of prevention, by employing a gearing that disengages the seed-wheels from the first mover when the machine is being moved and no discharge of seed required. Fig. 320 represents a very perfect and convenient arrangement of this kind, and which has been very successfully employed, but is a little more expensive than the chain-gearing. *a* is the seed-chest, *b b* a part of the carriage, and *o o* the middle and back transverse-bars of the same (corresponding to *b b*, fig. 316.) The bar *f e* is one side of a light cast-iron sheers, which is bolted to the bars *o o* (standing in the place of the middle longitudinal bar *a* of fig. 316;) and the three equal wheels *c c c* are set in the sheers—the first of the three being upon the carriage-axle, which is in halves as before, and the meeting-ends supported on the sheers *c*. The last of the three wheels takes into the wheel *h*, mounted on the central portion of the seed-wheel shaft, as before described in (1805); and *d* is a fourth wheel, of equal size with *c c*, mounted on the lever *g*, which is forked to receive the wheel *d*, and to embrace the sheers *f e* at *e*, upon which last point the lever turns as a fulcrum. It will be evident that by lifting the lever *g*, and throwing it forward upon the seed-chest, the wheel *d* will be ungeared from the first wheel *c*; and though it remains in contact with the middle wheel *c*, no motion will be communicated to the seed-wheels until the lever is returned to its original position.

(1809.) In using the broadcast machine, it is frequently drawn by one horse; but it forms a rather heavy draught, and is, therefore, more frequently the work of two horses. The chest is filled from end to end with the seed-corn, and, the horses walking in the furrow, the machine sows the half ridge on either side. When the chest has been filled, and the machine brought to that position which places the horses in the furrow—the sower having previously determined the degree of opening in the orifices that will deliver the desired quantity per acre, he throws each slide outward against its graduating screw, which will produce the proper opening, (1807); and this done, the horses are driven forward. On arriving at the farther end of the ridge, and before entering upon the head-ridge, the slides are withdrawn toward the center, closing up the vents; the machine is then turned round on the head-ridge, and takes up a position on the next furrow, when the process is repeated, and so on till the field is sown all over, the head ridges being the last portion of the work, and here the blinding of the extreme orifices come frequently into play, if the head-ridges are of less breadth than those of the field.

(1810.) It has often been suggested that a register screw or index would be a useful appendage to the machine, by which the sower could at once fix upon the extent of opening in the seed-vents. This addition, however well it may appear in theory, appears, in the practical application of the machine, to be of little value; for the eye of an experienced sower will, on passing over a few yards with the machine, by simple ocular inspection, be able to judge of the quantity of seed he is bestowing upon the soil. If experimental accuracy is required, the sower may then put into the chest as much grain as will just cover the seed-wheels, and then *measure* in one or two bushels, and proceed to sow this until as much remains as will just cover the wheels again, so that the measured quantity is found to have been discharged. By now measuring the number of yards in length that have been sown with two bushels, he will ascertain by calculation the proportional quantity required for an acre. Thus, let the intended quantity to be sown upon an acre be 5 bushels, and that one bushel has been sown in the experiment which has covered 140 yards of the 18-feet ridge, or two half-ridges equal to 18 feet, or 6 yards. The imperial acre contains 4,840 square yards, and this divided by 6, the yards in the breadth of the ridge, we have 806⅔ as the number of lineal yards in length of an 18-feet ridge to make up an acre; and 1-5 of this, or 161.2 lineal yards, is the extent that should have been covered by 1 bushel of seed-corn. The machine having, as supposed, covered only 140 yards, it follows that the sowing is about ¼ part of the bushel too thick; the graduating screws, therefore, must be turned forward about half a turn, and the experiment repeated if thought necessary. It is seldom, however, that such experiments will be required in the hands of a practical sower.

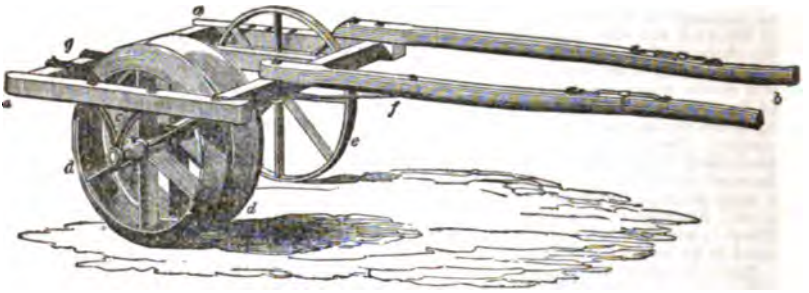
(1811.) In reference to the inconvenience attending the great length of the seed-chest as taken notice of at (1800) when it is in one length, there remains to be observed that the method by which it is shifted is this: in its working state the chest is kept in its bolsters by means of two quadrants attached to the lower part of the chest, one being on each side of the carriage; these are formed concentric with the curvature of the bolster *y y*, fig. 317, and a bolt, over which the quadrant slides, is screwed into the side of the carriage, and this retains the chest in its place. When it is found necessary to move the chest, the two bolts are unscrewed, which sets the chest at liberty; it is then lifted from its bolsters and laid longitudinally on the carriage. In this operation, however, the pitch-chain, when that medium of power is employed, has to be disengaged by withdrawing a coupling-link from the chain; but when the medium, fig. 320, is employed, there is nothing required but the unscrewing of the quadrant-bolts to set the chest at liberty. It is then lifted and laid longitudinally on the carriage as before. The price of these machines ranges from £10 to £12.

(1812.) *The Presser-Roller* is an implement of very recent introduction to the operations of the farm, and, like many others of the useful class of agricultural machines, its origin is to be traced to England. Although the presser does not take its place in the first rank, yet it possesses qualities whose effects on the soil give it a position by no means low in the scale of usefulness. The chief object of its application is to produce consolidation in the soil over a narrow space, in which space the seeds of plants are to have root; hence its effects are applicable only to the drill system of culture, and that only under particular circumstances, namely, consolidating soils whose texture is too loose and friable for the continued support of wheat plants, and to produce close contact in the furrow-slices of lea when plowed for a seed-furrow.

(1813.) The *Presser-Roller* is represented in its most common form by fig. 325, which is a view of the machine in perspective, and is of extremely simple construction. The carriage consists of a

rectangular frame *a a*; its length over the front and back bars is 3 feet 8 inches, and its breadth over the sides 4 feet 8 inches; a third longitudinal bar is introduced between those of the back and front solely to increase the rigidity of the carriage-frame. A pair of horse-shafts *b*, are bolted

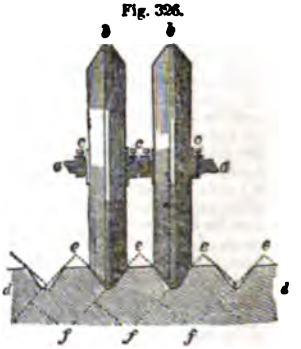
Fig 325.



THE PRESSER-ROLLER.

upon the frame, the nigh-side shaft being laid upon the side-rail, and the other at the usual distance, to afford space for a horse to travel. A cast-iron bracket is appended by bolting to each side-rail; one of these is seen at *c*; its eye or center descends to a distance of 8 inches below the bottom of the rail: an axle of 2 inches square extends between, and is supported in the eye of the bracket in which it turns upon its journals; this axle carries the two pressing-wheels *d d*, which are fitted to turn with the axle, but are movable in the transverse direction, and provided with the means of being fixed at any desired distance apart, though 9 to 10 inches is the usual space. The axle carries also the light carriage-wheel *e*, of 2 feet 10 inches diameter, which may be placed either outside or inside of the carriage-frame, and is usually made of cast-iron, turning upon the axle, this being requisite for the more convenient turning round of the machine. The off-side shaft *b* having but an imperfect connection to the carriage-is supported by the iron stay-rod *f*; and two iron scrapers *g* are attached to the hind bar for the purpose of throwing off any soil that may adhere to the wheels. Fig. 326 is an edge-view of the two pressing-wheels detached from the carriage, in which *a a* is the axle broken off, *b b* are the two pressing-wheels as they appear edgeways; they are 2 feet 10 inches of extreme diameter, and their breadth 5½ inches, their weight being about 2 cwts. each; the rim or periphery of the wheel is sloped off on both sides to an angle of about 70°, forming two opposite conical frusta, but a cylindrical band is left in the middle of about 1½ inches in breadth. The pressing-wheels are held at the required distance by the square collars *c c c* fitting round the axle and sliding upon it to the proposed distance apart, where they are fixed by the pinching-screws *c c c*. *d d* represents a transverse section of ground undergoing the pressing process: the shaded part of the section exhibits the state of a soft, loose soil, when pressed by the roller, and the dotted lines *ef*, *ef*, that of newly plowed lea undergoing the operation of consolidation.

Fig. 326.



EDGE VIEW OF THE PRESSING-WHEELS.

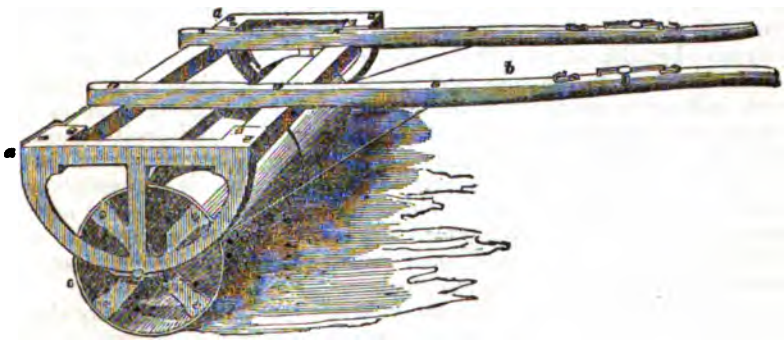
(1814.) As explained in the text above, and with reference again to fig. 325, the pressing-wheels are to be understood as running always upon the last turned up furrows but one; while the carriage-wheel runs always upon the solid land, where the horse also walks, the shafts being placed at that side. But the presser is now being more advantageously used as to *time*, in the consolidation of soft soils, by being constructed with *four*, *six*, or more pressing-wheels; and in this form the carriage-wheel is not required. In using the presser of this construction, the field must be plowed for the seed-furrow all over, either entirely or in part, before the pressing is begun; and the field is regularly gone over by the presser, which, from its now increased weight, will require two horses. In this form, with six pressing-wheels, and with two horses, the machine will press-roll from eight to nine acres in a day. There remains to be observed, in regard to the last form of the machine, that, in order to secure facility of turning about, the wheels must either be all set upon a round axle, or they must be set upon an axle in two lengths, if it is continued of a square form; and there is consequently required a middle *bearing* for the meeting ends of the axle. For this purpose, a third bracket is appended to the middle rail of the frame, fig. 325. I have found both of these modes of construction perfectly suitable in practice; and the entire weight of the six-wheel rollers amounts to about 12 or 13 cwts. The price of the two-wheeled presser is £6 10s., and for each additional wheel, with its mounting, £1 12s.

(1815.) The common *Land-Roller* is an implement of great simplicity of construction, the acting part of it being a cylinder of wood, of stone or of metal, and in many cases its only appendage is a rectangular frame of wood, consisting of two strong end-bars, selected for having a curvature to keep clear of the ground. In these the gudgeons of the roller are borne, and which

are connected by two transverse rails, to one of which the horses are yoked. Simple as this implement appears, there is hardly an article in the establishment in which the farmer is more liable to fall into error in his selection. From the nature of its action, and its intended effects on the soil, there are two elements that should be particularly kept in view—*weight* and *diameter* of the cylinder. By the former alone can the desired effects be produced in the highest degree, but these will be always modified by the diameter. Thus, a cylinder of any given weight will produce a greater pulverizing effect if its diameter is one foot, than the same weight would produce if the diameter were two feet; but then the one of lesser diameter will be much worse to draw; hence it becomes necessary to choose a mean of these opposing principles. In doing this, the material of the cylinder comes to be considered. In the first place, wood, which is frequently employed for the formation of land-rollers, may be considered as least adapted of all materials for the purpose; its deficiency of weight and liability to decay render it the most objectionable of all others. Second, stone, though not deficient in weight, possesses one marked disadvantage, liability to fracture; this of itself is sufficient to place stone rollers in a doubtful position as to fitness. This brings us to cast-iron, which is undoubtedly the most appropriate of all materials for this purpose. It is unnecessary here to enter into the inquiry as to the most advantageous diameter for a land-roller; the subject has already been elaborately discussed;* let it suffice to say that experience has proved that a diameter of 2 feet is, under any circumstances, the one that will produce the best effects with a minimum of labor from the animals of draught; the weight being of course proportioned to the force usually applied, which is in general two horses. The weight of roller, including frame corresponding to this, is from 12 to 15 cwts.; but it is better that the roller itself be rather under the weight, and that the carriage be fitted up with a box, in which a loading of stones can be stowed, to bring the machine up to any desired weight. In a large and heavy roller, in one entire cylinder, the inconvenience of turning at the headlands is very considerable, and has given rise to the improvement of having the cylinder in two lengths; this, with a properly constructed carriage, produces the land-roller in its most perfect form.

(1816.) Fig. 327 is a perspective of the land-roller constructed on the foregoing principles. *a a* is the carriage-frame, consisting of two semi-circular ends of cast-iron, connected by two trans-

Fig. 327.



THE LAND ROLLER.

verse bars of hard wood, and these last are crossed by the horse-shafts *b*. The cylinder *c* is in two lengths of 3 feet to 3 feet 3 inches each, and 2 feet in diameter; the thickness of the metal is from ¾ of an inch to 1 inch, according to the weight required; and each half length of the cylinder has a cross fitted into each end, through the centers of which the axle passes. The axle, in consequence of the cylinder being in two lengths, requires to be of considerable strength, usually 2¼ inches diameter, and of malleable iron; upon this the two sections of the cylinder revolve freely, and the extremities of the axle are supported in bushes formed in the lower part of the semi-circular end-frames. Two iron stay-rods pass from the end frames to the shafts as an additional support to the latter. The price of the land-roller, fitted up as here represented and described, is, according to weight, from £10 to £14.†

[† We cannot forbear recommending here the use of a machine invented by, we think, a Mr. Gray, of Lower Virginia. It was brought to our notice by one of those too rare men among farmers—one who *thinks*—Hon. W. Carmichael, of Queen Anne's County, Maryland. The simple name of this implement indicates the simplicity of its construction, being called the *drag-log*. It is made of a log of wood say 5 feet long, more or less, and 12 or 14 inches square, with the tongue of a common ox-cart pinned down in the middle on *the top* of it, instead of a pair of shafts, as in the land-roller here represented. To this tongue is to be hitched a span of oxen and the log thus dragged over the surface of cloddy plowed land. It will be found to pulverize the land more at one operation than rolling at two. Instead of burying the clods it mashes and grinds them to powder as it proceeds. *Ed. Farm. Lib.*]

* Quarterly Journal of Agriculture, vol. i.

12. SOWING OAT-SEED.

"Though ley land you break up when Christmas is gone,
For sowing of barley or oats thereupon,
Yet haste not to fallow till March be begun,
Lest afterward wishing it had been undone."
Tusser.

(1817.) After what has been said of plowing lea ground (919), and of the mode of sowing seed upon the land by hand, fig. 322, and of the properties of different kinds of oats cultivated in this country (1519), little requires to be added here on the sowing of oats, except the manner in which that operation is *finished*.

(1818.) Beans and spring wheat are not sown upon every species of farm, the former being most profitable in deep, strong soils, and the latter is only to be commended after turnips, on land in good heart, situate in a favorable locality for climate, and the crop eaten off by sheep; but oats are sown on all sorts of farms, from the strongest clay to the lightest sand, and from the highest point to which arable culture has reached on moorland soil, to the bottom of the lowest valley on the richest deposit. The extensive breadth of its culture does not, however, imply that the oat is naturally suited to all soils and situations, for its fibrous and spreading roots indicate a predilection for friable soils; but its general use as food among the agricultural population has caused its universal culture in Scotland, while its ability to support the strength of horses has induced its culture to be extended throughout the kingdom; and it is certainly a remarkable fact with what admirable effect this plant has adapted itself to the various circumstances in which it is cultivated, and this result is, most probably, owing to the same food, namely, the decomposed grasses with which this plant is uniformly supplied.

(1819.) All the varieties of oats cultivated may be practically classed under three heads, the *common*, the *improved*, and the *Tartarian*. The common varieties include all those having a pyramidal spike, soft straw, long grains possessing a tendency to become awny, and which are late in reaching maturity. Among the *named* varieties are the following in common use: early and late *Angus*, *Kildrummie*, *Blainslie*, white *Siberian*, fig. 307, *Cumberland*, *sandy*, and *Dyock*, which last two are recent varieties, and others. It is unnecessary to point out the superior characteristics of each variety, for in the respective districts in which they are sown, each is considered best suited to the locality in which it is cultivated—an opinion which may safely be disputed. The four last named are in high repute at present, owing to their recent introduction; and it is probable that any recent variety will answer best for a shorter or longer period. All common oats are sown on the inferior soils, and in the most elevated fields of farms, and the season for sowing them is the beginning of March. Of the improved varieties are the *potato oat*, which has long been cultivated as the only variety; but of late years the *Hopetoun oat* has been added to the short list. Before it the Georgian was introduced, but did not succeed. Both the potato and Hopetoun oats have long, strong straw, large spikes, come early to maturity, and are chiefly cultivated on the best and lowest lying ground. The grains are very similar, the Hopetoun being distinguished by a tinge of red on the bosom, fig. 306. These oats

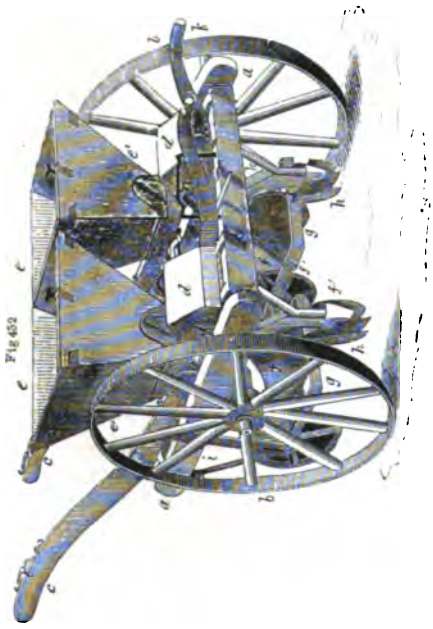
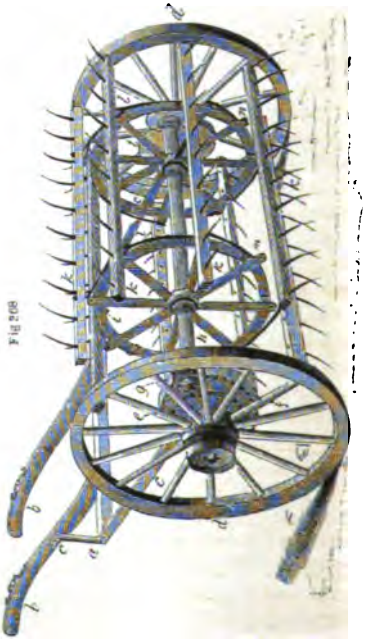
HAY TEDDING MACHINE.





are sown a fortnight after the common. The cultivation of the *Tartarian* varieties, both *black* and *white*, is chiefly confined to England, for the use of horses, and are there called *feed* oats. I am surprised that this oat should be cultivated at this time of day, both on account of its coarseness, as well as the disagreeable work which it occasions in the barn by its long hygrometric awns.

(1820.) The plowed lea-ground should be dry on the surface before it is sown, as otherwise it will not harrow kindly; but the proper dryness is to be distinguished from that arising from dry, hard frost. It will not be proper to wait until every spot of the field is dry alike, as even thorough-draining will not insure that; though spottiness shown in spring is a good criterion whether land has been enough drained, or where it most requires it. Should the lea have been plowed some time before, and from young grass, the furrow-slices will be found to lie close together at seed-time; but should it have been recently plowed or from old lea, or on stiff ground in a rather wet state, the furrow-slices will not lie close together, but be as far asunder as to allow a good deal of the seed to drop down between them, and where this happens the seed will be lost, as oats will not vegetate from a depth of 6 or 7 inches. In all cases of lea where the furrow-slices are not close, in order to save a part of the seed, and avoid a thin crop, the ground should be harrowed a single tine before being sown. The tines of harrows should be particularly sharp when used for covering in seed upon lea. When oats are sown by hand upon dry lea-ground, the grains rebound from it and dance about before depositing themselves in the hollows between the crests of the furrow-slices, and thus accommodating themselves to the form of the ground, are not so liable to be *happerga'ed* in sowing as other grains. Were the ground only harrowed in along the ridges, so as not to disturb the seed along the furrow-slices, the germs of the crop would come up in as regular rows as if sown by drill; but as the land receives cross-harrowing as well as along, the braird comes up broadcast, notwithstanding the position the seed assumes when it settles on the ground. The quantity of common oats sown is usually 6 bushels to the imperial acre; and in deep friable land in good heart, 5 bushels of potato oats suffice. A man does a good day's work if he sows broadcast 16 imperial acres of ground in 10 hours, that is, scatters 80 bushels of potato oats and 96 bushels of common oats in that time. Some men can sow 120 bushels of common and 100 of potato in that time, that is, 20 acres; and double-handed sowers can sow more than this latter quantity. Two sowers keep one seed-carrier fully employed, and indeed if the sacks are not conveniently placed (1756), one will not be able to supply them both, but 2 seed-carriers will easily supply 3 sowers; and every sower employs 2 pairs of harrows breaking in after him, with a double tine. So that the number of sowers is regulated by the number of pairs of harrows that a farm can furnish. The arrangement of the labor for sowing an oat-field may be seen in fig. 322, where 2 sowers and 1 seed-carrier are represented, but the harrows of 1 sower only are shown in view. See from (1762) to (1766) inclusive. After the land is broken in with a double tine, it is harrowed across with a double tine, which cut across the furrow-crests, and then along another double tine, and this quantity generally suffices. At the last harrowing the tines should be kept clean, and no stones should be allowed to be trailed along by the tines, to the manifest ribbing of the surface. On old lea, or on hard land, another single turn across or angle-ways may be requird to render the land fine enough; and, on the other hand, on a free soil a single tine along after the double one cross may suffice. In short, the harrowing should be continued as long and no longer than the ground feels uni-

formly smooth and firm under the foot, having no hard places, or others sinking into hollows by the pressure of the foot (1770). The head-ridges are harrowed round by themselves at last. See (1771). The land, after the oat-seed is sown, is always *water-furrowed* in every open furrow (1778); and it should also be rolled (1777), according to circumstances; that is, the young braird on strong land being retarded in its growth, when the earth is incrusted by rain after rolling, it is safe to leave the rolling of such land until the end of spring, when the crop has made a little progress, and when the weather is usually dry. Light friable land should be rolled immediately after the seed is sown and harrowed, if there is time to do it; but the rolling of one field should cause no delay to the sowing of others in dry weather. There will be plenty of time to roll the ground after the oat-seed and other urgent operations at this season are finished, and especially as rolling *may* be speedily performed. The cutting of *gaws* should never be neglected in finishing off an oat-field, to carry off water along hollows or in the open furrow beside the lowest hedge-ridge, as particularly described in (918). Oats are sown broadcast by machinery as well as by hand. The machine is the same as is used for sowing grass-seeds, and figured at fig. 316, Plate XXVI., and already described by Mr. Slight in (1798) to (1811). As constructed at first upon two wheels, this machine, when loaded with a full complement of oat-seed, was too heavy for a horse's back, especially on going down hill; but the addition of the third wheel disposes of that objection, and I believe it is now pretty extensively employed in sowing corn.

(1821.) But oats are also sown in rows by such drill-machines as are represented in figs. 325 and 326, Plate XXVII., and described below by Mr. Slight. In using drill-machines, the land should first be harrowed a double tine along, and then a double tine across the ridges, and again a single tine *along*. The drill then sows the oats *across* the ridges, and the land is finished by harrowing a single tine also *across* the ridges. The water-furrowing and rolling should be executed in the manner described (1820) for broadcast sowing. The drill seems to me not well adapted for sowing corn on *lea* ground. It cannot pass through it, even after it has been well cut with the harrows, with the facility it does through ground in a soft state; and on hard ground and upon old lea it is questionable whether the coulters can penetrate so far as to deposit the seed at a depth to be out of reach of birds and drouth; and every stone in such ground being rather firmly imbedded, will be apt to cause the drill to go out of its proper course, while at the same time the risk at least of partially displacing the old, uncorrupted turf will be imminent. In these latter cases I would recommend the broadcast machine or the hand in preference to the drill; and I would confine the drill in sowing oats to tender land as in the neighborhood of towns, where it is made tender by the application of large quantities of street-manure, and where drilling is advisable as affording a facility for cleaning the land of surface-weeds, a multitude of which, and especially wild mustard, *Sinapis arvensis*, are apt to spring up from the use of street-manure. In England, however, where the drilling of grain is followed out, it must be owned that their plowing with the wheel-plow and sowing with the drill-machine are so perfect in their operation that the seed is laid in the furrows with certainty, and without at all disturbing the furrow-slice.

(1822.) At a time when a less rational system of husbandry was pursued than now happily prevails—that is, when land was allowed to be overrun with surface-water; when lea was plowed, out of choice, in a wet state, because the labor of doing it was easier for half-starved, jaded horses; when land was harrowed with small, light, loose harrows, furnished with short, blunt tines; when the lea-turf consisted chiefly of the tough roots of perennial weeds—in these circumstances lea

ground required a great deal of harrowing to bring it to a tolerable degree of tilth, eight or nine double times being considered no more than necessary. The great length of time required to do this, obliged the oat-seed to be begun early, so early indeed as Tusser recommends it to be begun in January:

"In January, husband that poucheth the groats,
Will break up his ley, or be sowing of oats;"

if the husbandman desires to pocket the gain of a good crop; and by the time the crop was finished, every creature, man and beast, were almost worn out with fatigue. The land being now made tender and fertile by draining, cleaning and manuring, oats have time to come to maturity when sown long after January, and its harrowing is now finished in one-third of the time, and with one-fourth the labor it was then.

(1823.) The oat crop, when very young—that is, when the plant has not pushed its leaves more than 2 inches above the ground—is subject to a very serious disease called the *grub*, a name derived from the grub or larva of a particular insect, the *Tipula oleracea, Meadow-crane-fly*, attacking its roots, and causing the plant to decay, and even to die when seriously injured by this insect. The perfect female insect is represented of the natural size at *a*, fig. 328, and which will at once

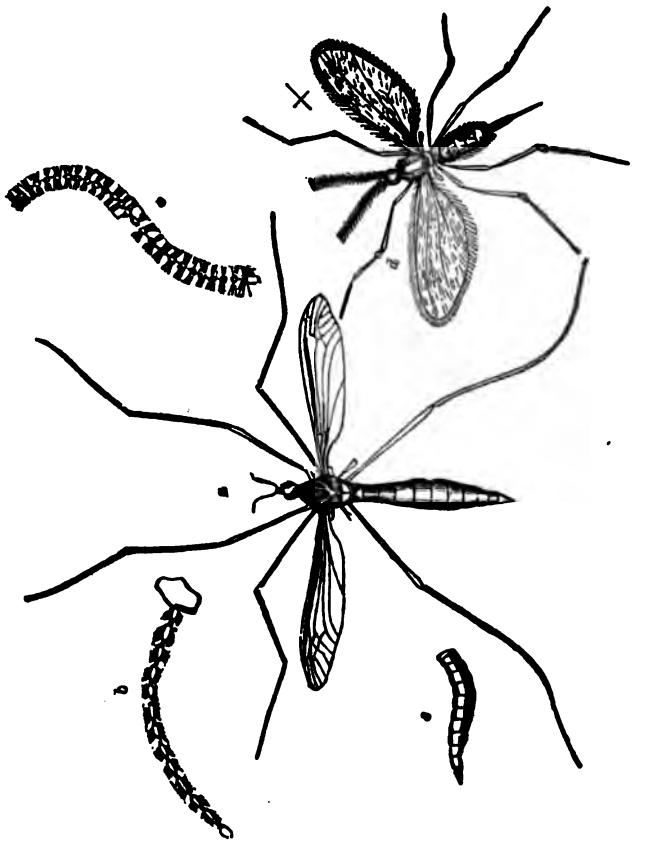


Fig. 328. THE LARGE INSECT WHICH PRODUCES THE GRUB IN OAT-FIELDS.

be recognized as that well known by the familiar names of *Long-legs, Tailors, Jenny-the-spinner*. Its body is near 1 inch long, of a brownish-gray color, and its wings pale-brown. In the female the abdomen is thickest near the middle, from which it tapers to a point at the hinder extremity; that of the male is thicket at the hinder extremity, which forms a kind of club. "This insect," says Mr. Duncan, "is very plentiful during the summer months in all parts of the country. Its long legs are of great advantage to it in places it frequents, as they enable it to skip over the grass as if on stilts; and it still farther facilitates its motions while so doing, by keeping the wings expanded, to render it buoyant. The female lays a great number of eggs, which are very small in proportion to the size of the insect, and of a black color. These she places at some depth in the earth, which she pierces for the purpose with her ovipositor. The insects may easily be seen performing this operation, and it will at once be known that they are so employed by the singular position they assume. The body is placed in a perpendicular direction, supported on the hinder feet and extremity of the abdomen, while the wings are expanded, and the anterior legs

rest on the surrounding plants. When a sufficient number of eggs have been laid in one spot, the insect moves on to another, without changing the vertical posture of her body, merely dragging herself forward by her fore-legs, aiding her movements with her wings." It is in the larva state that these insects injure crops, meadow-grass not being their only food; they attack different kinds of corn, especially oats, the effects of *grubbing* in which are well known to every farmer. When full grown, the larvæ are in the shape of an elongated cylinder, somewhat suddenly attenuated at both extremities, and are of a dull grayish color, and without feet. The head is furnished with two hooks, one on each side. The pupa is not unlike the chrysalis of some kinds of moth; and it is nearly of the same color as the larva, the edges of the segments being furnished with pretty strong hairs. The larvæ reside generally about 1 or 2 inches beneath the surface, mining their way among the roots of the herbage, and causing it to wither for want of nourishment. They prefer a soil which has been long undisturbed by the plow; and if it contains some portion of peat earth, it seems thereby better adapted to their tastes. "In the rich district of Sunk Island, in Holderness, in the spring of 1813," say Messrs. Kirby and Spence, "hundreds of acres of pastures have been entirely destroyed by them, being rendered as completely brown, as if they had suffered a three months' drouth, and destitute of all vegetation, except a few thistles. A square foot of the dead turf being dug up, 210 grubs were counted in it; and what furnishes a striking proof of the prolific powers of these insects, last year it was difficult to find a single one."* "After mentioning their extensive devastations, it may occasion surprise," as Mr. Duncan well remarks, "to be told that many eminent observers are of opinion, that these maggots eat nothing but the fine mould they find at the roots of plants, and that the injury caused to the latter arises solely from their disturbing the soil, and preventing the rootlets fixing themselves. Such was the opinion of Reaumur: and the generality of subsequent writers on the subject have yielded to his authority. . . Mr. Stickney, who has published '*Observations on the Grub*,' made some experiments for the express purpose of determining this point, and they convinced him that the larvæ devour the roots of grasses. Indeed, unless this were the case, it would be impossible to account for the herbage withering to such an extent in places where the maggots prevail; for this could never arise from such small creatures, even though very numerous, burrowing in and loosening the soil. When earth-worms are plentiful, they must produce a considerable disturbance in the soil by their winding galleries; but these so far from retarding, have always been regarded as promoting the growth of plants. 'The grub of this tipula,' says Mr. Stickney, as quoted by Mr. Duncan, 'commits its ravages chiefly in the first crop, after the breaking up of the grass-land, also after clover and beans; the fly from which the insect is produced having deposited its eggs in the soil among the grass, clover, or beans. . . On investigating the habits of this insect, I found that it took the fly-state about the beginning of the month of August; I therefore concluded, as we got our clover-hay from the land a little after mid-summer that, if we plowed the clover stubble any time after that, and before the month of August, it would be nearly free from the grub, as instinct has directed the fly not to leave its eggs upon the naked soil where no vegetable is growing. I knew of no application to the land,' adds Mr. Stickney, 'that will in any way destroy the grub: but we are much indebted to the rook, and a variety of other birds, for keeping its depredations within limited grounds.'† The saturation of the soil," concludes Mr. Duncan, "with some caustic fluid, seems the only way by which this maggot can be destroyed. The perfect insects are easily caught; but they are so generally distributed, and usually so plentiful, that their destruction in this way would be a hopeless task."‡ The rook *(Corvus frugilegus)* may be seen busily engaged in turning over every loose turf clod on a grubbed field of oats, after the young crop has evidently assumed an unhealthy hue. This hue should not be mistaken for the yellowish tint exhibited by the plant when the support derived from the seed is exhausted, and before the rootlets have obtained sufficient scope in the ground to maintain the plant. The grub taint is of a bluish and reddish tint, and many of the plants evidently appear to be dying, and the consequence is, that large spaces are left without a plant. The usual expedient employed by the farmer is rolling the ground, especially in the night; but this is a useless remedy. Holes have been recommended to be made a few inches asunder with the dibble, into which the grubs, it is said will fall and perish; but why they should thus die when they can penetrate the ground, is what I cannot conceive. The ravages are generally committed in dry weather with an easterly wind, and when rain falls they cease. It is surprising how a field will recover from the effects of grubbing. One season a field of mine, of fine deep hazel loam, after two years grass, was dreadfully grubbed, and after trying the usual remedies to get quit of the insects without effect, a rainy night silenced them. Most of the field appeared bare after having exhibited a beautiful braird, but on the plants requiring renewed growth, they tillered out with great force, and covered the ground almost as thickly as desirable. At harvest the crop was a very strong one the straw being difficult for women to cut with a common sickle; the spikes were very large and full; the stooks, when set without hood-sheaves, stood about 6 feet in hight, and the yield was not less than 60 bushels to the imperial acre. On good soil I would have no fear of potato oats tillering out after being severely grubbed, sufficiently to afford a good crop; but such a result should not be expected of common oats upon inferior soil.

(1894.) [*Grain Drilling-Machines.*—The introduction of the drill-system into the agricultural practice of any country, will always form an era in the annals of its Agriculture: but it is often a difficult matter to define the precise time of its introduction, more especially when we find that, by tracing backward into the history of man in his social capacities, the practice of drilling grain extends backward to the most remote antiquity. A curious and interesting example of this, in an antiquarian point of view, is to be seen in the series of Hindoo models of agricultural implements in the Museum of the Highland and Agricultural Society in Edinburgh. Among them is to be seen a correct model of a rudely constructed drill-machine possessing all the essential points of the more elaborate modern implement; and among a people so little liable to change, there

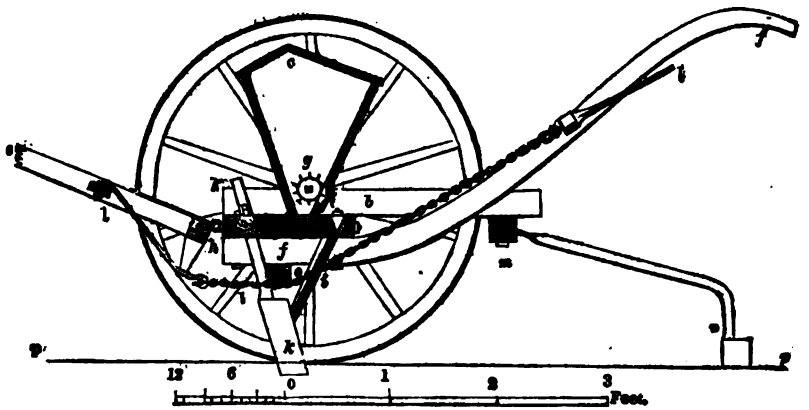
* Kirby and Spence's Introduction to Entomology, vol. i.
† British Farmer's Magazine, vol. vi. ‡ Quarterly Journal of Agriculture, vol. xi.

can be no doubt that the machine is of very remote origin, compared with which, the earliest of our modern drills are but things of the moment: and all of them, of whatever degree of merit, are but improvements on the Hindoo original. Among the early notices of the introduction of the system in England, we find Amos* recommending it as early as 1783 as the result of numerous comparative experiments; and the figures which he gives of the drill sowing-machine, which he recommends not as an original invention, but an amplification of that given by Duhamel, is almost identical in every essential point with the most approved drill sowing-machine used in the present day in England, and which may be held as the most perfect machine of its kind; but from the excessive elaboration employed in its construction, its high price lays an interdict upon its introduction into the economical practice of Scotch farming, the price being at least six times that of the common drill used in Scotland.

(1825.) The mode of distributing the seed adopted in the broadcast sowing-machine, from the simplicity of the principle, opened a ready means of acquiring a drill sowing-machine at a moderate price; it accordingly quickly followed the introduction of the broadcast-machine, and until very lately no change of importance has been made upon the common Scotch drill. Slight modifications, however, had been effected occasionally, such as varying the distance between the rows, the machine always covering the same breadth, but varying in the number of coulters. Thus, a machine to cover 7½ feet in breadth, could change the number of its coulters from 11 to 10, 9 or 8, the spaces between the rows being respectively 8, 9, 10, and 11 inches, or thereby.

(1826.) The *Common* or *East Lothian Drill Sowing-Machine*, has been here taken to illustrate the principles of the machine. Though it may be deficient in some points as compared with those of Berwickshire and Roxburgshire, yet its extreme simplicity and cheapness has brought it into

Fig. 329.



SECTION OF THE COMMON DRILL SOWING-MACHINE.

very extensive adoption, not only in East Lothian, but in other districts where the drill-system is followed. Fig. 325, Plate XXVII, is a view in perspective of this machine, and for the better elucidation of its construction, the annexed cut, fig. 329, shows the arrangement of the parts in longitudinal section, and for convenience of reference the letters mark corresponding parts in both figures. The figures represent a machine of six rows, which is the size most generally used, chiefly because it can be drawn by one horse; but also in the event of its being employed along swelling ridges, its covering but a small breadth secures a nearly equal depth for the deposition of the seed, which cannot be easily done under the same circumstances if the machine is mounted with a greater number of coulters. But it follows from the peculiarity of structure, the coulters being permanently fixed in position for the depth to which they penetrate the soil, that the machine is best adapted for sowing across the ridges, and hence it is almost invariably worked in that direction, though when worked in the direction of the ridge the breadth covered by the machine is equal to one-fourth of an 18-feet ridge.

(1827.) In the construction, *a* is a bed-plank 5 feet 1 inch in length, 14 inches in breadth, and 2½ inches in thickness. Across the ends of this are bolted the two side-bars *b b*, each 33 inches in length, 2½ inches in depth, and 2½ inches in breadth. These last are crossed by the bar *m m*, bolted to the side-bars, serving a special purpose, to be afterward noticed; and these four parts form the simple frame-work of the machine. The seed-chest *c* is 4 feet 8 inches in length, placed between the side-bars *b*, and attached to these and the bed-plank. The chest may be about 10 inches in depth, 2½ inches wide at bottom, and 15 inches at top, with a hinged cover. The chest, so mounted with the seed-wheels and axle *g*, fig. 329, and with side-plate, lever, and adjusting screw in all respects similar to the broadcast-machine (1801), except that, in place of the *apron* on which the seed falls in the broadcast, the orifices deliver the seed directly into a small hopper-shaped aperture formed in the bed-plank, immediately under the orifice *i*, fig. 329. The carriage-wheels *d d* are 3 feet 1 inch in diameter; the axle of one of them is seated in a strong bush or plummer-block, and coupled to the small shaft of the seed-wheels, thereby giving them the requisite motion, their revolution coinciding with that of the wheels, and the opposite wheel *d* turns.

* Theory and Practice of Drill-Husbandry. By William Amos, 1802.

upon an axle fixed permanently upon the bed frame. The horse-shafts *e* are jointed to the bed plank at *h*, and appear broken off at *e*, fig. 329, by strap-and hook hinges, and the handles *f f* are bolted to the lower side of the bed-plank. The coulters *k k* consist of an iron shank ¾ inch square, furnished at the lower end with a pointed sheath of sheet iron about 1-10 inch thick; the sides of this sheath, being about 3 inches broad, and 5 inches or more in hight riveted upon the bottom of the shank, which at this place is forged into a wedge shape, to receive the sheath. The coulters are fixed at top in mortises cut in the bed-plank, and fenced with plates of iron above and below, where they are secured by means of wedges; and they are farther supported by the coulter-bar *o*, seen in section in fig. 329. This bar is bolted under the heel of the handles, and to it the coulters are attached by eye-bolts. The seed on leaving the orifices, falls into the funnel-shaped receptacle *i* in the upper side of the bed-plank, from which it passes down the tube *i i* into the sheath of the coulter, by which it is deposited into the rut formed by the sheath.

(1828.) From the construction and action of this machine, and the resistance of the soil to the passage of the coulters through it, there is a constant tendency, produced by the traction of the horse when the machine is in action, to elevate the extremity of the handles; and by thus swinging upon the axle of the wheels the coulters are withdrawn from their action on the soil, and from forming the rut for the reception of the seed. The tendency thus produced being greater than a man is capable of continuing to contend with, is counteracted by the application of the balance-chain *l l*, as shown in fig. 329, producing a change of direction in the line of draught, and of the point of attachment of the draught. In this machine the true point of attachment is in the hinge *h*, fig. 329; and the tendency of the draught, when applied simply to this point, is to cause the point *h* to approach an imaginary straight line lying between the horse's shoulder and the point of resistance at lower *k* in the figure, and the effect of this is to bring *h* forward and downward, or to throw lower *k* backward till it loose hold of the soil, thereby destroying the intended effect of the coulter. The counteraction of this is effected by the position of the balance chain, and its attachments to the machine. The first part of it is a simple rod, fixed to the shafts at *l*, and to the extremity of a pendant attached to the hind bar of the shafts at *h*; the chain then passes under the coulter-bar *o*, and on to the cross-bar of the handles, as seen in fig. 325, Plate XXVII., where it terminates in a handle furnished with a spring-catch, by which it can be hooked under tension, to the cross-bar of the handles, or by disengaging the catch, the chain hangs loose. When the chain is brought under tension, and the shafts borne up by the horse, the resistance to the coulters is transferred to the back of the horse, through the medium of the chain acting on the shaft at the point *l*, and on the pendant *h*, the point of which being below the plane of the shaft, changes the direction of the tractive force from *e h* to *e* middle *l*, and leaves the handles in a nearly quiescent state. The marker *m n* is another appendage to the machine, which, although not so necessary as the balance-chain, is generally applied to this drill-machine, especially when sowing across the ridges. It consists of the bar *m m*, and the marking-rod *m n*. The latter is swing-jointed on a stud fixed in the ends of the marker-bar *m m*, and having a stop on the joint, by which either of the markers can be retained in the position of that on the farther side of fig. 325, or let down, as in that of the nigh side. The use of the marker is to trace a line on the surface of the ground parallel to the direction in which the machine travels, and at a distance from the middle point of the surface covered by the machine, equal to the entire breadth, so covered; hence, on returning to sow the next breadth, the horse should walk exactly upon the line drawn by the marker. In sowing with the machine here described, the distance from line to line will be 4 feet 6 inches; the distance between the rows being 9 inches. The wheels are usually set 54 inches apart, measuring at the point where they rest on the ground; or their distance in any machine may be found by multiplying the number of coulters by the number of inches given to the interval between the rows or coulters; thus six coulters of 9 inches interval, give $6 \times 9 = 54$ inches. From the construction of the machine it is found, that when the balance-chain is under tension, the coulters are drawn to the ground, and the handles also drawn downward; but on releasing the chain, which is done at the land-ends and turnings, the conductor must support the handles to keep the coulter from the ground, and in this state, if the handles are let go when the machine is standing, the coulter will pass forward and the handles will fall to the ground. To prevent this last inconvenience, a crutch is usually appended to the marker-bar, which, on stopping, is allowed to drop to a perpendicular position, resting on the ground, and thus keeps the machine upon a level. This appendage not being of much importance, is left out of the figure.

(1829.) This sowing-machine has been long and successfully manufactured by Scouler and Company of Haddington; and with slight variations by various other implement makers, as Morton, Leith Walk, Edinburgh; James Slight and Company, Edinburgh, &c. The price varies according to the number of coulters, from £6 to £10.

(1830.) To render the expensive English drill-machines [which we have omitted, and which cost in England from $50 to $90,] more generally useful, it is not an uncommon practice in England for the owner of one to travel the country with it at seed-time, and undertake to sow the fields of any farm, where the farmer may choose to employ him. The charge is usually 2s. 6d. per imperial acre, the farmer supplying the requisite number of horses to work the drill, and undertaking to deliver it at the farm on which it is to be next employed.

13. THE LAMBING OF EWES.

"Ah gentle shepherd, thine the lot to tend,
Of all that feel distress the most assailed,
Feeble, defenceless; lenient be thy care;
But spread around thy tend'rest diligence
In flow'ry spring-time, when the new dropt lamb,
Tott'ring with weakness by his mother's side,
Feels the fresh world about him; and each thorn,
Hillock, or furrow, trips his feeble feet:
O guard his meek sweet innocence from all
Th' num'rous ills that rush around his life."

DYER.

(1831.) The lambing season of Leicester and other heavy breeds of sheep, reared in the arable part of the country, commences about the 11th of March, and continues for about the space of 3 weeks. There is no labor connected with the duties of the shepherd which puts his attention and skill to so severe a test as the lambing season; and a shepherd whose unwearied attention and consummate skill become conspicuous at that critical period of his flock's existence, is an invaluable servant to a stock farmer—his services, in fact, are worth far more than the amount of wages he receives; for such a man will save the value of his wages *every year*, in comparison with an unskillful shepherd, and especially in a precarious season, by so treating both the ewe and lamb, during the time, and for some time after the lambing season, that the lives of many are preserved that would otherwise have been lost. To make my meaning more plain, suppose a shepherd that has attentively observed the tupping, and marked the reckoning of every ewe, and who has put the ewes in proper time in a suitable place to lamb in—that renders them requisite assistance, and no more, at the proper instant of lambing, and treats them afterward according to the circumstances of the weather—that sees the lamb supplied with milk by day and night, when its mother happens to be unkind to it, or feeds it with milk obtained elsewhere, when the ewe has too scanty a supply to support it—that knows how to afford relief to the ewe in case of sickness and inflammation after lambing, and who castrates the lamb at the proper period of its strength, and in the proper state of the weather—that knows the manner how, and the time when, to put an additional lamb to a ewe that has abundance of milk, and to take it from another which has too little for a pair—suppose that by doing all this in a skillful manner, night and day, until the lambing is not only entirely completed, but the lambs reared beyond danger, he saves the lives of 10 ewes worth 40s. each, and of 20 lambs, that will come to be worth 20s. each, and this is no extravagant supposition in a large standing flock of fifteen scores of ewes, it is clear that, in so doing, he will save his wages of £40. Few shepherds are so successful, although I have known two instances of such success; and no better proof need be adduced of the fewness of skillful shepherds, than the loss which every breeder of sheep sustains every year, especially in bad weather. I knew a shepherd who possessed unwearied attention, but was deficient in skill, and being over-anxious, always assisted the ewes in lambing before the proper time; and as he kept the ewes in too high condition, the consequence was, that every year he lost a number of both ewes and lambs, and in one season of bad weather the loss amounted to the large number of 26 ewes, and I forget of how many lambs, in a

flock of only 10 scores of ewes. I knew another shepherd who was far from being solicitous about his charge, though certainly not careless of it, yet his skill was so undoubted that he chiefly depended upon it, and his success was so eminent that the loss of a ewe or a lamb under his charge was matter of surprise. Of these two sorts of shepherds—the attentive and the skillful—it would appear that the skillful is the safer, and of course the more valuable, though it must be owned that it is better to *prevent* evils by skillful attention, than to *cure* them by attentive skill; yet it is only by the union of both these qualities that a perfect shepherd can be formed. In contradistinction to a skillful shepherd, whose qualifications have been just noticed, let me advert to a few particulars mentioned by Mr. Price as occurring, apparently as a matter of course, at the lambing season. He says that in preparing ewes for lambing, "the ewes are driven into a pound, and the looker takes them singly, *throws them down*, and removes with the shears the wool on their tail, udders, and inside of their thighs." If this is a common practice, think of its barbarity, of throwing down a ewe on the ground big with lamb, nay, on the eve of lambing, in order to remove a trifling impediment to the lamb's sucking, which can be removed at any time after lambing. But there is a reason, it seems, for this treatment, called *clatting*, and it is this: "The removal of the wool renders the part much *neater*,"—neatness of appearance being preferred at this particular time to the comfort and ease of the animal—"and enables the lamber to see *when the ewe has lambed*, from a stain which generally appears on the back part of her udder. Were *not* this appearance to take place, the *lamber would sometimes be at a loss*, as the young ewes frequently desert their young, and endeavor to escape along with the other ewes grazing with as much unconcern as if nothing had happened." Observe here the great skill and attention of a shepherd who is at a loss to know whether a ewe has lambed or not; and who, it seems, does not even know whether a ewe is in lamb or not, until he has thrown her down to remove the wool; for "the barren ewe, or those which are not pregnant, *are distinguished at the time of clatting* by not having any swelling in their udder or belly, and by their skipping about nimbly." Think also of what sort of care is bestowed on a newly lambed flock in a low country, when such losses as these are incurred: "I have known thousands of lambs lost from being drowned in a wet stormy night; I once beheld 30 or more lying together drowned in a ditch. The ewes and lambs seek the corners of pasture-fields during the continuance of severe weather, and when the lambs get under these high shores and fall in, it is utterly impossible for them to extricate themselves; besides, as there are many huddled together, they often push one another in." That lambing paddock must be strangely managed which presents such a scene as this: "Lambing presents a scene of confusion, disorder and trouble, which it is the lamber's business to rectify, and for which he ought always to be prepared: some of the ewes perhaps leave their lambs, or the lambs get intermixed, and the ewes which have lost their lambs run about bleating, while others want assistance." It seems a shepherd cannot recognize the lambs of ewes, and so they must be marked. "The twins are marked with a mixture of tar and lampblack, by means of small figures fixed in an iron handle about 8 inches long;" "and the twin lambs are easily separated, for the ewe very frequently walks away with one lamb, leaving the other in the field, *to the confusion of the lamber; therefore* they should be marked as early as possible to prevent this confusion." "The lamber must take the lamb to its mother, which he will find out by its number;" and yet the number, it seems, will not always enable the lamb to find out the mother; for "if the lamber

finds a young lamb, and is *not certain which may be its mother*, a circumstance which sometimes occurs when ewe's drop twins, and leave one of them, he may readily discover her by taking away the lamb she is fostering, and putting the doubtful one on in its stead, when she will display evident tokens whether it belongs to her." This method of trial and error the shepherd may have, of course, to put to every ewe before he discovers the true mother; for as he knows neither the mother nor the lamb, the lamb may chance to belong to a ewe which has a single lamb as well as to one which has twins, unless the single lambs are left unmarked; or, at any rate, he may present the marked and known-to-be-a-twin lamb to a ewe that has a single one, as readily as to one that has twins. It will excite no surprise to learn that with shepherds *so* wretchedly qualified for their profession as the above particulars show, in "most years not more lambs than one to each ewe" were obtained; and that out of 800 ewes of a certain flock only 100 pairs were saved, though it is stated by Mr. Price that with more skill afterward the number of pairs increased to 200. Here, then, is an instance where the improved skill of one man saved the lives of 200 lambs, which would come to be worth £200, equaling the wages of at least 4 good shepherds.* I would not have noticed these egregious blunders, said by Mr. Price to be committed by shepherds in a low country like Romney Marsh, in Kent, so prominently, had not Mr. Youatt adopted the sentiments of Mr. Price in the very particulars quoted above, in his excellent treatise on the history and diseases of sheep.† Were a shepherd of a Leicester flock in Scotland made aware that he was suspected of such ignorance of the nature of sheep he would be quite ashamed, and so would shepherds even of the hill country, who cannot have so intimate a knowledge of every individual of their flock, usually occupying a wide range of mountain land, as their brethren of the profession tending flocks within much more limited bounds.

(1832.) Before the season of lambing arrives, the shepherd should have a small field of 1 or 2 acres or a sheltered corner of a grass-field of like size, conveniently situated as near the steading as possible, fenced round with nets, and fitted up with sheds made of hurdles set up in the most sheltered part, against a wall or hedge, and lined in the inside and comfortably roofed with straw. Such straw-sheds form most comfortable places of refuge for ewes that may lamb in the night, or that have lambed in the day, and require protection from frost, snow, rain, or cold in the night, until the ewes are perfectly recovered from lambing, and the lambs sufficiently strong to bear the weather in the open field. The small hand turnip-slicer, fig. 245, will be found on such occasions a very convenient instrument, for cutting turnips in such turnip-troughs as fig. 225, for the ewes in the paddock, or in small boxes for them in the shed. Common kale or curly-greens is excellent food for ewes that have lambed, the nutritive matter of which, being mucilaginous, is wholly soluble in water, and beneficial in encouraging the necessary discharges of the ewe at the time of lambing. According to the late Geo. Sinclair, 1 lb., or 7,000 grains of green curled kale, (*Brassica oleracea viridis*,) yields 5,680 grains of water, 880 grains of wood fibre, and 440 grains of nutritive matter, which last is all soluble in water.‡ In these respects kale is better food for ewes *after* lambing than Swedish turnips, which become rather too fibrous and astringent in spring for the secretion of milk. A large lantern which sheds plenty of light is an essential article of furniture at night to a shepherd. As foxes are apt to snatch away young lambs at night even close to the lambing-houses, I have found

* Price on Sheep. † Youatt on Sheep.
‡ Sinclair's Hortus Gramineus Woburnensis; edition of 1824.

an effectual preventive to their depredations in setting a shep-net, as in fig. 217, in front of the lambing-houses, leaving a sufficient space for a few ewes with their lambs taking up their lair within the net. When thus guarded, the foxes are afraid to enter the net, being apprehensive that it is set as a trap to ensnare them. Such an expedient is even more necessary in the corner of the field chosen for the lambing-ground. A large lantern fixed on a stake within the lambing-ground, and so placed as to throw light upon the whole ground, will be found a useful assistance to the shepherd in showing him the ewes that evince symptoms of lambing. A net and lantern are also good safeguards against foxes at night in the grass-field where the recovered ewes with their lambs should be gathered for the night. This expedient of net and lantern I was induced to try after losing, for a year or two, several lambs by the fox; and such was its efficacy in deterring that nightly prowler from visiting the lair of ewes and lambs, that not a lamb was lost ever after. A fox will not meddle with a lamb above a month old.

(1833.) Being thus amply provided with the means of accommodation, the shepherd, whenever he observes the predisposing symptoms of lambing in as many ewes as he knows will lamb first—and these symptoms are, enlargement and reddening of the parts under the tail, and drooping of the flanks—he places them of an afternoon, within the enclosed lambing-ground in the paddock or field, as described above, and provides them with cut turnips. The more immediate symtoms of lambing are when the ewe stretches herself frequently; separating herself from her companions; exhibiting restlessness by not remaining in one place for any length of time; lying down and rising up again, as if dissatisfied with the place; pawing the ground with a fore-foot; bleating as if in quest of a lamb; and appearing fond of the lambs of other ewes. In a very few hours, or even shorter time, after the exhibition of these symptoms, the immediate symptom of lambing is the expulsion of the bag of water from the vagina, which, when observed, the ewe should be narrowly watched, for the pains of labor may be expected to come on immediately. When these are felt by her, the ewe presses or forces with earnestness, changing one place or position for another, as if desirous of relief. Up to this time, not a hand should be put upon her, nor until the hoofs of the fore-feet of the lamb, and its mouth lying upon them, are distinctly seen to present themselves in the passage.

(1834.) The natural presentation of the lamb is the same as that of the calf, described in (1653). When time has been given to observe that the ewe is not able to expel the lamb by her own exertions, it is the duty of the shepherd to render her assistance, before her strength fails by unavailing pressing. The exact moment for rendering assistance can only be known by experience; but it is necessary for a shepherd to know it, as there is no doubt that hasty parturition often superinduces inflammation, if not of the womb itself, at least of all the external parts. When assistance should be rendered, the ewe is laid gently over upon the ground on her near or left side, and her head a little up the hill; and to prevent her being dragged on the ground when the lamb is being extracted, the shepherd places the heel of his left foot against the belly of the ewe, and kneels on his right knee on the ground across the body of the ewe, which lies between his heel and knee, with his knee pressing against her rump. Having both his hands free, and his face toward the tail of the ewe, he first proceeds to push out *from* him, with both hands, one leg of the lamb and then the other, as far as they will go; then seizing both legs firmly, above the fetlock joints, between the fingers of his left hand, he pushes them from him downward from the ewe's back, with considerable force, while by

pushing in the space between the tail of the ewe and the head of the lamb *toward* him, with the side of his right hand, he endeavors to slip the the vulva of the ewe over the cantle of the lamb. These pushes are only given simultaneously with the pressing of the ewe, merely to assist her, and keep good what is obtained at each pressing, and not, as it were, to tear the lamb from her per force. Whenever the head is cleared, the shepherd seizes the neck of the lamb behind the head with the right hand, and pulls out the body. The lamb is then placed at the ewe's head, for her to lick and recognize, which she will instantly do, if her labor has not been severe; but if it has she will likely become sick, and be careless of the lamb as long as the sickness continues, which is evinced by quick breathing. If the pains have been very sharp, and thisher first lamb, and she is not overcome by sickness, she may start to her feet, and run away from the lamb. The attempt should, of course, be prevented, and the tail of the lamb put into her mouth to make her notice it. While still lying on her side, her abdomen should be felt, to ascertain if there is another lamb to come; and if there is, the pains accompanying its passage may have been the cause of her carelessness for the first lamb; and if the second one is in natural position, it will most probably by this time be showing itself in the passage, and if this be the case, the best plan is to take it away in the same manner as the first, and the ewe feeling the attempt, will at once assist on her part by pressing. The existence of a second lamb is worth attending to on another account, inasmuch as some ewes become so engrossed with the first lamb, that the pains attending the second are neglected by them, and they will indicate no signs of it for a time. When a second is found in her she must be watched, that whenever it comes into the passage, it may be taken away; but unless it actually makes its appearance there, it should not be attempted to be taken away. Should it not make its appearance in a reasonable time, it may be suspected that the lamb is either dead, or not in a natural position, and examination should be made by the fingers into the state of the case. A dead lamb is easily known by the feel, and should be extracted immediately, as it can afford no assistance of itself; but should the lamb be alive, it may be necessary to introduce the hand to ascertain its position. Before the hand is introduced, it should be smeared over with goose grease. If the head is bent back, it must be placed straight, or if one leg or both be folded back, they must be brought forward, one by one, into the proper position. In short, all the presentations offered by a lamb require the same means to be used to place them in a proper position, as in the case of a calf; but with a Leicester ewe there is the additional difficulty of two, and even more, lambs at a birth, and mistaking a leg of one lamb for that of another. The method of extracting a lamb as described above, is adopted by a shepherd who has no assistants; but when he has assistance, he adopts another and more easy plan for himself. The assistant holds the ewe in any way the most easy for her and himself, so as to prevent the body being dragged along the ground while the shepherd is extracting the lamb, which he does by placing himself behind the ewe, and performs the extraction by pulling the legs *toward* him, while the assistant endeavors to make the vaginal skin pass over the lamb's head, which, when accomplished, the shepherd seizes the neck by his left hand, and holds the legs still in his right, takes away the lamb as quickly as he can, and places it before the ewe. There is a great difference in the disposition of ewes to assist in lambing. Some, when they find they are assisted, give themselves little trouble; while others press with vigor from first to last; and others only press at long intervals. A ewe that presses strongly and continuously, will become sooner exhausted than one that

takes more leisure, and in the former case the
ing to make examination of the presentation
ewe has become exhausted. I remember of s
any of the legs protruded by the ewe, and, be
state too long, the lamb was found strangled
pressing. This was a case of neglect, as the

Indeed, it is a good plan for a shepherd to gi

in this way, as it not only saves it much trouble, and puts it in the way of gaining strength rapidly, but affords himself a favorable opportunity of examining the state of the udder, whether it is in a proper state for yielding milk, or feels hard, or is inflamed. The proper treatment of the udder when in an inflamed state will be found below. Gimmers have so scanty a supply of milk that it is expedient for the shepherd to support their lambs partially on cow's milk, until they can afford the requisite supply, which will be induced partly by suckling, and partly from new grass. When the shepherd has lambs to support for a short time, he should supply them with milk at regular times, such as in the morning and evening, and see that the lambs are suckled by their mothers during the day, and thus endeavor to bring on a sufficiency of milk. The dairy-maid should put the cow's milk for the shepherd in bottles, at the hours when the cows are milked, in the morning and evening, and he administers it to young lambs while warm from the cow, and it is done in this way: Sitting down, let him take a mouthfull of milk from a bottle, and holding up the open mouth of the lamb, he pours the warm milk into it in a small stream from his mouth; and thus mouthfull after mouthfull until the lamb is filled. This auxiliary supply of milk should be withheld the moment the ewe can support her lambs herself, for cow's milk is not so congenial to a lamb's constitution as that of its own mother. The ewes are kept on the lambing ground till they have completely recovered from the effects of lambing and the lambs have become strong, and the ewes and lambs have become well acquainted with each other. The time required to accomplish this depends on the nature of the lambing, and the state of the weather. The ewes, with their lambs, are then put into a field of new grass, where the milk will flush upon the ewes, much to the advantage of the lambs. It is generally a troublesome matter to drive ewes with young lambs to any distance to a field, because of the ewes always turning round and bewildering the lambs. A dog more frequently irritates the ewes than assists the shepherd in this task. I believe the best plan is to lead the flock instead of driving it, by carrying a single lamb, belonging to an old ewe, by the fore legs, which is the safest mode of carrying a lamb, and walking slowly with it before the ewe, while she will follow bleating close at the shepherd's heels, and the rest of the ewes will follow her of course. If the distance to the field is considerable, the decoy lamb should be set down to suck and rest. With plenty of food, and a safeguard of net and lantern at their lair at night, to keep off the foxes, the flock will not fail to thrive apace. In case this safeguard is not adopted, and which I believe is rare, it may be proper to tell you the distinctive marks of the attacks of a dog from that of foxes on a lamb flock. The fox always attacks a lamb on the neck behind the head, and, if scared from his purpose, distinct holes made by the teeth will be found on each side of the neck, whereas a dog seizes any part of the body, and worries by the under part of the neck. Some ewes will fight off either dog or fox, and be able to protect a single lamb; while others become so frightened at once from an attack, that they do not know whither to flee for refuge. After such an attack, the bleatings of the ewes and lambs in search of each other, which is an unusual occurrence at night, will soon acquaint the shepherd that some disaster has happened to his flock. The fox, if not immediately disturbed, carries off his prey, while the dog worries and leaves behind him what he does not eat.

(1836.) All the preceding cases of lambing are easy to the shepherd, but others usually occur which put his skill to the test. Malformations of the body of the lamb create difficult parturition, and endanger the life of

the ewe. It is almost impossible to bring the head of a wry-necked lamb into the passage of the womb, but it must be done before the entire body can be extracted, and if not, the head of the lamb should be taken off rather than the ewe should lose her life. Sometimes twin lambs die in the womb several days before the period of lambing, and as they cannot present themselves to the birth, they must be extracted by force, or even cut away in pieces, or they may be pulled away in pieces. In such a case the placenta will be corrupted, and it may be a considerable time before it is entirely got rid of by the ewe by pressing. I have seen it so corrupted that it came away in discharges from the ewe as black and as viscid as tar. When twins are about to be lambed, the only care required is to ascertain that each is presented separately. A breech presentation is a difficult one, and the extraction is impracticable until the hind-legs are first brought out; and in extracting by the breech, the operation should be done quickly at the last to prevent the lamb drowning in the liquor amnii. In all cases of extraction, it should be made a point to have the back of the lamb next to the back of the ewe.

(1837.) Much trouble is experienced by shepherds when ewes will not take their own lambs. A ewe that beats off her own single lamb and endeavors to purloin one from another ewe, should be immediately put into the shed and confined to a spot by a short string tied above the fetlock joint of one of her fore-legs to a stub driven into the ground. When she endeavors to leave her lamb, the string pulls her foot off the ground, and while her attention is taken up with the string, the lamb seizes the teat and sucks in the mean time. The stratagem often repeated takes the courage from her, and makes her take with the lamb. In every case of a ewe refusing to let her lamb suck, the shepherd should particularly examine the udder, and see there is no inflammation or uneasiness in it; and if there is, he should endeavor to remove it before putting the ewe under discipline. It is surprising how soon a lamb learns to steal a suck from a ewe; if it cannot approach by the flank, it will seize the teat from behind between the hind legs. When a ewe will allow but one of her twins to suck her, she should be held till both suck her, and in a little time she will take with both. It is not surprising that one ewe should refuse to take the lamb of another; and yet it is necessary when a lamb is left an orphan, or is a supernumerary, to *mother* it, as it is termed, upon another ewe. For example, when a gimmer that has little milk has twins at a time when another ewe that has plenty of milk produces a single lamb, it is for the benefit of both ewe and lamb that the ewe which has plenty of milk should bring up two lambs; and the transference is easily enough accomplished while all the lambs are still wet, and two of them are placed before the ewe at once; but when a ewe does not die till two or three days after she has lambed, it will be difficult to make another ewe that lambs a single lamb, as the other ewe dies, take the older lamb along with her own. The usual plan in such a case is to rub the body of the older lamb with the new dropped one, before the new lambed ewe has had an opportunity of recognizing her own lamb, and to place both before her at the same time; and she *may* take both without scruple; but the probability is that she will reject the older one, when she should be put into a dark corner of the shed and confined in it by a board placed across the corner, only giving her room to rise up and lie down, and to eat, but not to turn quickly round upon the stranger lamb, which, rubbing against her wool, and sucking her against her inclination, will soon acquire the odor of her own lamb, and ingratiate itself in her favor. Another case of difficulty is when a twin lamb dies at birth from a ewe that has plenty of milk, while

another ewe has had twins and is unable to support them; and the expedient is to strip the skin immediately off the new-born dead lamb and sew it on the body of one of the lambs belonging to the other ewe, and present both the foster-lamb and her own at the same time to the ewe that has plenty of milk. It is probable that the dark corner will require to be used before a cordial reception is given to the foster-lamb. Should all the above expedients fail to *mother* the lambs upon the ewes—and they *may* fail, though under the guidance of a skillful shepherd they seldom do—the lambs should be taken away and brought up as *pets* on cow's milk.

(1838.) The lamb of a *fat* ewe is always small when lambed, and is plump and lively, but the ewe in that state runs a great risk in lambing of inflammation in the passage of the womb. A *lean* ewe bears a lamb large in the extremities, and thin and weak in the body. A very *old* ewe's lamb is both small and weak. The lamb of a gimmer is small, and she not having sufficient milk to rear it, continues small; and the lamb of a hogg is still worse off. The best plan of managing ewes for rearing good lambs, is to keep them always in fair condition in winter, and until they have lambed, after which event they should have the best grass the farm can afford. New grass always produces abundance of milk, and it springs earlier than old. In case of snow covering the ground in spring, when the ewes are heavy in lamb, they should get a few turnips and plenty of hay, and clover-hay if possible, until the ground is again clear; but in open weather in winter, there is nothing better for them than grass which had been kept rough for the purpose in autumn. While confined on the lambing-ground, ewes should have turnips and hay to support them; and after lambing there is nothing better for them than cabbage or kale, in default of which a little oil-cake will encourage, at that time, the necessary discharges and purify the body. New grass also operates medicinally on the system.

(1839.) It is necessary to say a few words on the rearing of *pet lambs*. Wherever these are there must be orphans or supernumeraries in the flock, and, in either case, the deserted creatures would die were they not reared by hand. As a remarkable instance of lambs being obliged to be made pets from supernumerary births, I remember one season, in a small flock of Leicester ewes, 50 in all, 48 having twins, and two trines. The two lambs which constituted the trines were properly taken away to relieve the ewes, and brought up by hand as pets. When ewes die it is scarcely possible avoiding having pets, on account of the improbability of ewes lambing single lambs just in time to receive those that have become orphans. Pet lambs are supported on cow's milk, which they receive warm from the cows each time they are milked, and as much as they can drink. In the intervals of meals, in bad weather, they are kept under cover, but in good weather they are put into a grass paddock during the day, and under shelter at night until the nights become warm. They are fed by hand out of a small vessel, which should contain as much milk as is known each can drink. They are first taught to drink out of the vessel with the fingers like a calf (1683), and as soon as they can hold a finger steady in the mouth, a small tin tube, about 3 inches in length, and of the thickness of a goose quill, should be covered with several folds of linen, sewed tightly on, to use as a substitute for a teat, and by which they will drink their allowance of milk with great ease and celerity. A goose quill would answer the same purpose, were it not that it is easily squeezed together by the mouth. When the same person feeds the lambs—and this should be the dairy-maid—the lambs soon become attached to her, and would follow her everywhere; but to prevent their bleating, and to make them

contented, an apron or a piece of cloth, hung on a stake or bush in the paddock, will keep them together.

(1840.) A very common method practiced by shepherds of Leicester sheep, when they wish to catch a ewe to give a weakly twin lamb a suck, or to examine the state of her udder, is to stoop down and run in upon her from behind and seize her by a hind leg. This is a safe enough mode of catching a sheep when dexterously done; but when it fails, that is, when the captor cannot keep himself out of view until he seizes the ewe, she will start and run off, and alarm the other ewes beside her, and every alarm to a ewe, whether lambed or about to lamb, is injurious, and at any rate cannot do any good. In these circumstances, a *crook* does the same thing more quietly and as securely. It consists of a round rod of iron, bent in the form shown in fig. 325, furnished at the point with a knob, that the animal may not be injured by a sharp point, and at the other end with a socket, which receives a long shaft of wood, 5 or 9 feet long, according to fancy. The hind-leg is hooked in at *a*, from behind the sheep, and it fills up the narrower part beyond *a*, while passing along it until it reaches the loop, when the animal is caught by the hock, and when secured its foot easily slips through the loop. Some caution is required in using the crook, for should the sheep give a sudden start forward to get away, the moment it feels the crook, the leg will be drawn forcibly through the narrow part, and strike the bone with such violence against the bend of the loop as to cause the animal considerable pain, and even occasion lameness for some days. On first embracing the leg, the crook should be drawn quickly toward you, so as to bring the bend of the loop against the leg as high up as the hock, before the sheep has time even to break off, and being secure, its struggles will cease the moment your hand seizes the leg.

Fig. 325.

THE SHEPHERD'S CROOK.

(1841.) When those male lambs which are not to be kept as tups attain the age of from 10 days to a month, they are *castrated*. Some breeders advocate castration in a day or two after birth, while others will not allow the operation to be performed until the lamb is one month old. My opinion is, that both these periods are extremes. A lamb of a day old cannot be confirmed in all the functions of its body, and indeed in many instances I question whether the testicles can then be found. At a month old, on the other hand, the lamb may be so fat and the weather warm, that cutting may be attended with febrile action. I prefer the operation being performed at from 10 to 15 days, when the creature has attained some strength, and yet its parts have not yet become rigid. Castration is performed in this way. Let the assistant hold the body and both legs, one in each hand, as represented in fig. 326. The shepherd then causes the testicles to press the scrotum *a* smooth; and making an incision through the integuments of the scrotum to the testicles, he pushes out one testicle farther than the other, seizes it with his teeth and draws out the spermatic cord until it breaks, and does the same with the other testicle, when the operation is finished. Advantage is taken of the opportunity to dock the tail, which is left at *c* as long as to reach to the meeting of the hams. In performing docking, the division should be made in a joint, otherwise the portion of the vertebra which has been cut through will have to be sloughed off before the wound can heal. Ewe lambs are also docked at this time, but they are not held up for the operation, being merely caught

and held until it is done. In England, docking is performed at the third joint, which leaves a mere stump of a tail. The male lamb, after being docked, is let down to the ground by the tail, which has the effect, it is said, of righting the parts about the scrotum after castration. The same opportunity is taken to mark the ears of lambs, and in the case of stock in hill farms, where it is not easy to gather flocks frequently, the operation is now easily performed; but as Leicester lambs are not marked in the ear at this time, I shall defer describing that operation until its proper season in summer. The scrotum does not bleed in castration, but the tail sometimes bleeds for a long time in two minute and forcible streams, though usually the bleeding soon stems. Should it continue so long as to sicken the lamb, a small cord should be tied firmly round the end of the tail, but this must not be allowed to remain on above 24 hours, as the point of the tail would slough off. The object of docking is to keep the sheep behind clean from filth and vermin; but as the tail is a protection against cold in winter, it should not be docked too short, as is the case in England. Tup-lambs are allowed to retain their full tails until a year old, in order to strengthen the back. Great caution is required in castrating lambs; it should not be done in rainy weather, nor in very cold weather, nor in frost; nor should the lambs be heated before the operation. It is best performed early in the morning, in fresh weather, with a westerly breeze. The ewes and lambs should be driven gently to a corner of the field, but not by the dog, whose duty is only to prevent a ewe breaking away. One assistant should catch the lambs, and another hold them while the shepherd operates. It is not easy to catch a lamb with a sheep's crook, their small, active limbs easily escaping from the loop, but it may be effectually used in hooking the neck, when the captor runs in upon the lamb and secures it. Where there is a bught or open shed in a field, the lambs and ewes may be driven loosely in, and the lambs captured there. The old-fashioned mode of castrating lambs is to cut off the point of the scrotum and extract both testicles by the large incision; but the extensive wound thus made takes a considerable time to heal, whereas the simple incision now made heals almost always by the first intention. In some cases, however, inflammation ensues, and the scrotum swells, and even suppurates, when the wound should be carefully examined, the matter discharged, and the wound soon heals up. The operation should always be done in the morning, that the several cases may be observed during the day; and should the weather have changed for the worse toward the afternoon, the ewes, with the lambs that have just been cut, should be brought into shelter all night. Besides the state of the weather, one cause of inflammation is the scratching of the wound of the scrotum by the points of the stubble among the new grass, and this irritation is most likely to be induced when the castration has been performed by cutting off the point of the scrotum. To avoid this source of irritation, the new cut lambs should be put into a field of new grass where the stubble is short, or into a field of old grass for a few days. Hill lambs should be driven the night before being castrated into a bught or inclosure where they will be ready and cool for the operation in the

Fig. 326.

THE CASTRATION OF LAMBS.

morning. The practice of applying turpentine to the incision on the scrotum gives unnecessary pain and serves no good purpose. Sometimes one of the testicles does not descend into the scrotum, in which case the lamb becomes what is called a *chaser*, that is, one who constantly chases the females of the flock, when near him, from morbid desire.

(1842.) These are the various risks which ewes and lambs are subject to, until they may be said to be beyond danger; and when they have passed through these several trials in safety, the shepherd may calculate on the result of his success—he may then endeavor to ascertain whether he has increased the breeding part of his flock in the proportion it should have increased. He should not be satisfied with his exertions, unless he has preserved one-half the number of ewes with twin-lambs, nor should he congratulate himself, if he has lost a single ewe in lambing. I am aware these results cannot always be commanded, but I believe an attentive and skillful shepherd will not be satisfied for all his toil, night and day, for three weeks, if he has not attained these results. The ewes may have lambed twins to greater number than the half, and yet many pairs may have been broken to supply the deficiencies occasioned by the deaths of single lambs. The death of single lambs is a vexatious matter to a shepherd, as it not only breaks his pairs, but imposes very considerable trouble on him in *mothering* the severed twins upon other ewes; and yet the trouble must be undertaken to retain the ewes that have lost their lambs in milk, and so maintain them in proper condition for future years. In fine, steady weather, the shepherd proceeds with his labor in comparative ease; but when stormy or wet weather prevails, or comes at unexpected intervals, the number of lambings are not only accelerated, but every ewe most probably creates some trouble even in the day time. True, "daylight has many eyes," and permits him to observe many casualties in time to remedy their effects; but at night, in bad weather, with glimmering light, difficulties increase tenfold, and so sensibly have I witnessed these difficulties myself, I am convinced every farmer of a large flock would find it repay it at the end of the lambing season, in the increased number of preserved lambs and ewes, to afford the shepherd assistance *at night* in the most busy period of the lambing season, according to the circumstance of the case. In regard to Cheviots, it is considered a favorable result to rear a lamb for each ewe; and with Black-faced ewes, 18 lambs out of the score of ewes is perhaps one as favorable. Cheviots yield a few pairs, Black-faced very few. The former sometimes require assistance in lambing, the latter seldom.

(1843.) The state of the new grass-fields occupied by ewes and lambs requires consideration. Ewes bite very close to the ground, and eat constantly as long as the lambs are with them; and as they are put on the new grass in the latter part of March, before vegetation is usually much advanced, they soon render the pasture bare when overstocked, and the weather is unfavorable to vegetation. In cold weather in spring, bitten grass soon becomes brown. Whenever the pasture is seen to fail, the ewes should be removed to another field, for if the plants are allowed to be bitten into the heart in the early part of the year, the greater portion of summer will elapse ere they will recover from the treatment. In steady growing weather there need be little apprehension of failure in the pasture. The sown pastures consisting chiefly of red clover and rye-grass, the clover is always acceptable to sheep; and in the early part of the season young shoots of rye-grass are much relished by ewes. On removing the stock from the first to the second field, it is better to eat the first down as low as it safely can be for the plants, in order to *hain* it, that is, to leave

it for at least a fortnight, to allow the young plants to spring again with vigor, and which they will do with a much closer bottom than if the field had been pastured for a longer time with fewer stock. Such a field eaten down to the end of May or beginning of June, and allowed to spring afterward in fine growing weather, will yield a much heavier crop of hay than if it had not been depastured in spring at all. Although the whole breadth of young grass on a farm pastured lightly with ewes and lambs in the spring were to grow, as the season advances more rapidly than the ewes could keep it down, it will never produce the fine, sweet, fresh pasture which field after field will yield that has been eaten down in succession, and then entirely hained for a time. But in removing ewes and lambs from a short to a full bite of grass, considerable caution is requisite in choosing the proper time for the removal. It should be accomplished in dry weather, and in the afternoon; because, continued damp or rainy, or cold wet weather, renders new grass so succulent and fermentable as almost certain to produce the *green skit* in lambs that are put upon it, although the damp weather should increase the ewes' milk.

(1844.) Carse farms have neither a standing nor a flying stock of ewes, and consequently, have no lambing season; neither have farms in the neighborhood of large towns, nor dairy farms, nor pastoral ones for the breeding of cattle; so that ewes and lambs are only found on pastoral farms that are devoted to the breeding of sheep, or on farms of mixed husbandry. But pastoral farms rear breeds of sheep very different in their nature from the breed, the management of which, I have described. On our hills, the Cheviot and Black-faced, or Heath sheep, were long the only inhabitants, but now the valuable Southdowns are added to the list. The Cheviot and Southdown range along semi-upland green mountain pastures, such as the Downs and the green hills of Cheviot, in England, and the green hills of Ochils, Sidlaws and the Lammermuir group, which stretches across the south of Scotland; while the Black-faced roam on the highest mountains, not only as far as a plant of heath can grow, but even beyond it, in the regions of the cryptogamiæ.

(1845.) In as far as the assistance of the shepherd is required to be given to ewes in the act of lambing, the observations I have made in reference to the lambing of Leicester ewes will apply to those of the Cheviot, Southdown and Black-faced breeds; but the ewes of these breeds do not require assistance nearly to the same extent as Leicester ewes, the lambs of the latter being generally larger in proportion to the ewes, and they are more square-built in form. Single lambs of the other breeds are generally brought forth without any assistance, and twin-lambs are so few that the ewes bearing them may be singled out for remarkable attention. A Cheviot single lamb soon gets on foot after being lambed, and its acute instinct as soon directs it to the teat. The Black-faced lamb is fully more active after being dropped, gaining its feet in a few minutes, and its rough coat of wool serves to protect it at once from the weather. Placed in shelter derived from one of the many natural inequalities of the ground common in a pastoral country, both these breeds may easily be tended in the lambing during the day; but the constant attention required of the shepherd limits his ability to superintend, at this particular period, a lambing flock beyond a certain number; 400 ewes are as many as one shepherd can superintend in the course of the day, to render them the assistance they may stand in need of; to see that the new lambed ewes and lambs are placed in shelter until they have both perfectly recovered, and are able to take to the pasture; and, in case of bad weather, to see that the ewes are supplied with some turnips and hay, to enable them to support their lambs until the weather becomes favorable. If one shepherd fulfills these duties in the day, he does quite enough, so that it will be necessary to have an assistant for him in the night, to see that the ewes are gathered into the shelter at nightfall, and to take a weakly lamb, or all the lambs that have dropped during the night, into sheds erected on purpose as a protection against bad weather. To ascertain the state of his flock, he should go through them with a lantern, at least every two hours, and oftener if necessary. Lord Napier recommends the construction of a "*lambing park*," for the use of ewes, and gives the cost of making one to comprehend 25 acres of ground, which shall accommodate 200 ewes, with 2 stells and 2 stell-houses, and hay-racks, at £90, which, at 7 per cent. interest, with repairs of racks, &c., will incur an annual cost of £7 5s. 8d. for sheep.* Such a place of shelter and of inclosure would, no doubt, be useful to a certain extent, but only to a limited extent: for such a park can only be in one part of the grazings, where at times it will no doubt be exposed to the weather, and as 25 acres would only contain 1-5 of the flock at a time, in stormy weather the rest of the flock, whether already lambed or yet to lamb, require shelter as well as ewes expected to lamb; and the dividing of the flock every day to get the 200 ewes with their lambs out, and other 200 driven in, would make a serious commotion among them at a very critical period of the ewes. I cannot help thinking that a chosen spot selected to afford shelter, according to the circumstances of the weather, to all the ewes yet to lamb within a given time, and where they could be partly supported on artificial food, while those which have lambed could occupy at night a sheltered part of the best portion of the pastures, would disturb lambing ewes far less than a lambing park which was not constantly occupied by all the ewes. It should be remembered that hill sheep cannot be so easily shifted from one place to another as Leicester sheep, and especially in a grazing which has few or no inclo-

* Napier on Practical Store Farming.

sures. Small pieces of English blanketing, to be kept dry when not in use, to wrap round and keep warm a weakly lamb in the shed, until it has recovered by the effect of its mother's milk, or by warm cow's milk administered by the shepherd, will be found a useful article by every shepherd, and may be the means of preserving the life of many a lamb. Many a lamb I have seen recruited by this means, when it would have otherwise perished of inanition. The period of lambing, in hill sheep, is longer than that of Leicester, because the gimmers are not tupped in the autumn until a fortnight after the ewes, and, of course, do not begin to lamb in the spring until a fortnight later. The ewes begin to lamb about the 20th April, and the gimmers a fortnight after. To strengthen the gimmers, and to bring a flush of milk upon them, they are separated from the ewes about a month before *their* lambing time, and are supplied with turnips to the amount of a double horse-load, say 15 cwts., to every 100 or 120 gimmers. About a fortnight before the ewes lamb, they get the same quantity of turnips for every 160 ewes. In mountain farms, where there are no turnips, hay should be supplied in the same manner to gimmers and ewes. A quantity of hay, expended at this time, will be more than repaid in the safety of lambs and vigor of ewes, especially in unfavorable weather.

(1846.) These few observations of Mr. Little on the qualifications of a *hill shepherd*, are worth your attention, as containing much good practical sense and truth. "Much," he truly says, "of the success in sheep-farming depends on the skill and application of shepherds, as well as on the judgment of farmers. As the situation of a shepherd is one of considerable trust, he ought to be honest, active, useful, and of a *calm temper*; for if at any time a shepherd gets into a passion with his sheep, it is attended with great disadvantage in herding, or in working among them. I have known a hasty, passionate man, with a rash dog, give himself double the trouble in managing a hirsel of sheep, besides abusing the sheep, that a calm, good-tempered man, with a sagacious, close-mouthed dog, would have had in the same circumstances. The qualification required in taking care of a hirsel of sheep, is not in running, hounding and training dogs, nor in performing a day's work of any other kind; but to direct them according to the soil, climate, and situation of the farm, in such a manner as to obtain the greatest quantity of food at all seasons of the year. Their health and comfort should be carefully loooked after by the shepherd; and if his exertions are made with judgment, they are of very great consequence to the farmer. It is not by walking much, and doing a great deal, that a shepherd is a good one; but it is knowing *where* to walk, so as to disturb the sheep the least, and by doing at the time whatever is necessary to be done. There is not an experienced shepherd who has been any length of time on one farm, who does not, as soon as he rises in the morning, and observing the state of the weather, know almost to a certainty where to find every sheep on the hill, and will accordingly take his course to the places he knows his presence is most wanted. The object in looking over a hill every evening and morning is to ascertain if there be no trespassers nor diseases among the sheep which require looking after. If any of your own or neighbor's sheep have trespassed, it is very foolish to dog or abuse them, for the more gently you can turn them back the better. If the boundary should be on the top of a hight, to which sheep are apt to draw at night, it is better to turn your own a little closer to the boundary in the afternoon, than to turn back your neighbor's; and it will answer the same purpose; and if the two flocks are gently divided in the morning without dogs, they will become so well acquainted with their own side that at the very sight of the shepherd they will take to it without farther trouble. Those shepherds who dog, force and shed much about a march, I consider them as bad herds for their masters as for the neighboring farmer. If the boundary be a brook or low ground, where the sheep graze in the middle of the day, and if trespassers are likely to be considerable, the same plan of turning the sheep should be taken as on the hight, except that they are to be turned down in the morning, and set out in the afternoon. When a sheep dies on the hill, or any disease appears among them, the dead or diseased sheep should be removed immediately, but particularly so if the disease appears of an infectious nature. Looking regularly over a hill is of great consequence, also, in case of any sheep falling into a ditch, or lamb losing its mother, or when they are annoyed by flies or maggots, or by foxes or dogs worrying them, or when they fall on their backs and cannot get up again. All these incidents an active shepherd with a good eye will soon discover, however much a flock may be scattered over a farm. . . . . In good weather the shepherd may possibly do all that can be done among the ewes in the lambing season; but in bad weather it is the farmer's interest to afford every necessary assistance, for the want of which serious losses have often been incurred. . . . . Knowing sheep by head-mark often saves a shepherd much trouble, particularly in the lambing season, and at all sortings of the sheep; yet there are many good shepherds who do not know sheep by head-mark, and there are some very ordinary ones who have a talent in that way. Every individual may be known by the *stock* mark. To possess the knack of *counting* sheep readily is of no small service to the shepherd, for he ought always to be able to count his flock when he makes his rounds on the hills. There are few shepherds who accustom themselves to count sheep, who cannot, wherever they meet with them on a hill, count 100 going at large, or even 200, and it seldom happens that a greater number than 200 will be found together in an open hirsel. To know the number in the different lots is of great use in case of a hasty blast, as you can in that event know, almost to a certainty, whether or not any sheep are wanting, and from what part of the farm. A shepherd ought likewise to be able *to do any kind of work about a sheep farm*, such as cutting lambs, smearing, slaughtering, dressing for the market, repairing stone-dykes, cleaning out drains, mowing grass, making hay, casting and winning peat-turf for fuel, &c.; but he ought at no time to neglect the sheep for such work. Shepherds are generally accounted lazy, but those who really care for their sheep will not be so. Much walking unfits a man for hard labor, as much as hard labor unfits a man for much walking; but laborers will generally be found more lazy in a hill, or among sheep, than shepherds will be found at field work."*

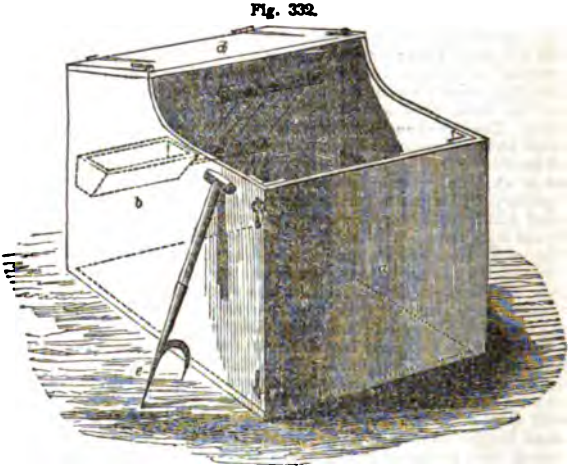
(1847.) Ewes in lambs are liable to abortion, or *slipping of the lamb*, as it is usually termed, as well as the cow, but not so much so, nor is the complaint considered epidemical in the sheep.

* Little's Practical Observations on Mountain Sheep.

Various causes produce it, such as severe weather in winter, having to endure much fatigue in snow, leaping ditches, being frightened by dogs, over-driving. It is stated by Mr. Youatt, that too liberal use of salt will produce abortion. The wool is apt to come off in spring after abortion. It is scarcely possible to predicate abortion in sheep on account of their woolly covering; but its immediate effects of dullness in the ewe, and of a redness under the tail, will be symptoms noticed by an observant shepherd. "The treatment after abortion," observes Mr. Youatt, "will depend entirely on the circumstance of the case. If the fœtus had been long dead, proved by the fetid smell of it, and the vaginal discharge, the parts should be washed with a weak solution in water (1 to 16) of the chloride of lime, some of which may also be injected into the uterus. If fever should supervene, a dose of Epsom salts, timeously administered, will remove the symptoms. If debility and want of appetite should remain, a little gentian and ginger, with small doses of Epsom salts will speedily restore the animal. Care should be taken that the food shall not be too nutritive or too great in quantity." In protracted labor when the ewe is becoming weak, she will be much relieved by receiving a table-spoonfull of brandy and sweet spirit of nitre in equal parts, with a drinking-horn. To produce pains in a ewe when she becomes apathetic in lambing, 2 table-spoonsfull of a strong infusion of the ergot of rye, repeated in a second dose in a quarter of an hour, will produce pains and ease the labor. In cases where it is impossible to extract the lamb, and the life of both lamb and ewe are in danger, the Cæsarian operation, that is, extracting the lamb from the womb by an incision made in the side and the womb of the ewe, has been performed with success. "In some lambs that are born apparently dead, the vital principle is not extinct, but it would soon be so if the little animal were suffered to remain on the cold damp grass. Every lamb that is found in this situation should be carefully examined, and if there is the slightest degree of warmth remaining about it, the shepherd should blow into its mouth in order to inflate the lungs: many a little one has thus been saved. The shepherd need trouble himself very little about the expulsion of the placenta or *cleansing*, although a day or two may pass before it is detached. A couple of ounces of Epsom salts, with a little ginger, may be given if there should be a longer delay, or if symptoms of fever should be exhibited: but the farmer would do well to avoid the rough barley or the mistletoe, or in fact any stimulant, for there is at this time sufficient disposition to fever, without its being artificially set up." "The inflammation of the womb, after parturition, usually comes on between the first and the fourth day, and especially when any violence has been used in extracting the lamb. It is a most fatal disease, and speedily runs its course. The treatment should be bleedings and purgatives of Epsom salts. Connected with this disease are after-pains or heaving, to which ewes are subject, and which are frequently severe and destructive. They are apparently the same pains, but considerably stronger, which Nature uses to expel the lamb. It is evidently produced by the ewes being too well kept during their pregnancy. It cannot be too often repeated, that it is a fatal error to overfeed the ewes at this period with a view of giving them strength to support their approaching labor. It is an unscientific and injurious practice, and severely does the farmer suffer for it. But there is some epidemic influence at work, or the constitution of the sheep is at that time irritable almost beyond belief." Young lambs, as long as they are dependent on their mother for food, are subject to a few diseases. A change to new luxuriant grass in damp weather may bring on the *skit* or diarrhœa, and exposure to cold may produce the same effect. As long as it feeds and plays there is little danger; but should it appear dull, its eyes watery and heavy, and its joints somewhat stiff, remedial means should immediately be used. "A gentle aperient is first indicated in order to carry off any offensive matter that may have accumulated in and disturbed the bowels: half an ounce of Epsom salts, with half a drachm of ginger, will constitute the best aperient that can be administered. To that must be added a table-spoonfull of sheep's cordial, consisting of equal parts of brandy and sweet spirit of nitre, housing and nursing." But there is a species of apparent purging, which is a more dangerous disease than the skit. "In the natural and healthy state of the milk and the stomach, curd produced by the gastric juice gradually dissolves and is converted into chyme; but when the one takes on a morbid hardness, and the other may have lost a portion of its energy, the stomach is literally filled with curd, and all its functions suspended. The animal labors under seeming purging, from the quantity of whey discharged, but the actual disease is constipation. It is apt to occur about the time when the lamb begins to graze, and when the function of the stomach is naturally somewhat deranged. Chemistry teaches us, that while a free acid produces coagulation of the milk, an alkali will dissolve that coagulum. Magnesia, therefore, should be administered, suspended in thin gruel, or ammonia largely diluted with water, and with them should be combined Epsom salts to hurry the dissolved mass along, and ginger to excite the stomach to more powerful contraction. Read's stomach-pump will be found a most valuable auxiliary here. A perseverance in the use of these means will sometimes be attended with success, and the little "patient being somewhat relieved, the lamb and the mother should be moved to somewhat better pasture." Besides looseness, lambs are at times subject to costiveness in the bowels. In the first few days of its existence the fæces they void has a very viscid consistence, which, when it falls on the tail, has the effect of gluing it to the vent and of stopping up that passage. On the removal of the obstruction by scraping with a knife, the symptom will also be removed. A worse species of costiveness is, when a few drops of liquid fæces fall occasionally to the ground accompanied by straining, as it is generally accompanied with fever that may be dangerous. Half-ounce doses of Epsom salts should be administered every six hours until the bowels are evacuated, after which both ewe and lamb should be turned into more succulent pasture, as the cause of the complaint is to be found in bare pasture and dry weather. In cases of fever, which may be observed from the dullness of the lamb and its quick breathing, the administration of tolerable doses of Epsom salts will generally avert the malady *at its commencement*. After recovery from lambing, the only complaint the ewe is subject to is inflammation in the udder, or *udder-clap*, or *gargel*. Of this complaint Mr. Youatt gives a good idea of its origin and of its treatment in these words: "The shepherd, and especially in the early period of suckling, should observe whether any of the ewes are restless and exhibit symptoms of pain when the lambs are sucking, or will not permit them to suck at all. The ewe, like the cow, or oftener than that animal, is subject to in-

flammation of the udder during the time of suckling, caused either by the hardness or dryness of the soil on which she lies; on the other hand, by its too great moisture and filth; or by some tendency to general inflammation, and determined to the udder by the bumps and bruises, sometimes not a little severe, from the head of the lamb. If there is any refusal on the part of the ewe, or even disinclination, to permit the young one to suck, she must be caught and examined. There will generally be found redness and enlargement and tenderness of one or both of the teats, or sometimes the whole of the udder, and several small distinct kernels or tumors on different parts of the bag. The udder should be cleared of the wool which surrounds it, and should be well fomented with warm water, a dose of Epsom salts administered, and then, if there are no large distinct knots or kernels, she should be returned to her lamb, whose sucking and knocking about of the udder will contribute more than by any other means, to the dispersion of the tumor and the regular flow of milk. It may occasionally be necessary to confine her in a pen with her little one, in order that he may have a fair chance to suck. A day, however, having passed, and she not permitting it to suck, the lamb must be taken away, the fomentation renewed, and an ointment composed 1 drachm of camphor rubbed down with a few drops of spirit of wine, 1 drachm of mercurial ointment, and 1 oz. of elder ointment, well incorporated together, must be rubbed into the affected part, or the whole of the udder, two or three times a day. She must also be bled, and the physic repeated. If the udder should continue to enlarge, and the heat and tenderness should increase, and the knots and kernels become more numerous and of greater size, and some of them should begin to soften or evidently to contain a fluid, no time must be lost, for this disease is abundantly more rapid in its progress in the sheep than in the cow. A deep incision must be made into that part of the udder where the swellings are ripest, the pus or other matter squeezed out, and the parts well fomented again. To this should succeed a weak solution of the chloride of lime with which the ulcer should be well bathed two or three times in a day. When all fetid smell ceases and the wound looks healthy, the friar's balsam may be substituted for the chloride of lime. The progress of disorganization and the process of healing are almost incredibly rapid in these cases, and the lamb may sometimes be returned to the course of a few days. There are particular seasons, especially damp and warm ones, when there is a superfluity of grass, in which garget is peculiarly frequent and fatal. Without warning, the udder swells universally with hardened teats, which sometimes brings on great inflammation, and if it has not stopped in the course of 24 hours, part, if not the whole, of the udder mortifies, and the mortification rapidly spreads, and the sheep dies."*

Fig. 332.



THE EWE-HOUSE.

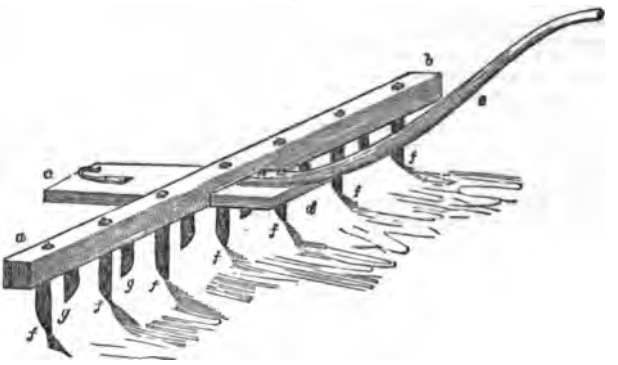
(1848.) In case of an individual ewe, of a large flock of a pastoral farm, straying a considerable distance from the shed erected to afford shelter to ewes, or has suffered in hard labor, or has a weakly lamb, or has twins which are apt to stray from her or she from them, or has been overtaken by a rude blast immediately after lambing, a contrivance to afford such ewes temporary shelter, especially under night, having been used by Mr. Nicholas Burnett, Blaik Hedley, near Gates-head, with success, seems to deserve attention. It consists of an inclosure of boards, or a box, as seen in fig. 332, whereof *a* is the front, which removes by hooks at the sides to admit the ewe and her lamb within, and where she is provided with a manger *b* to contain sliced turnip or oil-cake, and a rack *c* for hay, to fill both of which access is obtained by the lid *d*, movable on its hinges. I have been assured by Mr. Burnett, that in using this contrivance, which, being a light implement, can be easily carried to any spot, he has had the satisfaction of using it as a means of saving the lives both of ewes and lambs which would have otherwise perished from exposure. The size of the ewe-house, as it is called, may be made to suit that of the sheep bred on the farm and as it is not costly, any number can be made to be used at a time. The fork *e* leaning against the side of the ewe-house may be used to grasp a ewe's neck, while lying on the ground, and to fasten it down, while the shepherd is lambing her without other assistance; but the method of holding a ewe between the heel and the knee, which I have before described, renders such an instrument of little use.

(1849.) One of the greatest sources of loss among lambs on hill farms is a fall of snow at the lambing season or a continuance of snow to that period. Ground rendered wet by the melting of new-fallen snow, is in a worse state for lambs than when made wet by rain, as in the latter case the temperature of the air is higher, though, of course, wet ground of any kind is inimical to the

* Youatt on Sheep.

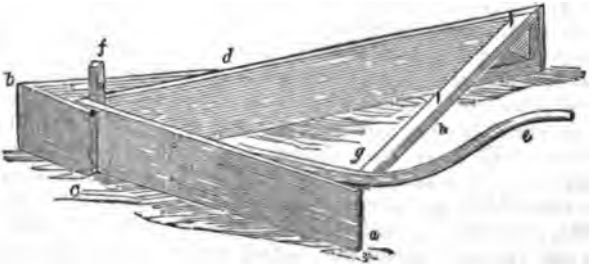
safety of new-dropped lambs. In such a case, the driest part of the farm combined with shelter should be chosen for the lambing ground, though it may be inconvenient in some other respects but should the best lambing ground be covered with old snow, especially in sheltered spots, and the temperature of the air be generally above the freezing point, could the snow be stirred by any means, it would melt much faster than it would of itself. A *snow-harrow* or *snow-plow* will be found a useful implement for the purpose, and those recommended by Mr. Hepburn of Culquhalzie seem to possess every requisite. The snow-harrow is represented by fig. 333. It consists of a single bull *a b*, 4½ inches square, and 6 feet long; and in the middle of which, on the under side, a piece of 1½ inch plank *c d*, 3 feet long, is sunk flush transversely, for the attachment of the draught-hook *c*, and the stilt *e* to steady the motion of the implement. In the bull are fixed by screw-nuts at intervals of 10 inches, 7 cutters *f f*, &c., 9 inches long and 1⅝ inches broad, sabre-shaped, with their points turned backward, so as to be less liable to be arrested by obstacles on the surface of the ground. Between these cutters are fixed 6 shorter ones *g g*, &c., 3 inches long, having their points turned forward. This implement, dragged by one horse ridden by a boy, and the stilt held by a man, cuts the frozen snow into strips of 5 or 6 inches broad, which are easily pulverized by the feet of the sheep, or divided by the snow-plow. The severe snow-storm of 1823 lay on the hills from February to May; and the protracted snow-storms of 1837-8, with repeated falls and alternations of frost and thaw, caused the death of many a sheep before and at the lambing season. The snow became so compacted in the latter year, that the common snow-plow was unable to penetrate the snow, and the common harrow to break its glazed surface. With the view of obviating both these inconveniences, Mr. Hepburn contrived the snow-harrow described above, and also the snow-plow, of which the following is a description in Mr. Hepburn's own words: "The severity of the winter of 1837-8 in mountain sheep pasture, led me to attempt the snow-plow, with or without the aid of the snow-harrow, for being applied in such situations. To enable the plow to clear tracks for the sheep along the hill-sides, it is necessary it should be made to throw the snow wholly to the lower side. To effect this I caused to be fitted to the plow *a a*, fig. 334, the body of which forms an isoceles triangle whose sides are 7½ feet, and its base 6 feet in length, the depth of the sides being 15 inches, a shifting head *b c d*, with unequal sides, one *b c*, being 18 inches, the other *b d*, 30 inches long, fixed by iron pins passing through to pairs of eyes as seen at *c*, attached to the head and to the sides of the plow respectively, so as to bring the point of the attached head of the plow nearly into the line of its upper side, or next the hill. The stilt *e* at the same time was made movable by a hinge-joint at its anterior extremity, fixed to the bottom of the head from the post *f*, so as to be capable of being fixed to the cross-bar or stretcher *g a*, either in a line bisecting the angle, as at *h*, which is the position for level ground, or in the line alternately, of either of the sides *b a* or *b g*, when to be used on a declivity. The draught-chain is fixed, not to the shifting head, but to the upright frame-post *f*, in the nose of the plow, which rises 10 or 12 inches above the mould-boards. When a plow so constructed is to be worked along a declivity, with the left hand toward the hill, the shorter limb of the shifting head is fixed on the left side of the plow, near the point, and the longer limb on the right side, toward the middle; and the stilt being fixed in the left extremity of the cross-bar, nearly in a line with a temporary point, the plow is necessarily drawn in the direction of its left side, so as to throw the snow wholly to the right down the hill. When the plow is to return across the declivity, with its right side to the hill, the movable head is detached by drawing

Fig. 333.



THE MOUNTAIN SNOW-HARROW.

Fig. 334.



THE MOUNTAIN TURN-WRIST SNOW-PLOW.

out the linch-pins, is turned up side down, and fixed in the reverse position; the shorter limb being attached to the right side, and the longer to the left side of the plow, while the stilt is brought to the right extremity *a* of the cross-bar. The plow is then drawn into the direction of the right side, and the snow is thrown wholly to the left, near the lower side. Should the lower side of the plow show a tendency to rise, it may either be held down by a second movable stilt, fixed to the middle *b* of the cross-bar, or a block of wood, or other ballast weight may be placed on that side of the plow. The plow will be found to remove considerably more than its own depth of snow. When a plow of 1 foot high passes through snow 18 inches or 2 feet deep, very little of snow falls back into the track, and what does so fall is easily cleared out by the plow in returning."* In lowland farms the snow remains around the fences long after the middle of the fields are clear. A speedy means of getting rid of the snow is to plow it with the common plow repeatedly. Had I not adopted this expedient in the spring of 1823, the oat-seed would not have been begun for a fortnight later than it really did.

(1850.) In regard to the treatment of sheep on turnips in spring, they are managed in the same way as in winter, until removed to grass, which they are, whenever the turnips fail, and are kept on for a short time, until the weather becomes mild enough to have them shorn of their wool, and then they are sold to the butcher; but other farmers prefer selling them fat, in a *rough* state off the turnips—that is, before the wool is clipped off them. The circumstances which regulate these different cases will be explained in a short time.

14. TRAINING AND WORKING THE SHEPHERD'S DOG.

"He was a gash an' faithful tyke,
As ever lap a sheugh or dyke,
His honest, sonsie, baws'nt face,
Aye gat him freends in ilka place.
His breast was white, his touzie back
Weel clad wi' coat o' glossy black:
His gaweie tail, wi' upward curl,
Hung o'er his hurdies wi' a swirl."

BURNS.

(1851.) The natural temper of the shepherd may be learned from the way in which he works his dog among sheep. When you observe an aged dog making a great noise, bustling about in an impatient manner, running fiercely at a sheep and turning him quickly, biting at his ears and legs, you may conclude, without hesitation, that the shepherd who owns him is a man of hasty temper. Most young dogs exhibit these characteristics naturally, and they generally overdo their work; and if you observe a shepherd allowing a young dog to take his own way, you may conclude that he also is a man who loses his temper with his flock. If you observe another shepherd allowing his dog, whether old or young, to take a range along the fences of a field, driving the sheep within his sight as if to gather them, you may be sure he is a lazy fellow, more ready to make his dog bring the sheep to him, than he to walk his rounds among them. Great harm may accrue to sheep by working dogs in these ways. Whenever sheep hear a dog bark that is accustomed to hound them every day, they will instantly start from their grazing, gather together, and run to the farthest fence, and a good while will elapse ere they will settle again. And even when sheep are gathered, a dog of high travel, and that is allowed to run out, will drive them hither and thither, without an apparent object. This is a trick practiced by lazy herds every morning when they first see their flock, and every evening before these take up their lair for the night, in order to count them more easily. When a dog is allowed to run far out, he gets beyond the control of the shepherd; and such a style of working among wether sheep, puts them past their feeding for a time; with ewes it is very apt to cause abortion; and with lambs after they are

* Prize Essays of the Highland and Agricultural Society, vol. xiii.

weaned, it is very apt to overheat them, and a considerable time will elapse before they recover their breath. Whenever a sorting takes place among the sheep with such a dog they will be moved about far more than is necessary; and intimidated sheep, when worn into a corner, are far more liable to break off than those treated in a gentle manner. A temperate herd works his dog in quite a different manner. He never disturbs his sheep when he takes his rounds among them at morning, noon and night, his dog following at his feet as if he had nothing to do, but ready to fulfill his duty, should any untoward circumstance require his services, such as breaking out of one field into another. When he gathers sheep for any purpose of sorting, or of catching particular ones, the gathering is made at a corner, and to gain which he will give sheep the least trouble, making the dog run out to the right and left, to cause the sheep to march quietly toward the spot, and after they are gathered, he makes the dog to understand that it is his chief duty to be on the alert, and with an occasional bark prevent any of the sheep breaking away. When a sheep does break away and must be turned, he does not allow the dog to bite it, but only to bark and give a bound at its head, and thus turn it. In attempting to turn a Black-faced wether in this way, the dog runs a risk of receiving an injury from its horns, and to avoid this I have seen him seize the coarse wool of of the buttock, and hang by it like a drag, until the sheep was turned round in the opposite direction, when he lets it go. In short, a temperate herd only lets his dog work when his services are actually required, he fulfilling his own duties faithfully, and only receiving assistance from his dog when the matter cannot be so well done by himself, and at no time will he allow his dog to go beyond the reach of his immediate control. Dogs, when thus gently and cautiously trained, become very sagacious, and will visit every part of a field where sheep are most apt to stray, and where danger is most to be apprehended to befall them, such as a weak part of a fence, deep ditches or deep furrows into which sheep may possibly fall, and lie *awalt* or *awkward*—that is, lie on the broad of their back and unable to get up, and they will assist to raise them up by seizing the wool on one side and pulling the sheep over upon its feet. Experienced dogs will not meddle with ewes having lambs at foot, nor with tups, being quite aware of their disposition to offer resistance. They also know full well when foxes are on the move, and give evident symptoms of uneasiness on their approach to the lambing ground. They also hear footsteps of strange persons and animals at a considerable distance at night, and announce their approach by unequivocal signs of displeasure, short of grumbling and barking, as if aware that those noisy signs would betray their own presence. A shepherd's dog is so incorruptible that he cannot be bribed, and will not permit even a known friend to touch him when intrusted with any piece of duty. So far as my observation extends, I think there are two varieties of the shepherd's dog—one smooth, short-haired, generally black-colored on the back, white on the belly, breast, feet and tip of the tail, with tan-colored spots on the face and legs; the other is a larger and longer-bodied animal, having long hair of different colors, and long, flowing tail. In their respective characters I conceive them to be very like the pointer and the setter. The small, smooth kind, like the pointer, is very sagacious, slow, easily broke and trained, and admirably suited to work in an inclosed and low country; the other, like the setter, is more swift, bold, ill to break, and requiring coercion, and fitter for work on the hills. The former answers the habits of Leicester sheep, the latter those of the Cheviot and Black-faced. The latter requiring a great range to work in, on account of the nature of the sheep and of the ground which

they frequent, are bold and rough in action; still they should be trained to work with judgment and caution, and not with recklessness and fury. Most shepherds profess to be able to train young shepherds' dogs, and therein many display much ignorance of the nature of the animal, and of the aptitude of the particular animal for the peculiar work, and the consequence is, many dogs are rendered unfit for their work. Every shepherd's pup has a natural instinct for working among sheep, nevertheless they should always be trained with an old dog. Their ardent temperament requires subduing, and there is no more effectual means of doing so than keeping it in company with, and making it imitate the actions of, an experienced, sober dog. A long string attached to the pup's neck, in the hands of the shepherd, will be found necessary to make it acquainted with the language employed to direct the various evolutions of the experienced dog while at work. With this contrivance it may be taught to "*hold away out by*," to "*come in*," to "*come in behind*," to "*lie down*," to "*be quiet*," to "*bark*," to "*get over the dike or fence*," to "*wear*," that is, to intercept, to "*heel*," that is, to drive on, to "*kep*," that is, to prevent getting away; it will learn all these evolutions and many others in a short time, in imitation of its older companion and guide. It is supposed that the bitch is more acute than the dog, though the dog will bear the greater fatigue. Of the two, I believe that the quietly disposed shepherd prefers a bitch, and is careful in working her as little as he can when in pup. I may mention that the shepherd's dog claims exemption from taxation; and I believe that a well-trained one costs at least £3.

---

15. SOWING BARLEY-SEED.

"Such land as ye break up, for barley to sow,
Two earths at the least, ere you sow it bestow,
If land be thereafter set oating apart,
And follow this lesson to comfort thine heart."

TUSSER.

(1852.) It may be laid down as an axiom, that land which has borne turnips which have been eaten off by sheep should receive two plowings of some sort before it is sown with *barley*. I have seen the experiment tried of sowing barley on a single furrow on land ranging from clay to gravelly, and the invariable result was a manifest deficiency of crop compared to what had received two furrows; and this result is not surprising, when it is considered that barley requires a deep, well-pulverized soil to its perfect development, and that it is impossible to render any land so with a single furrow, that has been trampled firm by sheep, after carrying a heavy crop of turnips. Strong land yields, with a single furrow, a tough, waxy clod, very inimical to the growth of barley; and light turnip soil, when ridged up with a single furrow, exhibits the growth of barley in drills corresponding exactly with the drills which had been manured for turnips. The least difference of crop with one and two furrows is observed on fine hazel loam, still the superiority is to be found with the two furrows. Lay it, therefore, down as a rule, that barley land shall receive two furrows; and the only question is in what form these should be given, bearing in mind, at the same time, that the land must be deep and well pulverized, and to settle what that form should be shall be our present endeavor.

(1853.) On clay loam in good heart it is possible that some of the turnip land that had been ridged up for spring wheat had been, from some cause, prevented from being sown with that grain, and, of course, it must be sown with barley. The land had likely been gathered up from the flat, as in fig. 133, or it may have been cast, as in fig. 135; in either case the barley land will be desired to be seed-furrowed in the same manner, that the ridging of the whole field may be uniform. Since the furrow for the spring wheat was the seed-furrow, and its ridges had been formed with a view to make the surface of the field uniform from side to side, it will be impossible to re-plow those ridges with one furrow of the *common* plow, without disturbing their form. Such ridges must either be plowed *twice* with the common plow, to bring them back to their present form, for which repetition of work there may not be sufficient leisure, or they may be stirred with the grubber, a class of instruments with the importance of which you will be made acquainted below by Mr. Slight, or ribbed with the small plow, fig. 314, without affecting their form. The choice of these various modes of stirring the ground may be taken according to circumstances. If the ridges have become much consolidated in consequence of being plowed a considerable time, or of much rain having fallen, and if the soil itself be naturally firm, two furrows with the common plow will best put the land into a state for receiving barley; but should they be in a somewhat soft state, with perhaps rather too much moisture below, though with a kindly state of the surface, capable of affording a fine *tid* with the harrows, then the grubber is the most proper implement for making a deep bed for the barley-seed, while it at the same time retains the dry surface uppermost; and should the soil be naturally free while it is desired to retain the upper stratum of soil still uppermost, it may be ribbed with the small plow. Putting these ridges thus into the best state for the barley-seed, there will be no difficulty with the remainder of the land. The first furrow given to barley land, which is at the same time in the best direction, is the *cross-furrow*, as in fig. 312, because being plowed in an opposite direction to the seed-furrow to be afterward given, the best means are taken to pulverize it. I need not here repeat what has already been said so fully on cross-plowing in (1718) to (1723) inclusive. Although the land may not be all so cleared of turnips as to allow the cross-plowing to extend from one side of the field to the other, it should be divided into two portions, one of which should be plowed and sown while the other is clearing, and which may perhaps be cleared by the time the sowing of the first part is completed. After a passage of the harrows a double tine over the cross-plowed land, the ridges should be feered and plowed up for the seed-furrow, and the usual form of seed-furrow is either gathering from the flat, as shown in fig. 133, or yoking two ridge-breadths together, as in fig. 135. Every plow should be employed in ridging up the seed-furrow for the barley-seed, for it is essential to the success of that crop that the seed be sown on the soil fresh turned-up, or on a *hot-furrow*, as it is termed. Both the cross-plowing and seed-furrow should be *deep*. The former may be turned up with a broad, stout furrow-slice, but the latter should be plowed with a deep, narrow furrow-slice, in order to pulverize the soil as much as possible, and to make the crests of the furrow-slices numerous and narrow, so as to disseminate the seed more equally when sown by hand; for the sowing of seed on a fine pulverized surface requires assistance of this sort to cause it to be equally disseminated, inasmuch as on whatever spot every seed falls, there it lies, the soft earth having no elasticity like the firm furrow-slice of lea, and hence, of all the sorts of grain, barley is the most likely to be *happerga'ed* in the sowing, and on that ac-

count every handfull requires to be cast with greater force than other sorts of grain. The walking on soft ground in sowing barley is attended with considerable fatigue, and as short steps are most suited for walking on soft ground, so small handsfull are best for grasping plump, slippery barley. Barley may be sown any time that is proper for spring wheat, and it may be sown as late as the end of May; but the earlier it can be sown, the better will the crop be in quality and uniformity, though the straw will be less. The average quantity of seed sown broadcast is 3 bushels to the imperial acre; when sown early less will suffice, and when late, more; because the later it is sown there is less time for so quick a growing grain as barley to tiller and cover the ground. Mr. Brown has some judicious remarks on this subject: "Among the farmers," he says, "it seems a disputed point whether the practice of giving so small a quantity of seed (3 bushels per acre) to the best lands, is advantageous. That there is a saving of grain there can be no doubt; and that the bulk may be as great as if more seed had been sown, there can be as little question. Little argument, however, is necessary to prove that thin sowing of barley must be attended with considerable disadvantage; for, if the early part of the season be dry, the plants will not only be stinted in their growth, but will not send out offsets; and if rain afterward falls—an occurrence that must take place sometime during the summer, often at a late period of it—the plants *then begin to stool*, and send out a number of young shoots. These young shoots, unless under very favorable circumstances, cannot be expected to arrive at maturity; or if their ripening is waited for, there will be great risk of losing the early part of the crop—a circumstance that frequently happens. In almost every instance an unequal sample is produced, and the grain is for the most part of inferior quality. By good judges it is thought preferable to sow a quantity of seed sufficient to insure a full crop, without depending on its sending out offsets. Indeed, when that is done, few offsets are produced, the crop grows and ripens equally, and the grain is uniformly good."* There is no grain so easily affected by weather at seed-time as barley; a dash of rain on strong land will cause the crop to be thin, many of the seeds not seemingly germinating at all, while others burst and cannot germinate; and in moist, warm weather the germination is certain and very rapid. Indeed, it has been observed that unless barley germinate quickly, the crop will always be thin. I have seen the germ of barley penetrate the ground only 36 hours after I had sown it myself, and when it took place, the ground was smoking by the evaporation of moisture, caused by a hot sun in a calm atmosphere. I have also traced the germ of barley to the depth of 9 inches below the surface. The harrowing which barley-land receives after being sown is less than oat-land, a double tine being given in breaking in the seed, and a double tine across immediately after. Then the grass-seeds are sown with the grass-seed sowing-machine, formerly described in (1774); the land is harrowed a single tine with the light grass-seed harrows (1775); water-furrowed (1778); and finished by immediate rolling. On strong soil, apt to incrust on the surface with drouth, after rain the rolling *precedes the sowing of the grass-seeds*, and the process is finished with the light grass-seed harrows; but on all kindly soils the other plan is best for keeping out drouth, and giving a smoother surface for harvest-work. The head-ridges are plowed and sown by themselves. Barley may be sown with the broadcast machine as well as oats, and it is admirably suited for sowing with the drill sowing-machine, which deposits the seed at a uniform depth and breadth between the rows, with about two bushels of seed to

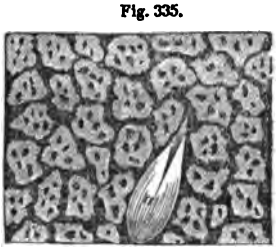
* Brown on Rural Affairs, vol. ii.

the acre; and such an arrangement affords opportunity for the exercise of the draw-hoe, to remove the wild mustard, which is apt to spring up among the spring crops in the vicinity of large towns, where street-manure is used to a large extent.

(1854.) Barley is sown after potatoes and beans, but never when the weather will permit the sowing of wheat. When intended for barley, the land is gathered up for the winter, water-furrowed and gaw-cut, to prevent water standing upon it; and in spring it is cross-plowed and ridged up with the seed-furrow. Barley is sown also at times after wheat or oats, and the sample in such a case is always fine colored, but the practice is bad farming, and should never be pursued. It is never sown in Scotland after lea, but might be after the land had received a partial fallowing in spring. When sown in autumn, it does not stand the winter well in Scotland, though it does in England. Winter barley is always early ripe, but is seldom a prolific crop, and when it tillers late in spring to cover in the ground, the produce is apt to contain a large proportion of light grain. As an instance of late sowing of barley, I may relate what has fallen under my own observation. The late Mr. Guthrie, of Craigie, near Dundee, had early plowed the greater part of a field of strong soil after turnips, and much rain had afterward consolidated. Being desirous of giving the land another furrow before sowing it with barley, he found the plow bring up large waxy clods, unfit to form a seed-bed for barley. He consulted me, and I advised him to rib the land with a small plow, fig. 314, instead of plowing it. His men never having seen land so ribbed, I showed them the way, and saw the ground sown and harrowed with one double tine along. The sowing took place on 26th May, 1819, and the ribbed land produced 12 bushels the Scotch acre more than that which was plowed with the common plow, because all the tender part of the land had been kept uppermost.

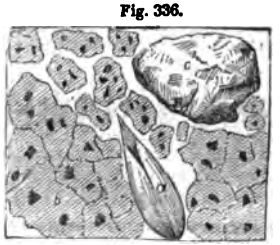
(1855.) Now that you have seen the termination of the sowing season of the various sorts of grain usually cultivated on a farm, it may prove useful to you to give you an idea of the principles of the germination of seeds, and which you will find given here in the words of Dr. Madden. [The process of germination consists chiefly of various chemical changes in the composition of the seed, by which its substance is rendered soluble, and in this state furnishes nourishment for the young plant. This change is effected by means of a highly azotized principle present in all seeds, and which, under the joint influence of *air, moisture* and a *certain temperature*, undergoes various chemical changes, during the occurrence of which it is capable of exciting similar changes in other substances with which it may be in contact. Seeds are for the most part composed of starch, gum, sugar, albumen, and various saline matters; of these the starch is in general the most abundant, and the most important change produced during germination is the conversion of this starch into sugar. I have stated that the necessary conditions for effecting this change are, independently of the vitality of the seed itself, *air, moisture* and a *certain temperature*; these three points are sufficient to regulate all the practical details of the sowing of seed, both as regards the weather and the condition of the soil in respect of water and tillage.* If the season, for example, be not far enough advanced, then germination is either retarded by the lowness of the temperature, or the vitality of the

Fig. 335.



SOIL WITH WATER AND WITHOUT AIR.

Fig. 336.



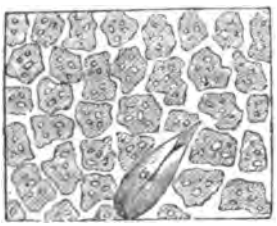
CLODDY AND STONY SOIL.

seed is altogether destroyed by the continuance of hard frost. If, again, the soil be too wet, the seed does not obtain a sufficient supply of air, owing to the interstitial canals already mentioned—

* See a paper by me on this subject in the Prize Essays of the Highland Agricultural Society, vol. xiv.

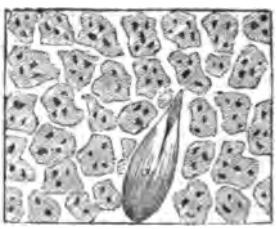
(884) to (886)—being filled with water. To give you a better idea of this condition, you will perceive, in fig. 335, that the seed *a* is not supplied with any air beyond what reaches it in the state of solution in water. Again, if the soil be not properly pulverized, it is very possible that the seed may be badly situated for the purposes of germination, owing to the obliteration of the interstitial canals by pressure, as is shown in fig. 336, where *b* represents a clod of earth, and *c* a stone, between which the seed *a* is placed. I need scarcely mention the remaining cause of imperfect germination, viz., the absence of moisture, as represented in fig. 337, where *a* is the seed, as this is far too rare an occurrence, under ordinary circumstances, to require notice. Lastly, the proper condition of soil for germination is, as before noticed, (885,) where the pores of each particle are filled with water, while the interstitial canals are filled with air. This condition is shown in fig. 338, and it will at once be observed that while the seed *a* obtains moisture by

Fig. 337.



SOIL WITH AIR AND WITHOUT WATER.

Fig 338.



SOIL WITH WATER AND AIR.

contact with the dark saturated particles of soil, it receives a continuous supply of fresh air from that circulating constantly through the interstitial canals. "Lest any one should suppose that the contents of these interstitial canals are so minute that their whole amount can be of little consequence, we may here notice the fact that in moderately well pulverized soil they amount to no less than ¼ of the whole bulk of the soil itself. For example, 100 cubic inches of *moist* soil—that is, of soil in which the pores are filled with water, while the canals are filled with air, as fig. 337—contain no less than 25 cubic inches of air. According to this calculation, in a field pulverized to the depth of 8 inches, a depth perfectly attainable on most soils by careful tillage, every imperial acre will retain beneath its surface no less than 12,545,280 cubic inches of air. Taking into the calculation the weight of soil, we shall find that every additional inch you reduce to powder by plowing, you call into activity 235¼ tons of soil, and render it capable of retaining beneath its surface 1,568,160 additional cubic inches of air.—H. R. M.]

(1856.) The subject of the condition in which seed is usually found deposited in the ground may be pursued a little farther, from the paper alluded to by Dr. Madden, and the first conditions that strike one are bad plowing and bad sowing. In fig. 339, the furrow-slices under *a*, *b* and *c* are all ill plowed, as you may easily perceive; and the soil being so arranged, of course the seed will be irregularly deposited, as seen at *a*, *b* and *c*, in fig. 340, where some are too deep, as under *b*, to

Fig 339.

Fig. 340.

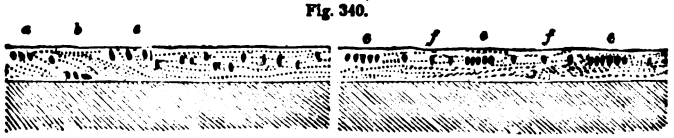


Fig 341

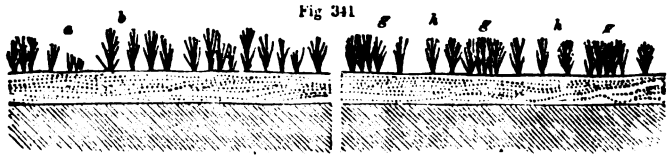
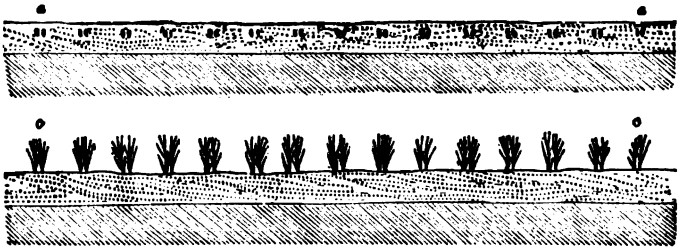


THE EFFECTS OF BAD PLOWING ON SEED. THE EFFECTS OF BAD SOWING ON SEED.

germinate quickly, if at all, and others much nearer the surface, as at *c*. In these various positions in which the seed is placed, it is obvious that the plants springing from them will appear and grow as irregularly, as seen in fig. 341, where the plants at *b* are much farther advanced than those at *a*. In regard to bad sowing, although the furrow-slices are regular and well plowed in the right-hand side of fig. 339, from *c* to *d*, yet the seed having been irregularly deposited on the

surface. they have arranged themselves in one place too thick, as at *e e e*, fig. 340, and too thin at *f f*; and the consequences are visible in the position of the plants in fig. 341, where they are too thick at *g g g*, and too thin at *h h*. Where such irregularities exist—and every farmer is liable to their consequences by the carelessness of their work-people, it is clear that the crop cannot be uniform; and it is a fact which cannot be disputed however it may be explained, that the more uniform a crop is, it is the greater, and affords better grain. If, on the other hand, you observe fig. 342, you will perceive that the seed has been deposited at uniform depths and intervals from *a*

Fig. 342.



THE GOOD EFFECTS OF THE EQUAL DEPOSITION OF SEED.

to *a*, and the consequence is that the plants grow at uniform hights and strength, as from *c* to *c*. Although the favorable result is obtained by drill-machines depositing every seed at a regular depth, which is not the case of broadcast by hand, yet there are objections against sowing corn in *rows*, which all drill-machines do; but could they be made to deposit seed at a uniform depth, and at the same time disperse it broadcast, the objection would be disposed of. The objection to all crops placed in rows is that the air, having free access along the rows, while it encourages the growth of the cultivated, so also it does of wild plants, and to destroy the latter, certain implements are used to stir the ground, while the former are, of course, allowed to grow; but as in their progressive growth the plants throw out innumerable root-fibres in every direction in search of food, the fibres which occupy the open space between te rows are destroyed in common with the weeds; and though no estimate can be formed of the amount of injury which plants sustain in the destruction of their root-fibres, yet it is consonant to reason that these fibres must be essential to the welfare of the plant, otherwise they would not be sent forth. It would therefore be worth while to ascertain, by experiment, the comparative results derived from depositing seed broadcast at a uniform depth with ordinary broadcast, and with rows.

(1857.) I have amused myself at times in calculating the quantity of seeds of different grains sown in an acre, and on comparing the amount of crop actually received, with what ought to have been their produce, and the deficiency which the results bear out appears incredible. Thus, Hunter's wheat gives 84 grains to 1 drachm weight; and taking it at 65 lbs. per bushel, the number of grains in a bushel is 698,870, and giving three bushels per acre for seed, there will be sown on an imperial acre, 2,095,510 grains, or 48 grains in the square foot. Now, I have counted ears of wheat to contain as high as 61, and as low as 24 grains each, the average thus being 44 grains; and allowing no more than one ear of produce from each grain sown, and allowing nothing for the tillering of the crop, the preduce ought to be 44 fold; but the largest produce of wheat in the Carse of Gowrie is 52 bushels per imperial acre, or only 17 fold for the seed sown: what then becomes of the other 27 fold? Again, 80 grains of Chevalier barley, at 69 lbs. per bushel, weighs 1 drachm, or affords 604,160 grains to the bushel, and at 3 bushels to the acre, 1,812,480 grains per acre, or 41 grains to the square foot. Now barley yields from 32 to 21 grains in the ear, the average being 28, and allowing 1 ear from each grain sown, the produce should be 28 fold; but 60 bushels per acre is the best crop, or 20 fold of the seed: what then becomes of the 8 fold which is wanting? Once more: Potato oats give 134 grains to 1 drachm, at 47 lbs. per bushel, or 806,144 grains to the bushel, and at 6 bushels an acre for seed, 4,836,864 grains per acre, or 111 grains per square foot. Now, potato oats differ in the yield of grains in the ear from 182 to 20, the average being 64, or 64 fold, allowing 1 ear from each grain sown without tillering. Now 72 bushels is a good crop per acre, or 12 fold of the seed: what then becomes of the 52 fold wanting? These are incredible discrepancies, and how can they be accounted for? Can the attacks of insects and vermin, or the effects of soil and weather, account for the loss? The subject is worth investigation, and were the result of investigation the discovery of the means to protect the seed while it is in the ground, the produce would either be greatly increased, or the quantity of seed to be sown would require to be much lessened.*

* See some speculations of mine on this subject in vol. iv. of Quarterly Journal of Agriculture.

16. TURNING DUNGHILLS AND COMPOSTS.

"The compost pile examine now and turn,
And if 'tis not completely decomposed
Into one mass of vegetable mould,
With an unsparing hand throw in more lime.
When unremitting cold retards the stage
Of fermentation, heat, then, genial heat,
Must be applied.

GRAHAM.

(1858.) The ordinary mode of treating dunghills of farm-yard manure is very simple—the principle upon which it is founded is quite consonant to reason—and the results of the application of the manure so treated is also satisfactory. The treatment is, to spread every kind of straw used in litter, and every kind of dung derived from the various sorts of animals domiciled in the steading uniformly in layers, as it is supplied, over the area of the respective courts; to take this compound of straw and dung out of the courts at a proper period, and form it into a heap in the field where the manure derived from it shall be needed, with as much care as to mix the different ingredients of the heap together as they were in the courts, and to prevent the fermentation of the whole until the manure is used; and to turn this heap over in such a way, and at such a time, as the manure it contains shall be ready to be applied to the soil when wanted. The principle of this treatment is the simple one of commixing the various ingredients of straw and dung so intimately together, first in the courts, then in the dung-heap, when led out, and lastly in the same dung-heap when turned over to be duly fermented, as that the fermented manure shall be as uniform a compound as the nature of the materials of which it is composed will admit. And the result is, when the manure so treated is applied to the soil, it is found to be the most valuable of any known manure for every purpose of the farm. You have already been told how the courts should be littered, and been shown the advantages of attending to this simple yet important part of rural management in (1596) and (1597). You have also seen how those courts are emptied of their contents, and the proper time when they should be so emptied, in (1598) and (1599). And you have witnessed how their contents are disposed of in heaps in the fields in which they shall be required, (1601), and the reasons why they are formed in the manner recommended, (1602). My present purpose is to inform you how these heaps should be turned in order to bring them into the degree of fermentation best suited for making them into good manure; and the mode of actually applying that manure will be shown to you when we come to consider the culture of the potato and turnip crops.

(1859.) Potatoes are the first crop which require a large quantity of farm dung. It is the practice of some farmers to drive the dung for potatoes direct out of the court, in its compressed state, and before it has been fermented at all. On strong soils, naturally unsuited to the growth of this plant, by reason of their heavy and tenacious character, long dung may be successfully used, because it assists to relieve the pressure of the soil upon the young plant. Indeed, on such soil, I have seen a drill of potatoes manured with dry twisted straw-ropes obtained from the coverings of the stacks in the stack-yard, and which was so manured for the purpose of ascertaining the difference, if any, betwixt it and the best made dung, pro-

duce as good potatoes as the dung. In like manner, potatoes may be raised well on soils of that character with horse-dung which has reached that state of worthlessness called *fire-fanged*. In all other sorts of soils the use of long-dung incurs imminent risk of a deficiency of crop, and therefore dung should generally be fermented for potatoes. Dung, when laid up in an uncompressed state in the court, as noticed in (1604), becomes sufficiently fermented for potatoes, and may be driven out at once without farther preparation. There is one objection to the use of unfermented dung for potatoes, which seems to me insuperable, and it is, that where grains of every kind find their way among the litter of courts, and it is impossible to have the straw threshed by the mill absolutely clean, or the seeds of weeds that may have been sifted out of the corn when cleaned, thrown upon the litter in the courts, though they ought to have been thrown away elsewhere; so long as these grains and seeds possess all their vitality, and that will escape destruction in unfermented dung, they will spring up among the potatoes, not in the intervals between the drills, where they might be removed by the horse-hoes in the process of cleaning the land, but actually among the potato-plants, having vegetated and grown along with them, and deriving as much nourishment from the dung as the potatoes themselves. I have frequently seen such an intermixture with potato plants at various places, and a very dirty and slovenly farming it makes. Having a piece of ground trenched from an old plantation, and being comparatively pretty clean, I was desirous of trying potatoes upon it for the first crop, and having no dung ready prepared for this extra space of ground, what was required was taken out of the court in which the corn-barn was situated, and the result was as I have just described. No doubt, the weeds thus sprung up among the potatoes can be removed by the field-workers with the draw-hoe, when they are cleaning the crop, but the labor of removing large plants from that position, and especially when forced in growth by powerful manure, is considerable, and the weeding cannot be accomplished but by removing a considerable portion of the useful soil around the young potato plant. It is clear that it is much better farming to have no plants in this position to take away, than to have to remove them.

(1860.) On commencing the *turning* of a dunghill, it should be considered from which end it will be most convenient to take the dung and lay it on the land. On the supposition that the dunghill occupies the position explained in (1595), the end from which the dung will be carted away will be the head-ridge. After determining this point, the next subject for consideration is, whether the dunghill will be once or twice turned before it is applied, and this point is determined by the crop for which the dunghill is preparing—if for potatoes, only one turning is requisite, and two for turnips. As the first dunghill is intended for potatoes, it receives one turning, and it should be begun to be turned at the end farthest from the head-ridge. The unturned dung-heap slopes at both ends, as observed in (1601), but the turned dunghill should be made of the same hight throughout. To attain this end, the space occupied by the workers at the commencement, between the turned dung and the dung-heap, should be wider than at the middle of the heap, and the dung should be thrown to a greater hight than the side from which it is taken. The usual width marked off on the dung-heap is 3 feet, which affords sufficient room for people to work in; but the first few spaces upon which the first divisions of the heap are laid, should be held narrower than 3 feet, until the desired hight of the turned dunghill is attained at the end. The effect of this arrangement is, as the turning approaches the middle of the dung-heap, where it is of the greatest

hight, the space upon which the dung is *turned upon* will be more than 3 feet in width, and the additional width will be required near and at the middle, that the extra hight of the dung-heap there may be reduced to the level of the end. After the middle has been passed, the spaces turned upon should be gradually lessened in width toward the end at which the turning is finished, where, as at the commencement, the turned dung will have to be thrown to a greater hight than the dung-heap, to attain the medium hight of the finished dunghill. There is much more of nice management in following these particulars of turning a dunghill than at first sight may appear necessary, because the turned dunghill will not ferment equally throughout if it is of different hights. The greatest heat will be at the deepest part, where the dung will become comparatively short and compact, while at the shallowest parts it will continue crude and unprepared; and these different states of manure have very different effects on the soil. In ordinary practice, miscalculations are always made as to the uniform hight of dunghills, for they are lower at the ends than at the middle; and if an endeavor is afterward made to equalize the hight, it is done by throwing high dung of the middle toward the ends, and the effect of this expedient is that no union takes place between the dung which was turned over in the regular way with what is afterward thrown upon it; they ever after remain in different states, and rise differently to the graip when removed into the cart; and the middle part, besides, becomes trampled down and harder than the ends.

(1861.) Laying these down as the rules by which dunghills should be turned, the mechanical part of the operation is done in the following manner: The people required to do this work are a man and a few field-workers, according to the size of the dunghills; and of this latter class, women are by far the best hands at turning a dunghill, because, each taking a smaller quantity of dung at a time upon a smaller graip than fig. 257, the dung is much more intimately mixed together than when men are occupied at this work, for they take large graipsfull, and merely lift them from one side of the trench they are working into the other, without shaking each graipfull loose, or scattering it to pieces. Turning dung is not a cleanly work for women, their petticoats being apt to be soiled in the trench by the dung on both sides; but there is a plan which Berwickshire women adopt of keeping the bottom of their dress clean, which is to tie the bottom of the petticoat with the garters just below the knee, as long as they are at work. The man's duty is to cut the dung-heap into divisions of 3 feet wide across its breadth with the dung-spade, fig. 308, in the manner described in (1603). When the edge of the dung-spade becomes dull, it is sharpened with the scythe-stone. The drier portions of the dung are put into the interior of the dunghill, and when different sorts of dung are met with, they are intermingled in small graipsfull as intimately as possible. Each division of the dunghill is cut down and turned over to the ground before another is entered on, and when the ground is reached, the scattered straws, and earth that has been damped by any exudation from the dung-heap, are shoveled up either with the broad-mouthed shovel, fig. 149, or the frying-pan shovel, fig. 176, and thrown into the interior. When straw-ropes are met with, they should be cut into small pieces and scattered among the dampest portions of the dung. Though the dung-heap is cut into parallel trenches, the dung from the top of one trench is not thrown into the bottom of the former, but rather thrown upon the breast of the turned dung, so as the turned dung may slope away from the work-people. The utility of this form is, that when the dung is carting away it rises freely with the graip. When a dung-heap is thus turned over, and its form

preserved as it should be, it constitutes a parallelopipedon, and is a well finished piece of work.

(1862.) Unless much rain has fallen from the time the dung was led out of the court until the heap is turned, the dung will not be very moist, and not at all wet, but in a free workable state, with a slight degree of heat in it, and evaporation would be observable from it, were the air cold when it was turning. Very little moisture will be observed as having come from the heap. After this turning over, shaking up and mixing together, which should be finished in the same heap as quickly as possible, that the whole mass may have the same time to ferment, the operation being performed about a fortnight before the time of planting potatoes, in the latter end of April and beginning of May, the ordinary temperature of the atmosphere is then such as a considerable degree of heat may be expected to show itself in the dung in the course of a few days. There is no danger of this first fermentation proceeding to a great degree of heat, as the air is still cool at nights and the largest proportion of the heap consists of the dung of cattle, which is slow of fermentation at all times, and particularly in the early part of the season. The first external symptom that fermentation is proceeding in the heap is subsidence of its bulk, which in the course of a fortnight may contract one foot of hight. A perceptible smell will then arise from the dung, accompanied with a flickering of the air over it, which is occasioned by the escape of vapor and some of the gases, but chiefly, I apprehend, aqueous vapor. By inserting a walking-stick into the heap here and there, a heat considerably more than that of the hand will be felt, and by pushing this stick into different parts of the dunghill, the relative heat of those parts will be ascertained, and the greatest heat may be expected to be felt at the side opposite whence the wind blows, if there be wind, or even a breeze. The substance of the dunghill becomes more consolidated in consequence of the fermentation, and also more uniform; and a black-colored liquid will be found in some degree to ooze from its sides. If the soil upon which the dunghill stands was soft when the dunghill was formed, the oozing will then be absorbed by it, and exhibit no wetness of surface; but if the soil be firm, then the moisture will remain on the surface, and form small pools in the ruts of the cart-wheels or open furrows. All the leakage, even if collected in one pool, would afford but a trifling quantity; indeed much moisture cannot exude from a dung-heap derived from courts in which the cattle are duly supplied with abundance of litter to keep them both dry and warm. So much for the *potato*-dunghill.

(1863.) As to the *turnip*-dunghill, it receives a somewhat different treatment, but still conformable to the purpose for which it is destined. It is turned twice, and on this account it is begun to be turned at the opposite end from that for potatoes; but the same rules are followed in doing it as just described for the potato-dunghill, and it also is allowed to ferment for about a fortnight. At the second turning, which is given about a fortnight or ten days before the dung is used, the operation is commenced at the end at which the former turning terminated, and it is much more easily performed than the first, inasmuch as the substance is easier cut with the dung-spade, more free to separate and shake with the graip, and less care required to retain the rectangular figure formerly given to the dunghill. The weather at the second turning will be warm, and the fermentation, of course, rapid, so that apprehension may be excited that it will proceed to an injurious extent for the materials composing the dunghill. For raising turnips, however, there is little dread of the fermentation proceeding too far, as it is matter of experience that the more effete the dung is, the more valuable it is for the nourishment of the turnip plant, as is well known to

every turnip farmer. When in this valuable state heat has almost entirely left it, it has become like soft soap, and rises in lumps with the graip, and would almost cut into pieces with the shovel. It is, moreover, sappy, cohesive, greasy, and of a dark-brownish black color. The larger the mass in which the dung in this state is found, the more valuable it is for turnips. To check rapid fermentation, a spitfull of earth around the dunghill thrown upon its top, will have that effect to a certain degree. It is supposed by many farmers who grow Swedish turnips to a large extent, that dung of the same year cannot be transformed into this state in time for Swedish turnips, which ought to be sown before the middle of May; and in the temperature of ordinary seasons in Scotland at that time, the observation, I dare say, is correct. To obviate the want of so valuable an ingredient as old muck, it is the practice of some farmers to keep dung on purpose over the year. This would no doubt be a difficult matter on farms which depend entirely on their own produce for the manure applied on then; but let the sacrifice be made for one year either to collect farm-yard dung from external sources, and form it into a dunghill for the succeeding year, or purchase other manure to a large extent for one year, to raise a crop of turnips, and reserve the farm-yard dung for the Swedish turnips of the next year, and the object is gained. I have known many farmers attain this object to a partial extent, but no one whom I have observed practice it to so great an extent as Mr. Smith, when he was at Grindon in North Durham, where he possessed the fine stock of Short-Horns that was admired by all who saw them. The dung of the year was made fit for white turnips, which were not sown for a month or so after the Swedes, and when both heat and time combine to bring it to a proper state for use.

(1864.) The subject of *composts*, when followed out in all its bearings, is an extensive one—for there is not a single article of refuse on a farm but what may form an ingredient of a compost, and be converted into a manure fit for one or more of the cultivated crops. At the same time there is great labor attending the formation of composts of every kind, as the materials cannot be collected together without horse-labor; and in summer, when those materials are most abundant, the labors of the field are most important, and to devote then the time required to collect them, would be to sacrifice part of the time that should be occupied in indispensable field-labor. I believe the most economical mode of forming composts is to collect materials at times when leisure offers for the purpose; and when they have accumulated in sufficient quantity in the space allotted for their use, they can be put together by the field-workers when not necessarily engaged in the field. This advice will not suit the temper of those who, wishing to obtain their object at once, would make the forming of composts, or any other thing they have in hand at the time, the principal business of the farm; but you should be very cautious in determining to execute any piece of work that diverts horse-labor from its legitimate pursuits. I speak on this subject in this manner from direct experience, for I was once strongly impressed with the benefits to be derived from using composts; and having plenty of materials at my command for making what I conceived should be good manure for the land, I persuaded myself that manure to any extent might be made on the farm. Having access to an unlimited quantity of rough bog-turf and peat, large quantities of dry leaves in autumn, black mould to some extent, and those usual refuse products of the farm—quicken and potato-haulms, with plenty of shell-marl and a stratum of fine clay associated with it, and, of course, lime-shells from the market-town at all times, I was in these circumstances perhaps fully more favorably situated for making composts than most farmers. But little did

I anticipate the labor I undertook. Two years convinced me that it was no child's play to collect together bog-turf, marl, lime, dry leaves and rubbish into one focus, and cart them all out again to the field or fields destined to receive the benefits of their composition. I put together the materials in the best manner I could devise or hear of, turned them at proper times with the greatest care, and certainly enjoyed the satisfaction of making a great deal of stuff apparently well adapted for the purpose intended; and in regard to its quality, I invariably found that the oldest made compost looked richest, most uniform in its texture, and most active in its effects, like old rotten muck; but notwithstanding these favorable appearances, unless very large quantities were applied, little benefit was derived from them; and even from 40 to 50 cart-loads to the imperial acre did not produce the good effects of 12 cart-loads of good muck. I could have managed the manual part of the work to any extent, for hired laborers could have been found to do it by piece-work, and the bog-turf was obtained on that condition; but the horse-labor was overpowering, for every acre thus required a cartage of 80 to 100 loads to provide no more than sufficient manure for it. An extra pair of horses could not have overtaken the additional labor thus imposed on the horses, and to incur that expense continually for the problematical good to be derived from the largest source of materials I possessed, namely, grassy-bog-turf, and peat-turf, was more than the most sanguine farmer is warranted in risking.

(1865.) It may, perhaps, prove interesting to relate a few of the composts I made with those materials. 1. The first was a compound of peat-turf and lime-shells. The turf was wheeled to the margin of the bog on hard land, and allowed to lie some weeks, to drip the water out of it, and to make it lighter for cartage. The lime was mixed in the proportion of 1 cart of lime to 27 of turf. After the compound was twice turned, the mass became a fine greasy pulp in the course of a few weeks in spring and the early part of summer—so greasy that no one could walk on it without slipping. It was applied to good turnip land, to raise turnips, and the rule adopted to determine the quantity requisite for an acre was, in the first place, to fill the drills with it, and the quantity required to do this was from 30 to 40 double cart-loads per acre. The crop of white turnips was only tolerable, and certainly not nearly equal to what was raised in the same field with 12 loads of farm-yard dung, while the field became troublesomely covered with the bog-thistle, as also the common field-thistle, and a few of the bur-thistle, the lime not having been in sufficient quantity to destroy the vitality of the thistle-seed contained in the turf, though the degree of heat created in the mass to reduce it to a pulp was considerable. 2. Another compost was made of peat-turf and farm-yard dung, with a sprinkling of lime, as directed by the late Lord Meadowbank in his celebrated treatise on that subject, and which you may consult.* The effect produced from this was better than the former compost, but still not equal to the usual quantity of dung. 3. A mixture of lime and black mould, on some head-ridges that had too much earth accumulated upon them, was only applied before the land was drilled up and dunged for turnips, to thicken the soil; and labor such as this is not thrown away. 4. I tried a compost of rape-cake and earth, the compound was not proportioned, but enough of the cake was sprinkled on while the earth was turning over, to bring a very brisk fermentation to the mass. After the heat had nearly subsided, it was applied for turnips, and with much success. I may mention that no accoun

* Meadowbank's Direction for Preparing Manure from Peat, edition of 1843.

was taken of the exact number of cart-loads per acre of this or any other of the composts that were applied, such particulars being seldom noted by farmers, who are chiefly guided by judgment in the quantity of manure which any crop should receive. 5. Shell-marl and bog-turf, when mixed, produced no heat, and of course were never reduced into a uniform mass, for without the agency of heat it is impossible to make any compost homogeneous. 6. The bog-turf burnt in the form of kilns, produced ashes which varied much in their specific gravities; those of a white color being light and ineffective as a manure, while the red color were heavy, earthy in appearance, and well suited to raise turnips; but I was unable to distinguish beforehand which turf yielded the white and which the red ashes. The trouble attending the casting of the turf in the bog, wheeling it to the side, exposing it to the air to dry, and afterward either burning it to ashes, or carting it away for compost, was much greater than the quantity of ashes obtained, or the quality of compost formed would remunerate. Two years' labor with this concoction of materials were sufficient to give me a distaste for the business, and at length I dropped it, and preferred going into the neighboring towns to purchase street and stable and cow-house manure, and bone-dust. These never disappointed me, and the eating off of the turnips which they raised every year with sheep, soon put the soil in a fertile state. Notwithstanding this resolution, I made a point every year of making up a large compost-heap of the quicken gathered from the fallow land, as it was preparing for the turnips—of the potato-haulms as they were harrowed together—and of the dried leaves in autumn, which would otherwise have blown about the lawn and shrubberies—and of any other refuse that could be collected together on the farm. These with the assistance of a little fresh horse-dung, and such water as the liquid-manure tank, which was situate in the compost court, afforded, a compost was formed every year, which assisted in extending the boundaries of the turnip crop; and if that portion of the crop was not always heavy, the greater or less proportion of the turnips eaten off by sheep enabled it to produce its share of the succeeding corn crops and grass, while, at the same time, the soil was thickened by the mould reduced from the compost. 7. Any of the animals that fall by disease, when their carcasses are subdivided, and mixed in a large quantity of earth powdered with a little quicklime, will make a compost far superior to any of the preceding vegetable materials, for raising turnips, especially Swedes. 8. The produce of privies, and pigeons' dung, as well as the dung of fowls from the hen-houses, form excellent ingredients for putting into the tank of liquid manure to melt, and afterward to distribute it over a compost. 9. Of late years saw-dust, which was long considered a useless article, and which may be obtained in quantity on some farms where saw-mills are at work, is now rendered useful in compost by being mixed with farm-yard dung, fermented to a considerable degree of heat, and then subdued with water;* and it may also be mixed with $\frac{1}{10}$ of its proportion of lime and road scrapings, and turned and kept in compost for 3 years.† Such a compost has raised crops of turnips, as evidenced by Mr. William Sim, Drummond, Inverness-shire, and Mr. H. H. Drummond of Blair-Drummond, Perthshire. 10. Spent tanner's-bark, when laid down for a time on the road around the steading and trampled under foot and bruised by cart-wheels, and then formed into a compost with either dung or lime, and allowed to stand for a considerable time, might be rendered into good manure for turnips. Saw-dust and tanner's bark, or refuse of the bark of fir-trees, will not bear the expense of a long

* Prize Essays of the Highland and Agricultural Society, vol. xiii. † Ibid., vol. xvi.

carriage; but where a supply of them is near at hand, their decomposition, though occupying a long time to effect, is worth the trouble. 11. In the vicinity of villages where fish are cured and smoked for market, refuse of fish heads and guts, or liver and oil refuse, make an excellent compost with earth. Near Eyemouth and Burnmouth, on the Berwickshire coast, 30 barrels of fish refuse, with as much earth from the head-ridges as will completely cover the refuse, is suffcient dunging for an imperial acre. The barrel contains 30 gallons, and 4 barrels make a cart-load, which sell for 1s. 6d. per barrel. From 400 to 600 barrels may be obtained for each farm in the neighborhood in the course of the season. 12. Whale-blubber when mixed with earth forms a good compost for turnips. As this is a most caustic substance in a fresh state, it should be compounded with a large proportion of earth, and turned over and kept for at least 3 years until the compost becomes inert. I have seen a blubber compost, 2 years old, applied as top-dressing on grass, burn up every plant by the roots, but after it becomes apparently effete it raises excellent turnips. 13. I have heard of a compost being made of whin and broom cuttings and earth, 3 loads of earth to one of the cuttings being mixed together and watered for 2 or 3 days, and to remain untouched for 8 or 10 days more, when it is turned and again allowed to rest for 10 days, when it is fit to be applied as manure. The cost of making this compost was estimated at 2s. per cart-load, and it is said to have raised wheat and oats well. But the fish refuse which I noticed before is to be obtained at some places at 2s. a load, and there can be no comparison in the relative value of it and the cuttings. You thus see how endless is the subject of composts for manure; and it is obvious, from what has been said, that the kind of compost which you may make depends entirely on the nature of the materials which can be supplied in your immediate neighborhood.

(1866.) So numerous are the articles which are now presented to the notice of the farmer in the name of manures, that but to notice each shortly would occupy many pages; nor is it incumbent on me to describe them at present, as the greatest number have yet to establish a character for themselves by repeated experiments in successive years. This will, no doubt, put some of them to too severe a trial; but it will be necessary, inasmuch as they may not be able in the second year to confirm the pretensions they assumed in the first. I remember of a compound which became celebrated some years ago, after one year's trial, for the turnips raised with it were really good, and could have stood a comparison with those grown by the best muck of the farm; but, alas, in the second year, even, the substance was almost a complete failure—not that the original composition would have failed in the second any more than it did in the first year, but the demand for it in the second year had probably increased so much in consequence of the success attending its use in the first, that the manufacturer, to supply the market with the desired *quantity*, had taken the liberty to injure its quality; and the consequence to him was exactly what he himself might have anticipated: the farmer lost faith in the manure and distrusted the manufacturer. I was induced by a flaming advertisement which appeared constantly in the papers at the time, to try a compound manure; but in this substance I was only once deceived—"once and for aye," for in truth it had no better effect in raising turnips, for which it was specially recommended, than black mould which was tried alongside of it. Such results as these should induce caution in the use of compound manures, the composition of which is unknown to you; still it is right to try them, as some one may turn out to be a really valuable substance; but the trials should be made at first on a small scale, if

you are among the first to try it; but if you hear of others having succeeded, then, of course, your confidence may be yielded to it with the greater safety. To make known whether any new substance has succeeded or not, I think it is incumbent on every farmer to do so for the sake of his brother farmers, and there are now many publications which devote themselves to the promulgation of rural practice. But I have been of opinion for many years that no farmer should purchase any compounded substance advertised as a manure, unless it happens to be a natural substance; for, even in the hands of honest men, compounds may fail to continue to afford the satisfaction they once did, as carelessness in compounding an article that is much in demand, and of which large quantities are made at a time, is a very natural and not an uncommon consequence. Besides, failure in a case of this kind is a very serious matter to the farmer. It is not merely the value of the article itself which constitutes his entire loss, though even that may be considerable, but the consequence to future years. The crop immediately dependent on the manure is not only deficient, but *the remaining part of the deficient crop is always of inferior quality.* This is an invariable effect in every crop; and its converse being equally true, that a full crop is always one of fine quality, and not only this, but every crop in the course of the rotation is affected by the state of the one which directly receives the manure, that is, if the fallow crop, as the turnip crop is called, be deficient and of inferior quality, the succeeding ones will not exhibit that vigor of growth by which a full fallow crop is invariably succeeded. I do not pretend to explain the cause of this result, nor have I ever seen it attempted to be explained, but as a *fact* it is indisputable, and I have heard the fact noticed by many farmers. You thus see how very much it is for your interest to be assured of the efficacy of every manure that you are to apply. To be assured of their efficacy, it has been recommended to analyze every manure before it is applied, in order to ascertain whether it is really the article it is given out for. As an instance of the necessity for such analysis, I will quote a case or two adduced by Mr. Madden. He says: "Three different specimens of nitrate of soda were submitted to analysis, when they were found to contain respectively 14, 25 and 26 per cent. of common salt. Now these specimens were purchased from extensive dealers in the article, and were contained in the bags in which it was imported, so that we have no reason for suspecting the honesty of the retailer; and it follows, therefore, that this shameful amount of adulteration must be effected prior to its being shipped for Britain. I would desire that you bear in mind, however, the fact that the presence of common salt, even to this enormous extent, may be natural, but yet the imposition upon the British farmer is equally glaring, whichever be the case, as will be seen by the following statement regarding saltpetre. This article, likewise, contains common salt, though in much smaller quantities; but in this instance the fact is not attempted to be concealed. Every cargo is analyzed at the India House before it is sold, and the per centage of salt marked upon it; and the amount of salt is deducted from the lot purchased. For example, suppose the saltpetre contained 10 per cent. of salt, if the purchaser buys 100 cwts. he receives the 100, but only pays for 90. Hence, therefore, there is no deception; but we would ask how it happens that the same is not done with the nitrate of soda, and that those specimens containing from 14 to 26 per cent. of salt, should all be sold at one and the same price? Why, if justice were done in this case, the specimen containing 26 per cent. should have sold at 22s. in place of 25s., if that be the fair price for the lot containing 14 per cent.; and if, on the contrary, 25s. is the proper price for the pure ar-

ticle, these three lots should have sold respectively at 21s. 6d., 18s. 9d., and 18s. 6d. per cwt." I may here mention, casually, in regard to the presence of salt in both the saltpetre and nitrate of soda, that it must be natural, and not placed there by human agents; for common salt in the countries whence these articles are imported, is much higher priced than the articles themselves. Strictly in connection with the purity of manures is the price demanded for them of the farmer. If other articles are charged in the same proportion as saltpetre is, as is shown by the following statement of Dr. Madden, the profits of the manure-dealer must be much greater than those of the farmer, even after all the risk he runs in using manures unknown to him. "Before leaving this interesting subject," continues Dr. Madden, "I would make one other observation, viz., concerning saltpetre. I find by reference to the most extensive purchasers of this article, that it sells at the India House in 5-ton lots at a price varying from 25s. to 29s. per cwt.; whereas it is retailed to farmers at the enormous charge of from 50s. to 55s. For example, I analyzed a specimen sold to a farmer at 55s. per cwt., and detected 2 per cent. of salt in it; whereas another specimen, purchased at the India House at 28s. 6d. per cwt., contained less than 1½ per cent. of salt; and, be it remembered, the lots were purchased at nearly the same time, during which there had been little or no fluctuation in the market." In a note, Dr. Madden mentions the practice of an extensive dealer in nitrate of soda in England, that he examines whatever he buys, and finds the average amount of salt to be from 8 to 10 per cent., and that he rejects as "*useless stuff*" any lot containing over 13 per cent.* The purity of so simple a substance as saltpetre or nitrate of soda can at once be ascertained by analysis, but the case is rather different with many of the compounds at present offered to the acceptance of farmers; their analysis can hardly prove so satisfactory. If experiments are to be made with substances extraneous to the farm, I think that chemist would act most judiciously who would suggest a mixture of a few of those simple substances which he conceives would benefit any particular crop, or the whole series of crops usual through a rotation, rather than any compound, however high sounding. A farmer can at once see what he is about when he himself forms a compound of various simple substances, differently proportioned, as suggested to him by an intelligent chemist. He can purchase each of these in as pure a state as they usually are made by practical chemists, who make them on a large scale. He himself does not know what may be the result of their application; he only expects results such as he is led to expect from the information given him by the chemist; but, working as he does, even in the dark, when he works under the guidance of a scientific man, who has no interest in the materials he recommends, he has confidence in what he is about to undertake, because he considers himself as his own agent in the business, purchasing simple ingredients, the nature of which is known to every one, and the commixing of which has been performed under his own eye. Far different is the case when he employs an article the purity or impurity, the efficacy or inefficacy, of which is equally unknown to him, and in the application of which he cannot anticipate a single result. Till some such plan is established for the use of extraneous manures, their results will be determined by mere chance, and the confidence of the farmer in them will fluctuate every year as the result turns out favorably or otherwise, till at length the use of them will be abandoned with contempt. All *natural* substances used as manure, such as bones, gypsum, guano, nitrate of soda, &c., are not the objects of the foregoing remarks; but

* Prize Essays of the Highland and Agricultural Society, vol. xiv.

should it be objected that the substance of the compound manures, being themselves natural compounds, cannot be sold as simple substances, it may be answered that all the natural compounds which they contain, by being rendered dry or concentrated, could be sold as natural compounds, which may perhaps become equally valuable as others; but as long as they are mixed up with other matter, no one can say whether the valuable or valueless materials in them predominate.

(1867.) A simple list of the various ingredients at present in the market for the use of farmers will puzzle you as to the choice you should make among them. The names and prices are taken from the Mark-Lane Express of 24th April, and the New Farmers' Journal of 8th May, 1843. They are as follows:

Animalized black, £3 3s. to £3 5s. per ton at Dunbar.
Agricultural salt, 34s. per ton.
Chie-fou, 21s. per cwt.
Clarke's desiccated compost, £3 12s. 6d. per hhd., sufficient for 3 acres.
Chloride lime, 28s. per cwt.
Daniell's new Bristol manure, 8s. per qr.
Graves, £6 10s. per ton.
Gypsum at the water-side, 32s. 6d. per ton; land and housed, 38s. to 42s. per ton, according to quantity.
Grimwade's preparation for turnip-fly, 10s. 6d. per packet, sufficient for 3 acres.
Guano, 10s. to 14s. per cwt., according to quality.
Hunt's bone-dust, 18s. per qr.
Hunt's half-inch bone, 16s. per qr.
Hunt's artificial guano, £8 per ton.
Hunt's new fertilizer, 13s. 4d. per qr.
Lance's carbon, 12s. per qr.
Lance's humus, 14s. per qr.
Liverpool Abbattoir Company's animalized manuring powder, £2 10s. per ton.
Muriate of ammonia, 24s. per cwt.
Muriate of lime, 12s. per cwt.
Nitrate of soda, 18s. to 18s. 6d. per cwt., duty paid.
Nitrate of potash (saltpetre) 26s. 6d. per cwt.
Owen's animalized carbon, 25s. per ton. free on board at Copenhagen.
Potter's artificial guano, 15s. per cwt.
Poittevin's patent disinfected manure, 13s. 6d. per qr.
Poittevini's highly concentrated manure, 30s. per qr.
Petre salt, 4s. per cwt.
Rape dust, £7 to £8 per ton.
Rape-cake, £6 10s. to £7 per ton.
Rags, £4 to £4 10s. per ton.
Soda ash, 14s. to 16s.
Sulphuric acid, 2½d. per lb.
Sulphur for destroying worms in turnips, 16s. per cwt.
Soap-ashes, 10s. per ton.
Sulphate of soda, 7s. 6d. per cwt.
Sulphate of ammonia, 18s. per cwt. at Dundee.
Trimmer's compost for clover, wheat and turnips.
Urate of the London Manure Company, £5 per ton.
Watson's granulated compost, 10s. per cwt
Wolverhampton imperial compost, (Alexander's,) 12s. per qr., subject to carriage to London, or forwarded from Wolverhampton.
Willey dust, £4 4s. per ton.
Wright's alkalies, 28s. to 42s. per cwt.

The following are the weights per bushel of some of the substances enumerated above:

	Per bushel—lbs.	lbs.
Agricultural salt	75	to 80
Alexander's compost	65	
Bone-dust	42	to 44
Clarke's desiccated compost	60	to 65
Daniell's Bristol manure	50	
Guano, foreign	56	
—— Potter's	65	
Gypsum	80	to 84
Hunt's new fertilizer	65	
Muriate of ammonia	65	to 70

	Per bushel—lbs.	lbs.
Nitrate of soda	80	
Petre salt	75	
Rape-dust	56	
Saltpetre	80	
Soda-ash	60	
Sulphate of ammonia	70	
—— of soda	60	to 65
Trimmer's compost for clover, wheat and turnips	60	to 65
Urate	50	

(1868.) To reduce farm-yard dung to the saponaceous state recommended and described in (1863). is contrary to the theory propounded by non-practical writers; and for the ordinary manuring of the farm, the recommendation, it may be acknowledged, is carried to an extreme; but for the purpose of raising a good crop of turnips, and especially of that invaluable kind the Swedish, it is beyond dispute that no manure, of whatever kind, is so congenial to their constitution as well-made old muck. Until, therefore, a substitute is found for this ingredient, equal to it in efficacy, and as attainable, it will be made and applied by every farmer who is desirous of raising a good crop of Swedish turnips. The recorded opinions of Sir Humphry Davy on this subject, though oft referred to to caution practical men against his conclusions, nevertheless deserve examination, because of the common-sense like manner in which he states his views, and on this account these should be the more explicitly refuted; and that they will one day be refuted I have no doubt, for I am persuaded that where practice and theory disagree, theory will be found to be in the wrong. In regard to the general principle of the action of vegetable manures, he says: "There can be no doubt that the straw of different crops, immediately plowed into the ground, affords nourishment to plants, but there is an objection to this method of using straw, from the difficulty of burying long straw, and from its rendering the husbandry foul." You observe at once, here, that the theory

of the use of clean straw as a manure is objected to solely on the score of a difficulty of using it in that state in practice. If *such* an objection may be valid against the use of straw, so may it be against the use of unfermented dung. If practice is to be respected in this instance, why not in the other; but Sir Humphry proceeds to render the straw more manageable when he says—"When straw is made to ferment, it becomes a more manageable manure; but there is likewise, on the whole, a great loss of nutritive matter. More manure is perhaps supplied for a rough crop; but the land is less improved than it would be supposing the whole of the vegetable matter could be finely divided and mixed with the soil." Here the remark suggests itself, that if straw is allowed to be fermented because of its being more manageable in that state for practice, so might dung be allowed to be more fermented for the same reason. If deference is paid to practice in one case, why not in the other? To obviate the inconvenience of burying long straw, Sir Humphry recommends it to be chopped thus: "It is usual to carry straw that can be employed for no other purpose to the dunghill to ferment and decompose; but it is worth experiment whether it may not be more economically applied when chopped small by a proper machine, and kept dry till it is plowed in for the use of a crop. In this case, though it would decompose much more slowly, and produce less effect at first, yet its influence would be much more lasting." I have no doubt that chopped straw would raise potatoes on strong clay land, and when applied on summer-fallow a good crop of wheat would also be raised; but in all free soils, straw, in whatever state, whether long or chopped, would only keep the soil so open as to let in drouth, retard vegetation, and it would be found lying at the bottom of the furrow in an inert state, as useless, in short, as *fire fanged* straw. In regard to the fermentation of farm-yard dung—which is a composite manure—Sir Humphry admits the propriety of its undergoing a slight fermentation, as thus: "A slight fermentation is undoubtedly of use in a dunghill; for by *means of it* a disposition is brought on in the woody fibre to decay and dissolve, when it is carried to the land or plowed into the soil, and woody fibre *is always in great excess* in the refuse of the farm." So that fermentation in the dunghill is necessary to the dissolution of woody fibre, and as woody fibre is in great excess in the refuse of farms, it follows that fermentation ought to be generally allowed in dunghills, so that the question of fermentation here is only one of degree. "Too great a degree of fermentation is, however, very prejudicial to the composite manure in a dunghill; it is better that there should be no fermentation at all, before the manure is used, than that it should be carried too far. The *excess* of fermentation tends to the *destruction and dissipation of the most useful part of the manure*; and the ultimate results of this process are like those of combustion." If it is here meant to convey the idea that *fire fanged* dung is fermentation to excess, the idea is correct, for I suppose no farmer thinks otherwise; but that the usual degree of fermentation allowed in dunghills renders the manure useless, is inconsistent with experience. It is quite true, as Sir Humphry says, that "it is a common practice among farmers to suffer the farm-yard dung to ferment till the fibrous texture of the vegetable matter is entirely broken down, and till the manure becomes perfectly cold, and so soft as to be easily cut by the spade;" but so far from the most useful part of the manure being dissipated when the dung attains this state, experience assures us that the finest Swedish turnips cannot be raised with dung in a less elaborated state; and this conclusion is inevitable, that if the most valuable part of the manure *is* dissipated by the fermentation usually allowed in dunghills, that most valuable part is not required for raising the best crop of Swedish turnips, and that being the case, it is unnecessary to trouble ourselves to retain it. But what are the best parts of manure? "During the violent fermentation," says Sir Humphry, "which is necessary for reducing farm-yard manure to the state in which it is called *short muck*, not only a large quantity of fluid, but likewise of gaseous matter, is lost; so much so that the dung is reduced one half to two-thirds in weight; and the principal elastic matter disengaged is carbonic acid with some ammonia; and both these, if retained by the moisture in the soil, are capable of becoming a useful nourishment of plants." No doubt both the fluid and gaseous products of decomposing vegetables perform important functions in the economy of Nature, but if they escape while dung is preparing in the best state for use, according to invariable experience, it follows, as an inevitable consequence, that these products of fermentation are *not requisite, in conjunction with short muck*, to raise a crop of turnips. They may be useful ingredients for other purposes, and at other times, but it is clear that the turnip crop can be raised to a better state without than with them. Why, therefore, attempt to retain their presence on the particular occasion?*

(1869.) Whether a more scientific mode of forming dunghills, in consonance with practice, will ever be discovered, I cannot pretend to say; but, as there seem no bounds to the discovery of science in other arts, we should not limit its powers of application to the art of husbandry. Experiments are at this moment in progress on the very subject of the formation of farm-yard dunghills, in connection with which I may mention the distinguished name of Professor Henslow, of Cambridge, who, in a series of letters addressed to the farmers of Suffolk, and which have appeared in the public prints, suggests the propriety of their performing experiments to ascertain whether the ammonia which escapes in the gaseous state as a carbonate of ammonia may not be retained in dunghills by the instrumentality of gypsum? Should the event prove successful, we may perhaps expect to hear of important improvement in the management of ordinary dunghills. Till the experiments are tried, which time alone can do, I am happy in placing before you the opinion of so distinguished a philosopher as Professor Sprengel on the *value of old dung*, when he says in his valuable essay on manures, which ought speedily to appear in an English dress, that "the longer the dung is left in the dunghill, the more advantageous will be the preparation of the compost, because the ammonia, disengaged from the dung and urine in it, will become chemically combined with humic acid." It will be observed that these sentiments bear a strong analogy to the subject which engages the attention of Professor Henslow. As a satisfactory conclusion to the theoretical part of this subject, I give you the following explanation of the fermentation of manure, and its effects, by Dr. Madden.—[Whenever dead organic matter, either animal

* Davy's Agricultural Chemistry, edition of 1839.

or vegetable, is exposed to air in a *moist* state, it absorbs oxygen, which, by entering into combination with its carbon, destroys its original composition, and gives rise to the production of various new compounds, which in their turn suffer decomposition by means of fresh supplies of oxygen being absorbed, and so on in a continued series until the whole mass is reduced to chemical compounds of such stability as to resist the farther action of oxygen under ordinary circumstances.—During this series of changes, the various solid compounds are converted first into fluid and then into gaseous products; which latter, by escaping into the air, become lost. Chemists are much divided as to what precise amount of decomposition is requisite to render organic matter in a proper state to become food for plants; all agree that decomposition must have *commenced*, some maintain that it must be *completed*. My own belief, founded on extensive observation and not a few experiments, is, that *all the products of decomposition, in every stage, are available as food for plants, provided they are either liquid or capable of dissolving in water*. These observations will, of course, regulate us in the management of the "midden." Whenever any moist organic matter absorbs oxygen, its chemical union with its carbon gives rise to an increase of temperature, which increase enables the surrounding portions to absorb oxygen more rapidly than they otherwise would do; these parts in their turn become heated, and thus the influence extends through the entire mass—the amount of heat being proportionable to the size of the mass, its degree of moisture, and quantity of air contained within its interstices. By careful management, you can retard or accelerate the fermentation of your "midden" to almost any extent, from scarcely any change taking place, to so great a rapidity as to endanger the whole taking fire from the heat evolved. The most profitable way for dung to ferment is slowly but steadily, so that by the time it is required for use, it will readily cut with a spade like soft cheese, and exhibit a uniform rich brown color, and emit no smoke unless the air be very frosty. During fermentation, the azote contained in the various constituents of the dunghill unites with hydrogen, and forms ammonia or hartshorn, which, being very volatile, is apt to escape with the watery vapor and other gaseous products of decomposition. Various means have been of late recommended to prevent this, but none of them appear to me at all satisfactory, and I believe have not as yet given very satisfactory results when applied to practice. The best condition for a "midden" to be in is when it contains a sufficiency of water to cut moist, and yield a little liquid by pressure, but not enough to run from it spontaneously; this is easily effected by draining the "midden" stance, if in the court, so that all superfluous moisture runs off into the drains, which, of course, must lead to the liquid manure-tank, from which in dry weather it should be pumped up and scattered uniformly over the "midden"; in this state of moisture, scarcely a perceptible quantity of ammonia is lost, as it all remains in solution; and I believe that this plan will be found in all cases to be superior to every other hitherto devised for preserving farm-yard dung.—H. R. M.]

17. PLANTING POTATOES.

"——— the potato plat
Should now be delved, and, with no sparing hand,
Manured: ———
The dibbling done, the dropping of the chips
Is left to little hands, well pleased to lend
Their feeble help: ———"

GRAHAM.

(1870.) The potato crop is cultivated on what is called the fallow-break or division of the farm, being considered in the light of a green or ameliorating crop for the soil. Following a crop of grain, whose stubble is bare in autumn, the soil is plowed early in the season, that it may receive all the advantages which a winter's sky can confer it in rendering it tender; and as potatoes affect a dry and easy soil, the piece of land intended for them may be plowed and even partially cleaned in spring. Time for *cleaning* is very limited in spring, and on this account the cleanest portion of the fallow-break should be chosen for the potatoes to occupy. The stubble will either have been cast, fig. 135, in autumn, or clove down without a gore-furrow, fig. 140, according as the soil is strong or free; and having been particularly provided with gaw-cuts, to keep the land as dry as possible all winter, for a crop which requires early culture in spring, as potatoes do, it is probable that the land thus appropriated will be able to be cross-plowed, fig. 312, soon after the spring wheat and beans are sown, if either is cultivated on the farm, and if not, the cross-plowing for potatoes constitutes the earliest spring work after the lea. After the cross-furrow, the land is thoroughly

harrowed a double tine along the line of the furrow, and then a double tine across it, and any weeds that may have been brought to the surface by the harrowing are gathered off, along with any isolated stones that would appear unseemly on the surface. If the land is clean, it will be ready for drilling; if not, it should receive another plowing in the line of the ridges, that is, across the cross-furrow, by being ridged up in casting, and then again harrowed a double tine along and across, and the weeds again gathered off. Should the surface be dry after the harrowing which succeeded the cross-plowing, and the weather appear not likely to continue dry, the grubber will be a better implement to give a stirring to the soil than the plow, as it will still retain the dry surface uppermost, and it will also bring up to the surface any weed that would entangle itself about the implement. The two-horse grubber is an excellent implement for stirring the soil when it has become somewhat solid by rain or by lying untouched for a time. The time occupied in doing all this, as the weather will permit, may be about a month, that is, from the middle of March to the middle of April, when the potato crop should be actively preparing for planting. As the land cannot receive more plowing in early spring than it should, to stir the land a little more, and make it still more tender, the drills first made for securing the manure of the potato crop should be set up in the double mode, as particularly described in (1740) and (1741).

(1871.) The state of the potatoes, when taken out of the pit, will depend on the temperature of the weather in spring, and also on the state they were in when pitted in autumn. In cold weather, they will not be much sprouted in the pit by the time they should be planted; but should they have been heated at all, in consequence of the wet state in which they had been pitted, or the unripe state in which they had been taken up and pitted, they will be sprouted independently of the temperature of the external air. When the sprouts are long, they should be removed, as it will be impossible to preserve them entire; but if the quickening of the tubers be mere buds, these can be preserved; and they are of advantage, inasmuch as they will push above ground several days sooner than sets that are not sprouted at all. It should be kept in mind, however, that sets with long sprouts, and sprouted sets which have been long kept after being taken out of the pit until planted in the field, are apt to set up puny plants. In selecting tubers, therefore, to cut into sets, the middle sized that have not sprouted at all, or have merely pushed out buds, will be found the soundest; and wherever the least softness or rottenness is felt, the tubers should be entirely rejected, and even the firm portion of these should not be used as seed. The small potatoes should be picked out and put aside to boil for poultry and pigs. Those potatoes which are not required for seed, but are nevertheless firm and of good size, whether intended for sale or for use in the farm-house, should be placed in an outhouse, until disposed of or used—the apartment having, if possible, an earthen floor, and kept in the dark, though with access to the air, and water thrown upon the potatoes occasionally, to keep them crisp, but not at all moist, and turned carefully over by hand, when the sprouts are taken off.

(1872.) To insure the vitality of the sets in the ground, even when planted under adverse circumstances, it has been recommended to dust them with slaked lime immediately on the potatoes being cut; and the sap, on exuding from the incised part, will then be immediately absorbed by the lime, which, on forming a paste, incrusts itself on the incised surface.* Others recommend to dip the sets in a thick mixture of lime and water, which, on drying, envelops them in a coating of plaster. This lay-

* Prize Essays of the Highland and Agricultural Society, vol. xiv.

its proper place. If the carts are *whole*-bodied, the steward proceeds, after the back-board is removed, to hawk out the dung; but if they are tilt or *coup*-carts, he elevates the front a few inches, by means of the hesp attached there, that the dung may be hawked out the more easily. The wheels of the cart and the horse occupy 3 drills, as at *i*, the horse being in the middle drill between them. The steward *h*, with the hawk in both hands, pulls out a heap of dung *i* upon the ground, and it invariably falls into the middle drill. The horse is then made to step forward a few paces and to halt again, by the voice of the steward, who then pulls out another heap of dung. An active man, accustomed to this sort of work, does not allow the horse to stand still at all, but to walk slowly on while he pulls out the dung. When the cart is emptied, the steward fastens down the body of the cart, if it is a coup one, puts on the back-board, and the cart again proceeds by its driver to the dunghill. When the distance to the dunghill is short, the carts are as slightly filled as to dispense with the back-board altogether; and when it can be wanted, labor is considerably expedited. After the cart has proceeded a few paces, and deposited a few heaps of dung, the foremost of the band of 4 women who spread the dung, as *k*, divides the heaps, as at *m*, with her small common graip into other two heaps, *l* and *n*, one in each of the drills beside her; and from *m* she goes to the next heap *i* and divides it into other two heaps, and so on with every heap of dung. The 3 field-workers, *n o p*, having each a small graip, fig. 151, then take each 1 of the 3 drills occupied by the horses and cart-wheels, and all spread the dung before them equally along the bottom of the drills *l m n*, each taking care to remain in her own drill from the one end of the field to the other, shaking to pieces every lump of dung, and teazing out any that may happen to be ranker than the rest, trampling upon the spread dung as she walks along the bottom, and keeping it within the limits of the drill. Meanwhile the plowman *a* makes double drills from *b* to *c*, if they have not been already formed, and proceeds with the making of them toward *e* and *d*. Immediately that a part of 3 drills are dunged and the dung spread, the potato planters, after having plenished their baskets or aprons with sets from the cart *t* upon the head-ridge, proceed to deposit the sets upon the dung along the drills, at about 8 or 9 inches apart. Some women prefer to carry the sets in coarse aprons instead of baskets, because they are more convenient. As setting requires longer time than dung-spreading, there should be two sets of planters, as at *r* and *s*, to one set of spreaders—that is, 6 planters to 4 spreaders. One set of planters, as *s*, go in advance of the other, *r*, till the latter comes up to the place where the former began, and then the set *r* goes in advance, and so one set after another goes in advance alternately, each set filling their baskets and aprons as they become empty, but all confining their labor to 3 drills at a time. Whenever 3 drills are thus planted, the plowman *u* commences to split the first and cover in the dung and sets in the double way. The drills are split in the same way as they were set up—that is, as the plowman *a* turns over the first furrow of each drill upon the plain ground, stretching from *a* to *e*, so the plowman *u*, in splitting the drills, turns over the first furrow upon the dung toward the planters *r* and *s*; because the *first* furrow being the largest, it should have complete freedom to cover the dung and sets. If the land had been sufficiently worked in spring, so as to be tolerably clean and free at the time of planting the potatoes, the plowman *a* may make up the drills in the single way, that is, making one drill in going away, as he is represented in the cut, from *b* to *c*, and returning with another drill in coming from *d* to *e*, because single drills will be sufficiently deep to contain the dung within them. Pota

toes always receive a large dunging, they being in the first place a fallow crop, when the ground is entitled to be dunged, and, in the next place, they are considered a scourging crop to the land, that is, taking much nourishment out of it, and returning little or nothing to it—yielding no straw but a few dry haulms, and the greatest proportion of the entire crop being sold and driven away from the farm. A large dunging to potatoes always *seems* great, for time is wanting to make the dung short, and, of course, to reduce its bulk in the dunghill. About 20 single-horse loads, or 15 tons, to the imperial acre, is as small a dunging as potatoes usually receive of farm-yard dung. In the neighborhood of towns, street-manure, to the extent of 30 tons per imperial acre, is given; but there the crop is forced for an early market, and the street-manure has not the strength of farm-yard dung, and indeed is found to be not nearly so good for them as for turnips. The spreading should be kept up as close to the cart as possible. The plowman *a* should not leave a single drill uncovered in the evening when he gives up work. If he cannot possibly split all the drills in the double way, he should cover up the dung and sets of a few drills at the last in the single way; or he should receive assistance from the plowman *a* to split them all completely, if he sees the weather showing symptoms of rain or frost. And even at the loosening from work at mid-day, or forenoon yoking, every drill should be covered in, even though the plowman should work a while longer in the field than the rest of the work-people; for which disadvantage he should be as long of yoking after them; and he should make it a point to cover in the drills at the end of the forenoon yoking in a complete manner, when the weather is hot and dry; because dung is soon scorched by the mid-day sun, and its dry state is injurious, not so much on account of the evaporation of any valuable material from it, the material being chiefly water, but because it does not incorporate with the soil so soon and so well as damp dung; and when both soil and dung are rendered hot and dry by exposure, their incorporation is rendered very difficult. If all the plows cannot cover in the drills within a reasonable time after the loosening time arrives, especially at night, much rather give up the dunging of the land and the planting of the sets a little sooner than usual, than run the risk of leaving any dung and sets uncovered.

(1875.) You will observe that the process of planting potatoes, as represented in fig. 344, is composed of a variety of actions, which, taken individually, are equally important, and none of which can be carried on without the assistance of the rest, and all of which, if not proportioned to one another, would end in confusion. Thus, the plowing of the drills, the dunging of the land, the spreading of the dung, the setting of the potatoes, and the splitting of the drills, are all equally important operations in potato culture. None of them would be of any use without the rest. There would be no use of making drills unless they were to be dunged, nor would the planting of the sets avail unless the dung were spread, nor would the planted sets be safe, even on the spread dung, unless the drills were split to cover the whole from the weather. But if these component operations are not proportioned to each other, the whole operation is thrown into confusion. Suppose, for example, that the plowman *a*, while making double drills, could not keep out before the party that is spreading the dung, it is evident that every other party would be constrained by his tardiness, and made to lose time; and the remedy for this inconvenience obviously is, that the plowman should have as many double drills made before the dunging commences, as that he shall not be overtaken in the drilling; or that the plowman should make single drills, when he finds

the dunging gaining ground upon him; or that another plowman should be sent to assist him in making double drills. Suppose, again, that more carts are employed in conveying the dung from the dunghill than the steward *h* can possibly hawk out, or the 4 women *k n o p* possibly spread; or, the same effect would be produced by employing more people than necessary at the dunghill to fill the carts; the result would be that the steward and women would be overworked, while the horses driving the dung, and the people at the dunghill would be comparatively idle, and of course losing time. Suppose there are fewer planters at *r* and *s* than can keep out before the plowman *u*, then time would not only be lost in covering up as many drills as might be, but the dung spread would lie exposed to the desiccating action of the sun and air between the planters of the sets and the spreaders of the dung. Were there, on the other hand, too many planters for those who spread the dung to keep out before them, then the planters would be comparatively idle. Suppose, lastly, that the plowman *u* cannot keep up with the planters, who, nevertheless, do not proceed on their part faster than the dung is spread, the effect will be that the spread and planted dung will become dry before it can be covered up. The remedy for this inconvenience is either to employ another plowman to split in drills, or to make one plowman cover the dung with one furrow, and let another finish the drills behind him at his leisure.

(1876.) I have dwelt the more fully on these particulars, because potato planting is one of those great operations which are made up of a variety of constituent operations that are performed simultaneously, and unless they form a harmonious whole, tending in all its parts to a common end, the entire operation cannot be completed in the best manner; but wherever this harmony is seen to exist, it is a satisfactory proof that the person who has so arranged the working materials as to produce it, possesses the knowledge of combining varieties of field-labor. In effecting such an arrangement as the above, he displays knowledge of a superior order to that which is usually displayed in conducting potato planting. A very common mode of dunging potato-land, for example, is to hawk the dung out of the cart for 5 drills instead of 3, though 3, or even fewer, women are sent to spread the dung over them. In doing this, each woman's attention is not confined to a single drill, but must be extended over the whole 5, when each spreads the dung from the heap she takes possession of; and it stands to reason that she cannot spread dung so *equally*, and of course not *so well, over* 5 drills as *along* 1; and the work is not done better, though faster, even though the 3 women are all employed to spread from the same heap, as each has still the entire 5 drills to attend to. Besides, when dung is hawked out of the cart for 5 drills, it is usually laid in large heaps at considerable distances, at from 5 to 10 paces apart, thereby increasing the difficulty of spreading; and a large space of the ground being thus heaped over, before the dung is begun to be spread, by the time it is spread, and the sets planted, the dung will have become quite dry. This plan may excusably be adopted on a small farm, where laborers are few, and it is desired to conduct operations with what is considered economy, by the employment of as few hands as possible; but on a large farm it has the appearance of great slovenliness, and it certainly encourages carelessness in work, and evinces confusion of ideas in arranging it. It is no uncommon sight, even on large farms, to see the dung carted out and spread in one yoking, and the sets planted and the dung covered in another, by the same people and horses; doing a great deal of work, no doubt, in each yoking and during the entire day; but the result would be much more satisfactory were the entire work finished as it proceeded. A great

number of dunged drills are usually begun to be planted with sets at the same time, instead of confining the setting to a few at a time, to get them finished as soon as possible, to be covered with the plow. In short, there is no end to the *many* ways in which field-work may be done in a slovenly manner; but there is only one *best* way of doing it.

(1877.) Drills of potatoes are recommended to be made at 30 inches apart, instead of 27 inches, which is the usual width for turnips, because the large stems of the potato-plant growing vigorously require plenty of air. Even 3 feet apart is recommended by some cultivators, and in deep, rich soils this width may not be too great; but I observe that, in the neighborhood of large towns, where the greatest extent of ground is occupied by potatoes, the drills seldom exceed 24 inches, owing partly to the great value of land in that locality, and partly because the earlier varieties of potatoes, which have small stems, are most profitable to cultivate there. The drills for potatoes are usually not made so *very* regular in width as for turnips, because the seed is not planted by a machine. It is very easy to ascertain whether the exact quantity of manure desired to be given to the potato crop is actually given. Knowing the length of the drill and its breadth, a simple calculation will inform you of the number of drills in an acre, and, by apportioning the number of cart-loads that should be applied on every 3 drills, the requisite quantity per acre can at once be ascertained with great precision; and this as precisely on the very first 3 drills that are commenced to be dunged, as if the calculation had been made over a large proportion of the field.

(1878.) As to the varieties of the potato I would recommend for field-culture, I find it impossible to tender an advice, because it would not be generally applicable. I have seen a potato transferred from England, where it was a favorite, to Scotland, another variety transferred from Scotland to England, another from Ireland to Scotland, and in each case produce a very inferior crop in its adopted country to what it ever did in its native one; and even in a transference from one part to another of the same country, I have seen a material effect produced upon the plant, increasing it in one case and diminishing it in another. The general result is found to be an increase of produce and improvement of quality in transferring the potato from inferior to better soil, and from an elevated to a lower situation. The tendency of the potato to improve on being *thus* transferred, is taken advantage of in its attainment as seed. When I mention that there are upward of 100 varieties of *field* potatoes described by Mr. Lawson,* and as many experimented on by Mr. Howden, Lawhead, East-Lothian,† you will not be surprised that I cannot confidently recommend any particular variety for a particular locality. Nevertheless a *good* potato has certain characteristics which distinguish it everywhere from an inferior one. A desirable potato is neither large nor small, but of medium size; of round shape, or elongated spheroid; the skin of fine texture, and homogeneous; and the eyes neither numerous nor deep-seated. The habit of growth of its stem is strong and slightly spreading, and color lightish green. I believe that the intensity of the color of the flower is in some degree an indication of the depth of the color of the tuber; and I believe, also, that white potatoes are generally fit to be eaten when taken out of the ground, but that red ones are the better for being out of the ground for a shorter or longer time, before being used, according to the fineness of their texture. But color is by no means a fixed characteristic of any variety of potato, as it changes by cultivation and other circum-

* Lawson's Agriculturist's Manual, and Supplement.
† Prize Essays of the Highland and Agricultural Society, vol. xi.

stances. Mr. Lawson relates a curious circumstance which gave rise to a permanent difference in the color of the same variety of potato. "In the first report of Messrs. Dickson and Turnbull's Agricultural Museum at Perth," he says, "a remarkable instance is given of a *white* variety of the Perthshire *red* potato, being obtained by Miss Bishop, New-Scone, from a red potato with a white eye, which she carefully cut out and planted by itself, the result of which is that the produce has for several years retained the same color as the original eye, without the slightest appearance of change."* Before determining the properties of a potato in a locality, it is necessary that it exhibit the same character for 2 or 3 years in the same circumstances of soil, manure and culture, otherwise errors may be committed in your estimation of varieties. The *intrinsic* value of a potato, as an article of commerce, is estimated by the quantity of starch which it yields on analysis; but as an article of domestic consumption, the *flavor* of the starchy matter is of greater importance than its quantity. Almost every person prefers a mealy potato to a waxy, and the more mealy it is usually the better flavored. The mealiness consists of a layer of mucilage immediately under the skin, covering the starch or farina, which is held consistent by fibrous matter. Light soil raises a potato more mealy than a strong, and I suppose every one is aware that a light soil produces a potato of the same variety of better flavor than clay. So that soil has an influence on the flavor, and there is no doubt that culture has—for potatoes, whatever may be the variety, raised from soil that has been dunged for some time, are higher flavored than those grown in immediate contact with dung.

(1879.) The most common varieties of potatoes cultivated in the fields in Scotland, are the common or Edinburgh Dons, very plentiful in the Edinburgh market. It is round, and is an early variety; that is to say, the stems are entirely decayed by the time the tubers are fit for use. It produces about 16-fold of the seed, and yields 576 grains Troy of starch from 1 lb. of tubers. The Buff is a mealy and superior-flavored potato, yielding about 15-fold, and 466 grains Troy of starch from 1 lb. of tubers. The Perthshire Red, an oblong flat potato, is largely cultivated for the London market. It yields about 15-fold, and affords as much as 777 grains Troy of starch from 1 lb. of tubers. Of the late varieties, that is, those the foliage of which, in ordinary seasons, does not decay until destroyed by frost, and the tubers of which generally require to be kept for some time before being used to the greatest advantage, the Staffald Hall, or Wellington, as it is sometimes called, is to be preferred. It is represented to yield 22-fold, and affords 813 grains Troy of starch from 1 lb. of tubers. The Scotch Black potato has long been cultivated in Scotland; and it seems to suit strong soil better than light, where it yields as high as 16-fold of increase, and affords 522 grains Troy of starch from 1 lb. of tubers.† Of the late varieties for field-culture suited for cattle, the Irish Lumpers and Cups appear prolific. The Lumper is a white, oblong potato of very inferior flavor, but yields 421 bushels, and 3,118 lbs. of starch per *Scotch* acre, I presume; and the Cups are an oblong red potato yielding 479 bushels, and 3,539 lbs. of starch per acre.‡ On recommending any variety of potato, however, it should be understood that potatoes will not permanently maintain their preëminence at all places; on the contrary, a few years may witness their utter decline. The Leather-coats, for example, were a variety in very great esteem and in extensive cultiva-

‡ Prize Essays of the Highland and Agricultural Society vol. xi.

tion some years ago, and now are hardly known. The small American white potato was extensively cultivated in the midland districts of Scotland about 20 years ago, but has yielded some of its ground to more prolific varieties. For the table, however, when raised in hazel loam—the true potato soil—there are few varieties cultivated superior to it in flavor, richness and beauty as a dish. It is now, I believe, chiefly confined to the garden. The finest flavored and most beautiful potato I ever saw on the table was a light red, small, round variety raised a few years ago in the sandy soil of the parish of Monifieth, in Forfarshire. It had quite the *nutty* flavor of a *fresh* Spanish chestnut—a state of that fine fruit unknown in this country.

(1880.) There are other ways of cultivating the potato in the field besides the one I have described. When light soil, in which the potato thrives, is clean and in good heart, it is frequently dunged on the stubble in autumn, and plowed in with a deep, square furrow by casting with or without a gore-furrow, fig. 139. Abundance of gaw-cuts are made to let off superfluous surface-water in winter. It is then cross-plowed in spring, and harrowed a double-tine, when it is ready to be drilled up in the single form, the sets planted, and the drills split in the double form, to complete the operation. In the neighborhood of towns this is an expeditious mode of planting a large breadth of potatoes in spring on light soil, but it requires the land to be in *very good heart*. I have tried it on good land in middling condition, but could not succeed in raising much more than half the crop produced from dunging the same land in spring.

(1881.) There is a modification of this plan which may be practiced with success in very light soil, which is that after the cross-plowing and harrowing in spring, the land is ridged again by casting without gore-furrows in the opposite way it was cast in autumn when the dung was plowed in; and at every *third* furrow two women follow the plow, and plant the sets in the bottom of the furrow. If the furrows are held 9 inches wide, the distance between the rows of potatoes will be 27 inches; and if they are 10 inches wide, the rows will, of course, be 30 inches apart; so that this plan admits of the rows being made wide enough.

(1882.) There is a sub-modification of this last method, which is, that the dung is spread over the smooth harrowed ground after the land has been cast into ridges in spring, instead of being applied on the stubble in autumn. The dung is raked in and spread evenly along the bottom of every *third* furrow by a woman with the small graip, fig. 151, following the plow, and immediately preceding the planters, and the plow which follows the planters covers up the sets. In both these modes the potato plants come up in *rows upon the flat ground* at the same distance they do in drills, and after their stems have grown up in summer, the earth is plowed up toward them, so as to convert the flat ground into a drilled surface by the time the culture is finished.

(1883.) Another mode of the field-culture of the potato is in *lazy-beds*, a mode more generally practiced in Ireland than in any other part of the kingdom. This system, however, will likely become less general, being much condemned by the good farmers there. Nevertheless, on lea-ground and on undrained bogs the small farmer cannot, perhaps, pursue a better one. "In bogs and mountains," says Martin Doyle, "where the plow cannot penetrate through strong soil, beds are the most convenient for the petty farmer, who digs the sod with his long narrow spade, and either lays the sets on the inverted sod—the manure being previously spread—covering them from the furrows by the shovel; or, as in parts of Connaught and Munster, he stabs the ground with his *loy*, a long narrow spade pe-

culiar to the laborers of Connaught, jerks a cut set into the fissure when he draws out the tool, and afterward closes the set with the back of the same instrument, covering the surface, as in the case of lazy-beds, from the furrows. The general Irish mode of culture on old rich arable lea (a practice very common in the county of Clare, and elsewhere among the peasantry who pay dearly for old grass land,) is to plow the fields in ridges, to level them perfectly with the spade, then to lay the potato sets upon the surface, and to cover them with or without manure by the inverted sods from the furrows. The potatoes are afterward earthed once or twice with whatever mould can be obtained from the furrows by means of spade and shovel. And after these earthings, the furrows becoming deep trenches, form easy means for water to flow away, and leave the planted ground on each side of them comparatively dry." "The practice in the south of Ireland is to grow potatoes on grass land from 1 to 3 years old, and turnips afterward, manuring each time moderately, as the best preparation for corn, and as a prevention of the disease called fingers and toes in turnips. In wet bog-land, ridges and furrows are the safest, as the furrow acts as a complete drain for surface water; but wherever drilling is practicable, it is decidedly preferable, the produce being greater in drills than in what may be termed, comparatively, a broadcast method."* The spade-culture of potatoes seems an appropriate mode for small farmers and cotters, but it is by far too expensive a mode to be introduced into a farm where horse-labor is employed.

(1884.) While speaking of the form of the double drill, I have said that one of its sides was larger or heavier than the other; that is, the first furrow with which it is made is much larger than the second, the effect of which relation of furrows is to make the line of their meeting at the side instead of at the top of the drill, (1744) and fig. 313. The germ of the potato, and of the bean too, in pushing upward, toward the top of the drill, finding the least resistance in the soil along the line of the meeting of the two furrows, finds its way to the day through the side instead of the top of the drill. Were the plants allowed to grow out from that part of the drill, they would not only be bent at the ground, but their stems would interfere with the horse-labor bestowed on the land in the hollows of the drills. To avoid this inconvenient and unnatural position of the plants, the practice is to harrow down the *tops* of the drills with harrows, so that the drill shall have the lightest part of the earth upon its crown; and, of course, the germ finding the least resistance directly upward, will push out at the top of the drill. The harrowing down of the tops of the drills is executed with the common harrows, or with harrows made for the purpose. The common harrows are passed either along or across the drills, according to the nature of the soil. Strong soil bears the harrows being driven along the drills, and in very hard land, particularly in dry seasons, they may be passed along a double tine, but a single tine will usually be sufficient. Harrowing across, *with tines well worn down*, will have the least chance of disturbing long manure when used for dunging potatoes, as the drill which first receives the fore part of the harrow supports it and keeps the tines from penetrating too deep at once; but the walking across the drills is irksome both for man and beast, so that the harrowing is most easily performed along the drill. The common harrow, however, is a harsh implement for harrowing drills, compared to a couple of curved ones, figured below, which embrace two drills at a time, and which when pulled along do their work admirably. A modification of this last method has been recommended to be adopted on strong land in

* Doyle's Cyclopedia of Practical Husbandry—art. *Potato*—second edition, (394).

dry weather, after much rain has fallen, and when such land has become very hard and cloddy. A wooden roller, curved so as to embrace two drills, is recommended to be passed along, and by it the clods at top are either crushed or displaced to the bottom of the drills. Two pairs of harrows of a triangular form, suited to work in the hollows between the drills, are then passed along, and they either remove the clods that were too hard to be broken by the roller, or they divide the large clods into a number of small ones, and bring them all, the clods of every kind, into the hollows of the drills. In every one of these modes of rolling and harrowing the drills of bean or potato land, the bean and potato germs are permitted to shoot perpendicularly up through their tops. This harrowing is given to the drills 8 or 10 days after the potatoes have been planted, if the land is dry, but, of course, it must be done before the germs have had time to penetrate the ground, although the weather be not altogether favorable for working heavy land. Of the two sorts of potato-harrows alluded to—the curved and triangular—the latter is best fitted to be used when the germs have appeared above ground, as its outmost tines work between the top of one drill and another, and not *over* the top of the drill like the curved harrows.

(1885.) The potato is subject to disease at a very early period of its existence, not merely after it has developed its stems and leaves but before the germ has risen from the sets. The disease which affects the plant is called the *curl*, from the curled or crumpled appearance which the leaves assume when under the influence of the disease. What the immediate cause of the disease is, it is difficult to say; but the puny stem and stinted leaves indicate weakness in the constitution of the plant, and, like weak animals affected with constitutional disease, the small tubers produced by curled potatoes, when planted, propagate the disease in the fu ture crop. The curl is so well known by its appearance, and the curled plant so generally shunned as seed, that the disease is never willingly propagated by the cultivator; still there are circumstances in the management of the tubers which induce the disease therein. The experiments of Mr. T. Dickson show that the disease arises from the vegetable powers of the sets planted having been exhausted by over-ripening, so that sets from the waxy end of the potato produced healthy plants, whereas those from the best ripened end did not vegetate at all, or produced curled plants.* It is the opinion of Mr. Crichton, "that the curl in the potato may often be occasioned by the way the potatoes are treated that are intended for seed. I have observed," he says, "wherever the seed-stock is carefully pitted, and not exposed to the air, in the spring the crop has seldom any curl; but where the seed-stock is put into barns and outhouses for months together, such crop seldom escapes turning out in a great measure curled; and if but few curl the first year, if they are planted again, it is more than probable the half of them will curl next season."†

(1886.) The other disease alluded to affects the seed or sets, and is called the *failure* or *taint*, which consists of the destruction of their vital powers. Many conjectures have been hazarded as to the cause of the failure, and most of them have ascribed it to the fermented state of the dung, to the drouth of the season, to the heating of the sets, to the tuber being cut into sets, and other secondary causes; but all these conjectures leave untouched the principal consideration in the question, how these circumstances should induce failure now, and not in bygone years? Cut sets have been used for many years without causing failure. Farm-yard dung, in various states of decomposition, has been used as long for raising potatoes. The extraordinary drouth of 1826 caused no failure, while in com-

* Memoirs of the Caledonian Horticultural Society, vol. i. † Ibid., vol. i.

paratively cool seasons the disease has made great havoc. Mr. John Shirreff takes a general and philosophical view of the cause of disease in the potato crop, and though, no doubt, his observations are particularly applicable to the *curl*, still they will apply equally well to the *taint*; for the connection between the two diseases is so intimate, that you have seen Mr. Dickson's observation is that some sets "did not vegetate at all," that is, *failed, or* produced *curled* plants." Mr. Shirreff adopts the general doctrine broached by Mr. Knight. "The maximum of the duration of the life of any individual vegetable and animal," he says, "is predetermined by Nature, under whatever circumstances the individual may be placed; the minimum, on the other hand, is determined by these very circumstances. Admitting, then, that a potato might reproduce itself from tubers for a great number of years in the shady woods of Peru, it seems destined to become abortive in the cultivated champaign of Britain, insomuch that not a single healthy plant of any sort of potato that yields berries, and which was in culture 20 years ago, can now be produced." Mr. Shirreff concludes, therefore, that the potato is to be considered a short-lived plant, and that though its health or vigor may be prolonged by rearing it in elevated or in shady situations, or by cropping the flowers, and thus preventing the plants from exhausting themselves, the only sure way to obtain vigorous plants, and to insure productive crops, is to have frequent recourse to new varieties raised from seed.* The same view had occurred to Dr. Hunter. The fact ascertained by Mr. Knight deserves to be noticed—that, by planting late in the season, perhaps in June, or even in July, an exhausted good variety may, in a great measure, be restored; that is, the tuber resulting from the late planting, when again planted at the ordinary season, produces the kind in its pristine vigor, and of its former size. It is obvious that all these opinions refer to the possibility of plants indicating constitutional weakness, and why may not the potato? I have all along been of the opinion that the failure has arisen from this cause, nor does it seem to me to be refuted by the fact that certain varieties of potato have been cultivated for many years in the same locality without fail; because it is well understood that every variety of potato has not indicated failure, and one locality may be more favorable to retention of vigor of constitution than another; at least, we may easily believe this, and discrepancies in the case may arise, since we do not yet know the circumstances which must of necessity produce constitutional weakness. I have no doubt in my own mind that, were seed-potatoes securely pitted, until they were about to be planted—not over-ripened before they were taken out of the ground—the sets cut from the crispest tubers and from the waxy end—the dung fermented by a turning of the dunghill in proper time—led out to the field, quickly spread, the sets as quickly dropped on it, and the drills split in the manner represented in fig. 344, and described in (1874), there would be little heard of the failure even in the driest season—at the same time, the precaution of obtaining seed frequently from an elevated and late district compared to where the seed is to be planted, should not be neglected. I own it is difficult to *prove* the existence of constitutional weakness in any given tuber, as its existence is only implied by the fact of the failure; but the hypothesis explains many more facts than any other, than atmospheric influence—for example, producing the failure like epidemic diseases in animals, for such influences existed many years ago, as well as now. The longer the cultivation of

* Memoirs of the Caledonian Horticultural Society, vol. i. See also a well-reasoned essay by Mr. Aitken, Castle-Douglas, entitled, "*The potato rescued from destruction, and restored to pristine vigor*; and who takes the same view of the subject.

the *tuber* of the potato, which is not its *seed*, is persevered in, the more certainly may we expect to see its constitutional vigor weakened, in strict analogy to other plants propagated by similar means; such as the failure of many varieties of the apple and pear, and of the cider fruits of the 17th century. This very season, 1843, contradicts the hypothesis of drouth and heat as the primary cause of the failure, for it has hitherto (to June) been neither hot nor dry, while it strikingly exemplifies the theory of constitutional weakness, inasmuch as the fine season of 1842 had so much over-ripened the potato—farmers, still unaware of the cause of the failure, permitting the potatoes they have used for seed to become over-ripened—that the sets this spring, to repeat again the words of Mr. Dickson, "did not vegetate at all," even in the absence of heat and drouth, and in the presence of moist weather. Had the potatoes been a little less over-ripened in 1842, the sets from them might have produced only curl this season, though it is not improbable that the *same degree* of over-ripening may cause entire failure *now* that would only have caused curl years ago; and as over-ripening was excessive last year, owing to the very fine weather, so the failure is extensive in a corresponding degree in this, even in circumstances considered by most people preventive of its recurrence, namely, in cold and moist weather. And observe the results of both 1842 and 1843 as confirmatory of the same principle, illustrated by diametrically opposite circumstances. The *under*-ripened seed of the bad season of 1841 produced the good crop of potatoes of 1842, in spite of the great heat and drouth existing at the time of its planting in 1842; while the *over*-ripened seed of the good season of 1842 has produced extensive failure, in spite of the coolness and moisture existing at the time of planting in 1843. How can heat, drouth, or fermenting dung account for these results?

(1887.) As fact, I may mention the effects of comparatively dry and moist soil, on cut sets and whole potatoes, which were brought to light by an experiment of Mr. Howden, and which results obtained no one could have anticipated. "On the 28th June," says Mr. Howden, "I selected from a store which had been repeatedly turned and kept for family use, 70 potatoes of the old rough black variety. I divided this number into 5 lots, sizing them, so as each lot of 14 potatoes weighed exactly 4 lbs. I made on that day one lot of 14 into starch, and obtained 9 oz. On the same day I put 14 potatoes whole, and 14 cut into 56 sets, into a deep box filled with *dry* mould. The remaining 14 whole and 14 cut I put into another box filled with *moist* earth, and which was watered from time to time. At the end of 3 weeks, with the exception of 5 sets, all the plants made their appearance. All this time the dry box had been kept from moisture. On the 21st July, however, I allowed it to be moistened with heavy rain, and on the 28th July I took up and extracted starch from the whole. Before doing so, however, I weighed the several lots, and what seemed to me curious was, that each lot of the *whole* potatoes had *gained* 8 oz.; while each lot of the *cut* ones had *lost* 6 oz. of its weight, and of their number 10 did not vegetate. The *sprouts* from the *whole* potatoes weighed 4 oz., and those from the *cut* only 2 oz.; yet the *starch* from the 28 *cut* potatoes was only 2 oz., and that from the 28 *whole* potatoes 9 oz., being exactly the produce in starch of half that number, namely, 14, which was made into starch at the commencement of the experiment."*

(1888.) The potato belongs to the natural order *Solanaceæ*, which also comprehends those remarkable but well-known plants, the deadly nightshade, the capsicum, the tobacco, the henbane, the stramonium, the tomato, &c. "The potato is now considered the most useful esculent that is cultivated, and who," Dr. Neill asks, "could *a priori* have expected to have found the most use-

* Prize Essays of the Highland and Agricultural Society, vol. xi.

ful among the natural family of the Solanaceæ, most of which are deleterious, and all of which are forbidding in their aspect*" The genus *Solanum* stands in the order *Pentandria monogynia*, of the Linnæan system. "The name is given by Pliny, but the derivation is uncertain: some derive it from *Sol*, the sun; others say it is *Sulanum*, from *Sus*, being serviceable in the disorders of swine; and others from *Solor*, to comfort, from its soothing narcotic effects; all these conjectures are, however, improbable. *Solanum tuberosum*, the common potato, has roots bearing tubers; stems herbaceous; leaves unequally pinnate; leaflets entire; pedicel articulated. It is a native of South America, on the west coast everywhere. The cultivated potato varies much in the leaves, color of the flowers, shape and color of the tubers, &c."* "Gerard," says Phillips, "describes two kinds of potatoes in his Herbal; and as the account is highly interesting I shall copy it *verbatim*. 'This plant,' says he, 'which is called *Sisarum Peruviorum*, or Skyrrits of Peru, is generally of us called potatus or potatoes. . . . . The roots are many, thick and knobbed, like unto the roots of peonies, or rather of the asphodill, twined together at the top into one head, in manner of the Skyrrit, which being divided into divers parts and planted, do make great increase, especially if the greatest rootes be cut into divers gobbets and planted in good fertill ground. . . . Of these rootes may be made conserves, no less toothsome, wholesome, and domestic, than the flesh of quinces. . . . . These rootes may serve as a ground or foundation whereon the cunning confectioner or sugar-baker may worke and frame many comfortable delicate conserves and restorative sweet-meates.' . . . . "This was evidently the sweet-potato," continues Phillips, "which was supposed to possess an invigorating property. Kissing-comfits were made of them in Shakspeare's time. Falstaff says in the Merry Wives of Windsor,

Let it rain potatoes, and hail kissing-comfits.'

Gerard commences his second chapter with the description of the common potato now in use, and says, '*Battata Virginiana sive Virginianorum, et Pappus*, potatoes of Virginia.' After an accurate description of the plant and flower, he adds, 'The roote is thicke, fat, and tuberous; not much differing either in shape, color, or taste from the common potatoes, saving that the rootes hereof are not so great nor long, some of them round as a ball, some ovall or egge fashion, some longer, others shorter.' The potato was introduced into Spain in the early part of the 16th century, and thence spread over the Continent, first to Italy, then to Flanders, and thence through Germany to Austria in 1598. It found its way to England by a different route, being brought from Virginia by the colonists sent out by Sir Walter Raleigh in 1584 and who returned in 1586, and probably, according to Sir Joseph Banks, brought with them the potato. This palladium against famine was not cultivated in Scotland until 1683, and was then confined to the gardens. In 1728, Thomas Prentice, a day-laborer, first planted potatoes in open fields at Kilsyth, and the success was such that every farmer and cottager followed his example. Potatoes were scarcely known in the East Indies 30 years ago, but they are now produced in such abundance that the natives in some places make considerable use of them. Bombay is chiefly supplied with this excellent root from Guzerat. And though the cultivation of this root is much increased in France within these last few years, the poor of that country cannot yet be prevailed on to eat it."†

(1889.) Rooks are very destructive to the potato crop just as the germs of the plants are penetrating the ground, and they seem to possess an exquisite sense of smelling to find out those which are most palatable to their taste They steal very quietly into potato fields, and are there pretty well hidden among the drills; and in this respect their tactics differ from what they pursue when alighting among corn, which they do in large flocks. There is nothing but gunpowder will deter them from a potato-field; they soon find out the innocuous character of a scarecrow, or *tattie-doolie*, as that sorry semblance of humanity is always misnamed. One cannot always be firing among crows with the gun, but an occasional shot does good, aided by that effectual check to their visitation of any field—the burning of gunpowder matches here and there and now and then along the windward side of the field, the fumes of which sweeping along the surface of the ground, being smelt by the rooks, put them in constant trepidation, and at length to flight.

(1890.) It may prove interesting to those of you who may possess a farm in the neighborhood of a large town, to know why it is that the street-manure of towns is not so suitable for raising potatoes as stable or byre manure. A paper on the subject by Dr. Madden enables me to give you an idea of the explanation he gives of the subject; to enable you, in the first place, to judge of the nature of street-manure. I will insert a part of a Table of his construction, showing the chemical difference between it and horse and cow-dung.

	MANURES.		
	Stable.	Byre.	Street.
Water, &c.	13·5	45.7	26·4
Organic Matter			
Soluble in Water	11·5	9·0	1·4
Soluble in Potassa	15·9	12·6	1·0
Destroyed by Heat	13·33	21·8	11·2
Saline Matter	45·77	10.9	60·0
Total	100·00	100·0	100·0

The sum of the *chemical* nature of these three substances used in raising potatoes is that *stable-dung* is the most heating, but not so durable—that *byre*-dung is *cooler*, and much more lasting—and that *street*-manure is very inferior to the other two in every respect, and, in fact, would be little better than soil, were it not for the highly azotized nature of its organic matter, and probably also for the presence of a considerable quantity of chalk. The effect of applying street-manure to the soil is this: "When any quantity of street-manure," says Dr. Madden, "is plowed into good

soil, the following changes takes place: The ordure and carbonate of lime, which are evidently the most powerful ingredients of this manure, will react upon the less decomposable organic matter, both of the soil and of the manure itself, and thus bring the whole into a state of fermentation, the extent and intensity of which will be regulated by the quality of these active ingredients, especially the ordure. This action depends upon the fact that when any organic substance in a state of fermentation is brought into contact, or mingled with any organic matter capable of fermenting, but not at present in that condition, the whole mass, after a time, undergoes the same series of changes, which are always accompanied with the escape of various gases, and the formation of certain soluble compounds, which latter constitute the chief food of plants. Moreover, it has been long ago proved that substances rich in azote are always the most prone to decomposition, and likewise are capable of exciting fermentation to a far greater extent in others of a less putrescible nature. Again, it is well known to farmers that chalk or carbonate of lime possesses the power of increasing the putrescent tendency of many vegetable substances, so that, when applied to soils, it renders them *richer*. But what is curious enough, at the same time that it causes the production of soluble matter by promoting putrefaction, it renders less soluble those portions already in a state of solution, by entering into chemical combination with them. On these accounts, therefore, and especially from the ordure being a very highly azotized substance, street manure will be capable of exciting putrefaction to a greater extent, considering the small quantity of organic matter which it contains, than one at first sight would be led to suppose. It must, however, be remembered that as the putrescent effect will only be produced in the immediate neighborhood of the active ingredients themselves, and as, moreover, these are mixed with a large quantity of other comparatively inert matters, their action is very liable to be confined to certain spots. Owing, likewise, to the presence of cinders, a certain portion of the soluble organic matter will be absorbed by them, and thus for a time at least, removed beyond the reach of plants. But, on the other hand, it will be observed that, from the highly azotized nature of its organic contents, the fermentation will be *rapid at first*, and, consequently, the manure will be hot in proportion to the quantity of real manure which it contains." In the actual effect of this manure in raising potatoes being ⅓ inferior to stable and byre dung, the following explanation of its inferiority is offered by Dr. Madden. "In the account of the culture of the potato, given in Professor Low's excellent work on Practical Agriculture, we find the following expressions: 'Dung will in all cases act most quickly upon young plants when it is well prepared, but extreme preparation of the dung is *not required* in the case of the potato. It is enough that it should be in *such a state of fermentation as that it may be readily covered by the plow*.' Thus proving that this plant does not require an instant supply of a considerable part of soluble matter. And, moreover, it is clear that as the useful part of this plant is produced during the *later* periods of the growth of the crop, the greatest supply of food will be necessary at that time. But we have already shown that street manure, from the nature of its constituents, ferments very *rapidly at first*, and, consequently, its *greatest effects* will be in the very *early* periods of the growth of the crop. The next sentence in Professor Low's work commences thus: 'The potato requires a *large supply* of manure.' But we have already shown that street manure does not contain ⅓ as much *real manure* as either that derived from dairies or stables. And a little below the above quotation occurs the following sentence: '*Lime* does *not* appear to act in a *beneficial* manner, and is *rarely* applied directly to this crop. But our analysis has proved that lime exists in considerable quantities in the street-manure of Edinburgh: and as it has been exposed to great heat—for it is evidently derived from the ashes—it will, of course, be in the same state as *mild lime* when it is applied, and will, most probably, therefore, have the same effect, which, according to Professor Low, is '*not beneficial*.' The potato possesses a spreading root, and, consequently, must require a *uniform manure*, in order that all its parts may be equally supplied with soluble organic matter. But we have before shown that street manure is *partial*. The potato requires the greatest quantity of azote at the *later periods* of its growth; because the tubers contain considerably more of that substance than the leaves. But street manure, from the nature of its organic constituents, will ferment rapidly, and allow most of its azote to escape during the *early* periods of the cultivation of the crop." As a general rule for the application of manure to potatoes, "We may hence argue," as Dr. Madden remarks, "that a manure to suit well for the potato crop, should possess the following qualities: It must be spread equally through the soil, so that the spongioles, at the termination of all the *spreading fibres* of its roots, may be supplied with nourishment." And surely there is no way of spreading dung so equally as along only three drills at a time, and by spreaders keeping to their own drills. "It must yield azote during the *whole* period of the growth of the plants; in fact, rather more is required during the *later* periods than prior to the development of the tubers; for, from M. Boussingault's analysis, it appears that they contain 5-100 per cent more of this substance than the leaves. In an economical point of view, therefore, the best manure for potatoes would be one which contained plenty of azote, but still did not decompose very rapidly—cow-dung, for example."*

(1891.) *Finlayson's Harrow or Grubber.*—Fig. 346, Plate XXIX., is a view in perspective of Finlayson's harrow of the improved form. The frame-work and the active parts are precisely the same as when the implement was manufactured under the patent, the improvement lying in the parts which have been introduced for raising the tine-frame from the ground. The figure represents the implements as carrying seven tines, and consists first of the body-frame, which is formed of two interior oblong frames a' c' and d' a, each 4 feet 6 inches in length, and 12 inches in width over all. These frames are welded solid at the angles, and rectangular; the sides a' and d' are 3 inches in depth, and ¾ inch in thickness, and are perforated to receive the tines at their full strength, whether of a square or oblong section; the bars a' and d' are therefore allowed to swell out on both edges at the perforation, to preserve strength. The sides c' and a, together with the ends of these frames, are only 2½ inches in depth, and ¾ inch in thickness, and the perforations are only sufficient to pass the screwed tail of the tine. The side-bars a a and a'' a'' are bolted upon the

* Prize Essays of the Highland and Agricultural Society, vol. xiii.

ends of the interior frames, as seen in the bar a'' a'', and each is prolonged forward from a and a'' to the point b, forming the triangular prolongation a'' a'' b, and are connected by a bolt at b. These side-bars are 2½ inches in depth, ½ inch in thickness in the parts a a and a'' a'', while in the triangle they are reduced to ¼ inch in thickness, and the distance from a', the front of the body frame, to the apex b of the triangle, is 4 feet 6 inches.

(1892.) The tines are always in this machine made of the swan-neck or self-cleaning form. They consist of the shank f', by which they are fixed in the interior frame, and of the prong m, which penetrates the ground. A cross section of the swan-neck and shank is either a square of 1¼ inches, or it is an oblong of 2¼ inches by ½ inch, some makers adopting the square, which was Finlayson's original form, while others adopt the oblong. The shank diminishes from the neck toward the tail, which terminate in a ¾ inch screw, by means of which and a nut the tine is held firmly in its place. The prong, or forward end of the tine, diminishes gently in depth to the extremity, which terminates in a chisel-shaped point of 1¼ inches broad, having a slight inclination earthward, without which the implement has a tendency to rise out of the ground.

(1893.) The body-frame, with its tines, is supported on the two hind-wheels d d, 20 inches diameter, which are mounted on the cranked-axle f e f, and upon the front castor-wheel g, of 12 inches, the former turning upon studs in the cranks f' and the latter in the sheers h. The axle e is supported in brackets, bolted upon the inside of the side-bars a a and a'' a'', as seen in fig. 345, where a a is the side-bar, and e the bracket, the eye of which, for receiving the axle, stands 3½ inches above the upper edge of the bar, and its thickness is ¾ inch. The sheers h, fig. 346, of the fore-wheel are jointed into the bent lever at i, forming a bell crank-lever i k l by which the fore-part of the machine is elevated or depressed. The hind-part is acted upon directly by the lever n u, which is also bent at n to nearly a right angle in the arm n o e, the extremity of which passes through the axle at e, and is secured with a screw-nut. This form of the lever, n n e is rendered, in its effects upon the hind-wheel and axle, a simple straight lever; but the angle which it forms at n o serves an essential purpose, as it affects the fore-wheels. It will be observed that the arm n o e takes a position nearly parallel to the arm k l of the fore-crank, and by the introduction of the connecting rod n p l, jointed to the lever n n e, and to the crank i k l, by this arrangement, whatever motion is communicated through the lever n n e, to the cranked-axle of the hind-wheels, a corresponding motion is simultaneously given to the fore-crank and its wheel, whereby the tine-frame is uniformly raised or depressed at pleasure. The lever n n e is about 5½ feet in length, and is under the control of the conductor; its position in the figure indicates the highest position that the tine-frame can attain: and to enable the conductor to retain it in any required position, the quadrant q r, with its upright support s r, is bolted upon the back frame d' a; the edge of the quadrant-bar is notched with serratures about ¼ inch deep, adapted to receive and retain the edge of the lever, as seen in the figure, occupying the lowest notch, which brings the tines entirely out of the ground. By removing the lever from this notch and putting the machine in motion by the horses, the tines immediately descend into the soil, and when they have attained the required depth the lever is laid into the notch suited to that depth, and the machine proceeds thus until the attendant sees it necessary to withdraw the tines from the ground, which must be done at every lands-end, or oftener if obstructions are met with.

(1894.) Fig. 345 is a geometrical elevation of the grubber to show more distinctly the relation and action of the elevating apparatus, the solid lines exhibiting the machine with the tines m and m nearly at full depth in the soil below the surface line, and the repetition of the figure in the dotted lines show it when the tines are fully raised out of the ground. In the first position, a a b is the tine-frame, e the brackets that support the crank-axle, and f the crank carrying the hind-wheel d. The fore-crank, including the sheers of the fore-wheel, takes the position i k l, and the back lever, which is broken off at n', has the position n' o e, o p l being the connecting-rod. It will be easily seen that that e o l k approaches to a parallelogram, and theoretically it ought to be such, but from matters of convenience to suit the diameter of the wheels, the side o e is usually made shorter than the side l k, and, to compensate for this difference, the arms f' f and i k of the cranks are made proportional to the arms o e and l k, and as these are the members of the machine by which the elevations and depressions are produced, and being connected by the rod o p l, the arms o e and l k will move through equal *lengths* of arc, but with unequal angles, the proportional arms f' e and i k will describe corresponding arcs and angles, and so produce a nearly parallel rise and fall of the tine-frame moving round the centers f' and h of the hind and fore wheels, fig. 346. In this complicated combination of levers, it will be observed that the principal lever n' o e, fig. 345, from its combination with the crank e f', is in effect resolved into a simple lever of the first order, whose fulcrum is f', its power is in n' and the point of resistance in o; for though kneed at o, and re-kneeded at e, yet from its construction, the parts n' o e f' form one rigid system and the result is the same as if a rigid bar were extended from n' to f', and then from f' to o, but in which case a jointed bar must fall from o to e, to bear up the tine-frame.

(1895.) In this, fig. 345, the dotted lines represent the changed position of all the parts where the tine-frame has been raised to its utmost limit; the same letters, with an *accent* annexed, mark the position of the different points: and here it will be farther observed that the change of position takes place by the parts turning about the centers of the hind and fore wheels.

(1896.) This form of Finlayson's harrow or grubber is a very well marked improvement on the original, arising from the facility now afforded of raising the whole of the tines out of the ground. In the original form, the only provision of this kind that the machines possessed was the elevation of the apex b of the triangle and with it, a partial elevation of the fore tines while those behind remained always in the ground at their working depth. It is true that this depth could be varied, but only by shifting a bracket that carried the axles of the hind-wheels, and the adjustment of them was a work of considerable time; a screw in some cases was attached to each bracket, by which it could be raised, but they were at best tedious and inconvenient compared with the new form of the elevating apparatus. The original harrow was, in consequence of this defect, a much less manageable machine, and having four of its tines always in the ground, it was much more liable to accident and to fracture. With the improvement also of the elevating apparatus, the bulk and

weight of the implement has been reduced, and it is now very frequently used with five tines, in place of the original seven-tined implement as here figured with the improvements.

(1897.) *Kirkwood's Grubber.*—Though in point of time, this instrument was introduced prior to that just described, it was several years later than that of Finlayson's original improved harrow, or about 1830.* In this machine the ingenious apparatus for elevating the tine-frame was, I believe, first brought out, and from it has been deduced all the various forms in which this effect is now produced, though, as we shall see, some of them are so much changed from the original as hardly to be recognizable; still the elements of the original are there, obtained in some cases at a greater, in others at a smaller expense. The present form, as figured here, differs in some minor points from the original, but not so much as at all to alter the character of the implement, which is still essentially Kirkwood's, though the figure is taken from those manufactured by James Slight and Company, Edinburgh. The chief points of difference are in the length of the axle of the hind-wheels: this, in the original, was so short as to bring the wheels close to the levers: in the figure the axle is extended so far as to place the wheels on the outside of the extreme tines. This extension of the axle gives the machine a broader base, and thereby a greater steadiness of motion, and to compensate for, and give support to, the extremities of the axle thus extended, it is supported by a trussed-tie with king-posts.

(1898.) Fig. 348, Plate XXX., is a view in perspective of this grubber; it may be considered as consisting of two parts, the tine-frame, and the carriage with its wheels and handles, the two being connected by means of the apparatus for elevating the tine-frame, and by a joint-rod which is common to both, the whole being constructed of malleable iron, except the wheels. The tine-frame is of an irregular triangular figure, composed of two sides *a a a*, &c.; these are forged to the peculiar form represented in the figure, and to the following dimensions: from extreme *a* to *b'* in the oblique straight, the distance is 25 inches, *b'* to *c'* 21 inches, and *c* to *a''* 39 inches; and the lengths on the opposite side correspond exactly with these; but the central distance from extreme *a* to *a''* is 6 feet 6 inches. The breadths measuring from center to center of the tines are at extreme *a* 4 feet two inches: *b'* to *a* 2 feet 19 inches, and *c'* to *a* 17 inches; the fore-part of the bars forming the neck, approach to within ¾ inch of each other, between the points *d'* and *m*, and at *a''* they come in contact, and are fixed by the bolt at *a''*; the muzzle *a'' z* is simply a prolongation of the bars, and is provided with several holes in which the draught-shackle and hook can be attached to regulate in some degree the tendency to earth. That part of the frame *d'* to *m*, forming the neck, is raised 9 inches above the line of the body, measuring from the upper surface of the one to that of the other, and lies parallel with the body of the frame. The side-bars here described are 2½ inches in depth and 1 inch in breadth, till they approach *d'*, when they are diminished in breadth ¾ inch, and go on diminishing to ½ inch at *a''*; the slot-holes for the tines are 2½ inches by ¾ inch. Besides the connection at the point *a''*, the side-bars are connected by the joint-rod *g*, which is 1¼ inches square at the middle, tapering and rounded toward the end, where it terminates in a screw and nut of about 1 inch diameter; and a light stretcher *a'* is also inserted as a farther support to the frame. The beam *b b* is 2½ by 1 inch from *b* to *u*, and diminishes from *u* to *d'* to ¾ inch; it is kneed at extreme *b*, so as to leave space sufficient to receive the slot-hole for the middle tine, and it is bent upward at *u* to the hight of 10 inches above the frame as before for the purpose of receiving the bridle *u u'*; at the end *b* of the beam is notched into the middle of the joint-rod *g* (which is here spread out to 2 inches in depth,) and fixed by a screw-bolt, tapped into the end of the beam, while its fore-end is secured between the side-bars by a through bolt at *d'*. The tines, of which this form of the implement contains seven, *h h*, &c., are at 1¼ inches by ¾ inch, bent at the point as in the figure, with a slight tendency to *earth*, and are flattened out at the point to a breadth of 1¼ to 1½ inches, their length from the level of the point to the top is 20 inches, and they are secured at any required degree of earth by one iron wedge to each tine.

(1899.) The carriage consists of the axle *d d*, on which are mounted the two handles or levers *c c o*, the axle passing through these, and fixed with cotterels on each side. At the distance of 13½ inches from the center of the axle, the levers are also perforated for the joint-rod *g*, the position of which in the tine-frame is such as just to allow the extremities *a* to pass the axle when the frame is being raised or depressed. A third perforation is formed in the fore-end of the lever at *o*, 2 inches forward of the joint-rod, for the attachment of the stays. The levers extend backward to a length of 4½ feet, and terminate in sockets, into which wooden helves are inserted; and they are farther supported by the stay-rod and bow *c'*. The carriage is now supported on the hind-wheels *f f*, of 22 inches diameter; and the fore-part of the castor-wheel *i*, of 13 inches diameter, with its sheers *k l*, and crank-lever *l m n*. The connections between the carriage and frame, and which also form the elevating apparatus, is arranged in the following matter. The right and left stay-rods *o p q* and *r p s* are bolted to the levers at *q o* and *r s*. The perpendicular distance *g p* being 12 inches, and the like distance from the center of the axle *d* to *p* 18½ inches, the two stays being brought together upon a stretcher-bolt at *p*, of 1 inch in length, having a screw and nut at each end. The connecting-rod *p l n* is 5 feet 2½ inches in length, ¾ inch diameter, and is jointed to the carriage by the short stretcher-bolt at *p*, and to the lever of the front wheel at *n*, which completes the arrangement by which the tine-frame is moved up and down in positions always parallel to the horizon.

(1900.) Fig. 347, Plate XXX., is a geometrical elevation of this grubber, showing in a more distinct manner the relation and action of the elevating apparatus. In this the solid lines represent the machine as with the tines in the ground, the surface being represented by the line *x' x''*; and the repetition of the figure in *dotted lines* represents it as when the tines are elevated, and the machine in a traveling condition, the same letters applying in both positions, but in this with an *accent*. In the first position, applying the same letters as in the former figure, *a a*, &c., is the tine-frame, *b* the beam, *c* the handles or levers, *d* the axle of the carriage, *f* the hind wheels,

* Prize Essays of the Highland and Agricultural Society, vol. viii.

g the position of the joint-rod of the tine-frame, and *h h* are the tines. The front wheel is shown in the sheers *k l*, and *l m n* is the crank-lever, *g p r* is the stays, and *t* the connecting-rod.

(1901.) In the apparatus of the front wheel, the distance from the sole of the wheel, where it touches the line *x' x''*, to the center at *m*, is 23 inches, and from *m* to *n* 11¼ inches; and as the carriage lever, though in a complicated form, is resolvable into a more simple one, which has the same proportions as the former, the point where the wheel touches the line *x' x''* is the fulcrum, and a line drawn from the point *x'* to the joint at *p* will be parallel with, and equal to *x'' m*, and *g p* will be equal to *m n*; and the point *p*. *n* acting simultaneously, by means of the connecting-rod *t*, the point *p* rises by turning round the fulcrum *x'*, while *m* rises through the same space by the point *x''* turning round the point *m* in the opposite direction. By these motions the tine-frame will rise and fall through equal spaces before and behind, and thus preserve the parallelism of the frame in any position.

(1902.) In working the machine, it is requisite that the conductor have it in his power to regulate and preserve a uniform depth for the tines, and be able to withdraw the tines from the earth. To accomplish this part, the connecting-rod *t*, fig. 348, has small mortices punched in it, to the number of 6 or 8, at very close intervals between *u* and *p*, the rod being square at this place. A nut or slide-box *y'* is fitted to slide easily upon it, and having also a mortice punched through it corresponding to those in the rod, it can be fixed at any point by dropping a pin through this and any required mortice. The bridle *u w'* consists of two similar parts bolted one on each side of the beam: and having the middle parts of its stay widened to admit the passage of the nut, it receives the folding link *v* upon the bolt, on which the link turns freely. The handle *v x w* is made of such length as will bring the eye *w* within reach of the conductor: it is furnished with a cross-head *x*, and the end *v* being screwed into the link *v*, the handle can be shortened or lengthened at pleasure; and this is done to make the cross-head fall in behind the end of the connecting-rod when the tines are in the ground, which thus lock them that they cannot rise out of the ground, although, from any malformation of the tines, they might have a tendency to do so were this lock not applied; but while the tines preserve their due form, the lock is not required. A prolonged screw-nut at *p* is also put upon the handle; it is forked in the prolonged part, and when the tine-frame is raised out of the ground for traveling, the nut is adjusted to fall in before the cheeks of the stays at *p*, and thus keeps up the tine-frame without the continued aid of the conductor.

(1903.) *The Drill-Harrow* is another implement of recent introduction; like the other members of its tribe, it is of extremely simple construction, and from its having been first applied to potato culture, it is frequently styled the *potato harrow*. This harrow is always worked in pairs; and to render it applicable to its intended purpose, it is made of an arch form, partially embracing the curvature of the ridglet or drill. The two leaves of the pair are connected by two coupling-rods, which are formed to expand or contract to any required width of drills; and each leaf is furnished with a chain, to which a draught-bar or swing-tree is attached, and to which again the horse is yoked: the bar and chains, in this mode of yoking, serve by their weight to produce such a catanarian curvature as to make the vertical line of traction leave the harrows nearly in a horizontal line, giving thus the full effect on the drill. Simple though the construction of this implement be, I frequently see a malformation in the placement of its tines; its breadth does not exceed 26 inches, and, therefore, the number of its tines need not exceed 18, though a streak at every 1½ inches should be required; notwithstanding this, we frequently see these harrows with as many as 24 tines, and with such a number, unless a very careful division is made in their placement, many of them will follow in the track of others, and are hence of no use. In laying out this simple harrow, if the rule laid down in (1789), as applicable to all harrows, is attended to, such useless waste of labor and materials might be saved, and the work for which the implement is intended will be equally well done.

(1904.) Fig. 349 is a geometrical plan of a pair of the rectangular drill-harrows, in which a regular division of the tines is observed, and as the harrows are 26 inches from center to center of the outside bars or bulls, and the number of tines 15, they will draw streaks on the surface at equal distances of 1¾ inches nearly: the three bulls *a b c*, and the three cross-bars *d e f*, form the body of the harrow; the breadth over all is 27 inches, and the length 33 inches; the bulls and bars are all 1¼ by ¾ inch. There is no slotting, as in the common harrow, but the bulls and bars are simply crossed, and secured by a small bolt and nut, or they may be riveted together, except where a tine falls in the crossing, when it is secured by the nut of the tine itself. The bulls and cross-bars are simply punched for the tines, which are secured by a screw-nut. The middle bull of each harrow is prolonged a little forward at *g*, and punched for the shackle of the draught-chain, which is affixed thereto by a bolt. The bolt which joins it to the cross-bar at each end is also prolonged upward 4 inches, having a collar above and nut below, forming a firm stud, on which the stretcher is placed, and retained by a nut above. The tines are about 4 inches in length below the bars, and are ½ inch square at the shoulder, tapering to a blunt point.

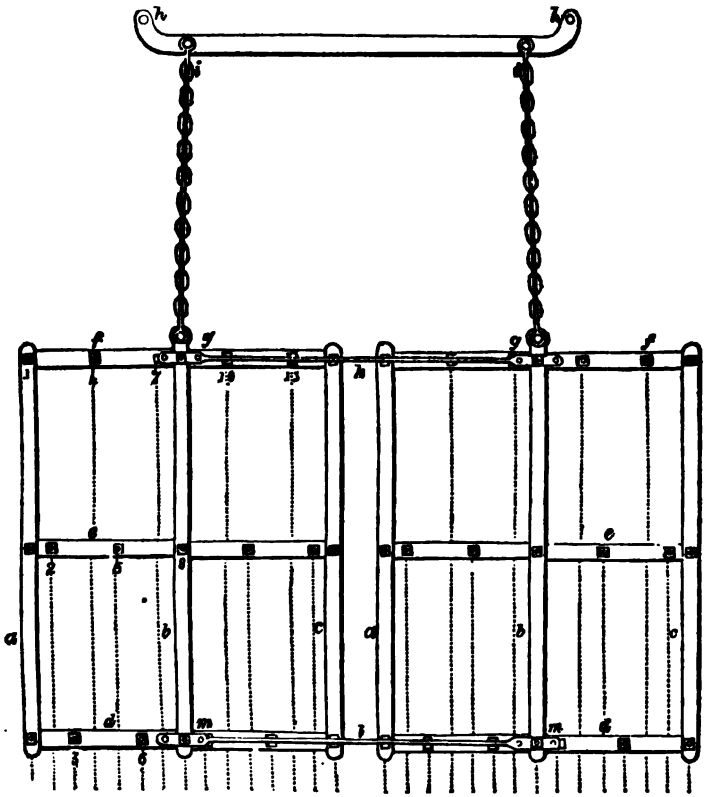
(1905.) Fig. 350 is a cross section, at the front-bar, of both the leaves of the harrow, showing the arched form and direction of the tines. The rise of the arch is 5 inches, but this may be varied, and if the arching is flat, the tines toward the apex should be shorter than those toward the sides of the harrow, to prevent injury to the young plants. In the front bar the right-hand tine may be left out, as its place may be taken up by that of the third bar, leaving 5 tines. In the second cross-bar there are also 5 tines, and in the third, 5. The two leaves are connected and kept at due distance by the coupling-rods *k*, which are ½ inch diameter, and flattened at the ends to the extent of 5 inches, and have 3 perforations made at each end, at 1¼ inches pitch, or closer if thought necessary; this construction of the coupling-rods affords the means of adapting the harrows to any width of drills. The draught-chains *i i*, fig. 350, are about 2 feet long, and are shackled to the draught-bar, to which the horse is yoked by the eyes at *h h*. The pair of harrows are drawn by one horse, walking between the drills: the weight of the pair, with the mounting, is about 90 lbs., and the price from 30s. to 35s. complete.

(1906.) *Triangular Drill-Harrows* are considered by some agriculturists as superior in effect

to the rectangular form: with due attention to the division and placement of the tines, they may no doubt be rendered equally effective, and probably more so, but the advantages are not permanently marked.

(1907) On farms where potatoes are raised only to supply the wants of the people who labor them, the drills may be made in the single or double way, as may suit the fancy of the farmer,

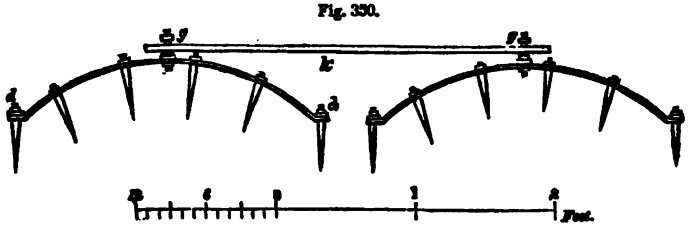
Fig. 349.



THE POTATO HARROWS.

but he should bear in mind that the more minutely the soil is pulverized, the better state it will be in for the crop. But where potatoes are raised for the London or the markets of other great towns, a mode of culture should be adopted to admit of much work being done in the limited pe-

Fig. 350.



SECTION OF THE POTATO HARROWS.

riod in which potatoes should be planted. Bearing this necessity in view, the land should be drilled up in the single mode in preparation for the dung, the dung then spread in the manner represented in fig. 344, and the drills split with a double mould-board plow: but as it is desirable that the earth in the drills should be as lightly put over the sets as possible, and as the common mould-board plow presses very much upon the lower part of the sides of the drills, the under part

of the hind-end of the mould-board should be cut away, and the plow otherwise formed—that is, of such size and length as to be worked by a pair of horses instead of one. The double mould-board, besides affording expedition, covers the dung equally with both furrows, puts less earth over the sets, permits the germs to grow upright at once, and thereby allows the access of more air to the sets. Still it will be requisite to harrow down the drills before the sets send up their germs to the surface of the ground.

(1908.) Being desirous of ascertaining the true cause of the failure in potatoes, I am ready to recommend to your notice every rational explanation that is offered on the subject. The following explanation is, I believe, from the pen of Professor Lindley of London, and therefore deserves attention. At the same time, I must own that the explanation is unsatisfactory to me, inasmuch as the tubers in the soil, in regard to their liability of being acted on by chemical agencies, would be the same many years ago, when failure was not so universal as it has been within these few years. "The potato crop," he says, "has of late years been seriously affected by a disease which consists in the production of tubers, instead of stems, when growth first commences after planting, and in the loss of all farther power of vegetation consequent upon this malformation. We have examined several specimens of the disease without succeeding in discovering the smallest trace of organic injury, and we feel satisfied that there is nothing in the visible formation of the potato which will account for it. All the tubers, young and old, seem perfect. It is therefore probable that Chemistry must be called upon to explain the source of the mischief, and that some deficiency or excess of the proximate principles lodged in the tuber will be found connected with it. Although we have nothing positive to state in confirmation of this suggestion, yet there are some facts which may possibly lead to the discovery. We know all that the potato shoots, when first produced, are fed by the matter lodged in the tuber from which the shoots proceed. That matter consists largely of starch—an insoluble substance, which only becomes capable of nourishing a young shoot by changing into gum or sugar. Chemists tell us that such change is effected by a form of matter which they name Diastase, in which nitrogen is an element. Since we know that the quantity of azotized matter found in a potato varies very considerably, it is probable that the quantity of diastase also varies, and that in some cases it may be altogether insufficient to render the starch soluble, except to a small extent. If that were so, the bud, when it springs from a tuber, would be unable to grow into a shoot-bearing leaves, but would develop itself in an imperfect way, and remain as a little tuber, without any power of growing farther. This *may* be the history of the disease in the potato now under consideration; and if so, it would perhaps be removed by adding azotized manure; for the latter, when decomposing in the soil, may furnish the nitrogen that is required. It is true that diastase is a peculiar compound, and that we have no authority for supposing diastase itself likely to be formed in a potato by the addition of azotized matter to soil. On the other hand, we know so little of nitrogen and its action in vegetation, except that its influence is most important, that it is a fair subject of speculation. If leaves cannot decompose carbonic acid, except in the presence of nitrogen, it may very well be that starch also cannot change into sugar or gum except in its presence, and that in any nascent state it may act just as well as if produced by the decomposition of diastase. We would recommend, then, those whose potatoes are thus affected to manure them at once with water containing ammonia. This can do no harm, and may do good. Experiment, too, is somewhat favorable to the trial; for lately, in the garden of the Horticultural Society, some potatoes which had not made their appearance above ground at the time when others, planted at the same period, were in full vegetation, were, at the desire of Mr. Edward Solly, watered with a weak solution of muriate of ammonia; when in a few days the leaves and stems came up, and are now the most vigorous of all."* This last recommendation, of course, can only be practiced in garden culture.

---

18. BREAKING IN YOUNG DRAUGHT-HORSES.

"Thy flattering method with the youth pursue;
Joined with his school-fellows, by two and two,
Persuade 'em first to lead an empty wheel,
That scarce the dust can raise, or they can feel;
In length of time produce the laboring yoke
And shining shares, that make the furrow smoke."
DRYDEN'S VIRGIL.

(1909.) Young draught-horses are never *broke in*. They are most frequently yoked with an old steady horse at once into the harrows, accompanied with a few restrainers of reins and ropes, or an additional hand or two to assist the plowman, to prevent any attempt at a run away; and, no doubt, when colts have been haltered and led out from the time they were weaned by a steady, quiet-tempered man, they will soon submit to work, and become harmless in the course of a few short yokings. But, notwith-

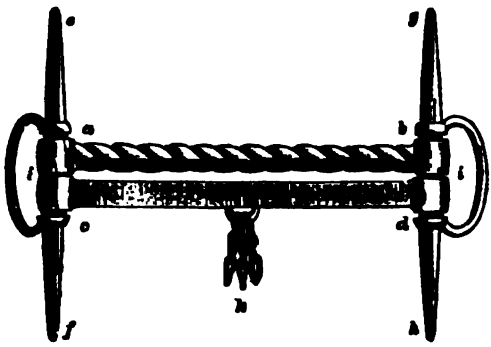
* The Gardeners' Chronicle for June 24, 1843.

standing their quietness, they cannot be said to be *broke in*, in the proper sense of the term; that is, they do not yield to the guidance of the plowman, because they either know or understand what he means, or would subject themselves to his control, but because they feel they are subdued, and are obliged to move along with an older and stronger horse, to which they are attached, as he may choose to lead them. Their mouth is quite intractable to the bit all the time they are apparently subdued; they seize the bit with their teeth, and press upon it, with their head hanging down, their neck arched, and their eyes set back, as if suspicious of harm overtaking them. In this way, day after day, or at least in every yoking they are worked, they look more like objects of oppression and pity than of pride to the farmer, on seeing the young and noble steed he has bred and reared first undertake its work. The rein may be pulled this way and that to no purpose; and in the end the dull, sulky-looking colt is confirmed in his natural temper, and the timid one rendered more afraid. No doubt time, in this as in every other thing, brings about a change; but why should the change, even for the better, be allowed to be effected by a lapse of time, to the discomfort and annoyance of the animal in the mean time, when he can be broke into his work with comparative ease? "Ay, break him indeed, but remember the cost," is the ready rejoinder to the question just asked; and the answer to the rejoinder is as ready. What although it does cost some money to break in a colt to do his work in a proper manner, in the most easy way for himself, and in the shortest time to his master? Is a little cost to be put in comparison to giving trouble to people to teach a colt how to perform his work, who know nothing of the rules of tuition, and who therefore run the risk of spoiling the colt for life? Is one guinea such a deadly sum as to induce any owner of a fine colt to run the risk of spoiling him—for no greater cost need be incurred in breaking in a draught-colt to his work.

(1910.) The easiest plan to make a draught-colt work well soon, is to employ a good horse-breaker to bridle, and handle, and lunge him for a short time—as long as is requisite to make his mouth yield to the bit—and then he will obey both voice and rein; and while employing the rein, the horse-breaker should be instructed to use the language that will be spoken to him while at work, the terms of which I have fully explained in (901). The harness required for this purpose is a breaking bridle, a cavesson, and pad for the back, all of which the horse-breaker will supply. I must remark, however, that most of the bits I have seen used in breaking bridles seem to me inefficient for the purpose. They are very thick at the guard, round, and jointed in the middle, a construction which gives the horse an opportunity of seizing the round thick part with his grinders, when folded back by the force of the rein acting on the joint, and of resting his head upon it. A more efficient bit is represented in fig. 351, which I have seen used many years ago in Berwickshire, by Thomas Middlemiss of Norham, who was reckoned in his day one of the best horse-breakers and grooms that had practiced in that part of the country. It consists of two bits, one twisted and the other square, both 8½ inches in length. The square bit *c d* is ¼ an inch square, and so is the diameter of the twisted one *a b*, and they both have a play of ½ an inch between the shoulders of the guards *a c* and *b d*. The guards *e f*, *g h*, are 7 inches in length. The ring *i* on each side is 2½ inches in diameter over all, and at *k* is a bunch of links to play upon the tongue, and make the horse move his jaws. The straps connected with the bit are, first, the *head-stool*; the *hand-reins*, 4½ feet in length; the *check-reins* to keep the horse's head in line, when strapped to the pad, and which pass *below* the neck-strap of the martingale. All

these 3 straps are buckled to the rings *i i*. There is, besides, a *martingale* to prevent the head being thrown forcibly up. The breadth of the straps is 1 inch; that of the counter strap of the martingale 1½ inches

Fig. 381.



THE BREAKING-BRIDLE BIT.

The bit can be buckled on in the reverse order shown in the cut, having the square bit *c d* uppermost, and the bunch *k* is then screwed to the twisted bit *a b*. The cavesson is well known, and requires no particular description, its figure and appointments being uniformly the same.

(1911). It is unnecessary to go through all the discipline of breaking in a draught-colt, as is required in the case of a saddle-horse, but a few preliminary steps are necessary, such as playing the bit in the mouth for 2 or 3 hours in the stable, twice or thrice a day, the colt standing in the reversed position in the stall, which has the double advantage of making the mouth yield to the bit and of keeping up the horse's head. The bit is buckled on slack for this purpose, so as to lie upon the gums, on the bare space of the lower jaws between the front and back teeth, upon which place either the square or twisted bit is felt to rub sharply, while the bunch of links *k* makes the mouth and tongue play as if desirous of getting quit of the whole concern. When the head is pressed forward to get hold of the bit with the back teeth, the straps being too long, the head finds nothing to *rest* upon, while the bunch *k* is brought too far back upon the tongue to be agreeable. After this discipline in the stable for two or three days, according as it is seen that the colt yields to the bit, with occasional walks out of the stable, he should be led out to *walk* two or three hours at a time by the nose-rein of the cavesson, to learn to step out, and to acquire a good pace; and this is the most essential discipline for a draught-horse. A short lunge or two backward and forward round a circle, on red land, will be useful, not to teach him to trot; but the trotting exercise will make him active, and sooner get the use of his legs in cases of difficulty. He should then be backed, and, while guided by the reins, should be spoken to in the language he will be addressed in the yoke. After that he should be guided along a road with long double-reins, while carrying the plow-chains to accustom him to their noise and feel, and addressed in the appropriate language. Now all this discipline may be gone through in the course of a week, or 8 or 10 days, according to the disposition of the animal, the handling he may have received since he was a weaned foal, and

the genius of the horse-breaker. The horse-breaker should groom the colt immediately after exercise, that the animal may become familiarized with the usages of the stable, and the degree of exercise given should be with a discrimination suited to the condition and physical strength of the animal. The colt's food, too, should be so administered as to harden his condition for labor; with the understanding, however, that, after the busy season of work is finished in the early part of summer, the young tyro shall be allowed to have a run at grass for a few weeks, and then fall into his own share of regular work.

(1912.) After the treatment and discipline received from the horse-breaker, the colt will be easily made to understand work. The sort of harness with which he is first invested is that of the plow, consisting of a bridle, collar, fig. 197, and back-band and chains, or *theats*, as these are called in some parts of the country. It is quite possible that the discipline received from the horse-breaker will make the colt suffer at once to be yoked with an old horse at the plow; but in case of accidents, and to err on the safe side, it is best to use precaution, even though it should be proved to have been unnecessary. The principal precaution is to attach the colt to a strong, steady horse, that will neither bite nor kick him, and be able to withstand the plunges the colt may choose to make. The attachment is made by a cart-rope being first fastened round the girth of the old horse, and then passed round that of the colt, leaving as little space between their bodies as is required for plowing; and to afford no liberty to advance or retire beyond a step or two before or behind the old horse. Besides the usual rein employed by the plowman, the horse-breaker should have another in his hand from the colt's head. Thus equipped in plow-harness, the first yoking of the colt should be to an old cart-wheel, placed on its dished face on plowed land, furnished with a swing-tree, which he should be made to draw, while the horse walks beside him; and, in drawing this, the reins should be used, and the appropriate language spoken, that he may associate the changes of his motions with the accompanying sounds, and which are indicated by the reins while guiding him. I remark in passing, how curious it is for us to have adopted the Roman method of breaking young horses by the employment of the wheel, as set forth in the motto selected from Virgil. Should the colt offer to wheel round, the gentlest means should be used in putting him again in his proper position, as the start may have been made from fear, or from the tickling of a part of the harness. When a hind-leg gets over a trace-chain, the chain should be unhooked from the swing-tree, and hooked on again after the colt has been put in his right position. Should he offer to rear or kick, from a disposition to break away, the old horse should be urged on to the walk, and be made to pull him along, while a smart tip of the whip will take the courage out of him. According as he evinces a disposition to go on quietly in the work, should the length of time be determined at which he should work at the wheel. When submissive, he should be yoked to the plow, for there is no species of work which calls forth the sympathy of horses to one another in so short a time as when working with this implement; and, after a few landings, it will be seen that he will work with energy and good-will, and then he should be kindly spoken to, encouraged, and even fondled. The probability is that his desire for the draught may be evinced too keenly, but the pace of the old horse should be subdued, and the keenness mitigated by the rein and *tug*, which the short reins are called that pass from the head of one horse to the collar of the other, and which, in this particular instance, is fastened to the rope round the girth of the old horse. It is interesting to the farmer to see his young horse put

his shoulder to the first work he has ever tried with a spirit even beyond his strength; and, while he continues at the work until his nostrils distend and flanks heave, his owner cannot help having a regard for him, heightened by a feeling of pity for the unconscious creature acquiring experience of work at which he is about to be doomed to toil for the remainder of his life. It should be mentioned, as a precaution, that all the harness employed about the first yoking of a young horse should be fresh and strong, and not likely to break, even by violence. The colt should be broke in to the cart as well as the plow. He is yoked into a single horse-cart, but great care should be used on the first yoking, that he get no fright, by any strap rubbing against him, or the shafts falling upon him when raised up to allow of his being backed below them; for, if frightened at the first yoking to a cart, a long time will elapse ere he will stand the yoking quietly. The horse-breaker should stand in the cart using double reins; and a rein should be held by a man walking first on each side of his head, and then at a little distance on the sides of the road. The chief danger is kicking, and thereby injuring the hocks against the front-bar of the cart; to prevent which, a rope should be placed across the top of the colt's rump, and fastened to the harness on the rump, and on each side to the shaft of the cart. There is little danger of his running away while all the reins are good. He will take with the traces of the cart more readily at first than with the trams, as they are so similar to the yoking he has felt at the plow, and he is conscious of having his companion behind him.

(1913.) On the first use of harness by a young horse, the shoulders and back are liable to become inflamed, and even the skin to be broken by the collar and saddle. It should be ascertained, in the first place, that the collar he is to work in fits him properly; and, if it does not, it should be made to do so before he use it, as the first day's use may so injure his skin as to give him pain for weeks thereafter. The usual affection is heated swellings in the line of the collar and seat of the saddle. A good lotion, to be applied to those parts whenever the colt comes out of yoke, is a solution of common salt in warm water, and, when cold, applied as a fomentation with a sponge. The water not only cools the skin, and keeps down the inflammation, but the salt hardens it for use; and in the course of a short time, particularly if the weather be dry, the skin will become inured to the pressure of the harness. A young horse may be broke in for work any time in the course of the spring, from the beginning of working the turnip-land to its completion. I can affirm the efficiency of the plan I have recommended by repeated experience, and it is one unattended with the slightest accident in practicing it.

(1914.) It is the usual practice to shoe and dock the young horse before putting him to the yoke. I think he should first be broke in, and then he will suffer himself to be shod the more quietly. At the *first shoeing* it will be useful, in making him stand quietly, and in diverting his attention, to take the old horse he has been working with to the smithy. By nailing a mat against the wall, and making him stand alongside the mat, it will save his skin being ruffled should he rub against the wall, while the wall will form a firm barrier against his retreating farther from the blacksmith. After the fore and hind feet of one side have been shod, these can next be turned to the wall to get his other feet shod. Gentle and coaxing means should be used, though a twitch on the nose has a powerful command over a horse. The first shoes of a young horse should be light, with no heels, and the hoofs should not be pared down much at first. Rather renew the shoes, and pare the hoofs down again in a short time, than incumber a colt at first with heavy shoes with heels, to the risk of tram-

pling himself, as to cure the effects of a severe tramp may cost much more than the price of many sets of new shoes. As to *docking* a draught-horse, I think it a necessary operation, because a long rump is very apt to get injured when the horse is yoked in the trams, by coming against the body of the cart, and in coup-carts especially it can scarcely escape being nipped when the body of the cart is brought down upon it when lying on the front-bar, and besides a draught-horse has no use for a *long* tail. A neat swish is all that is requisite at any time, and in winter even that is apt to be loaded with mud on dirty roads. Some writers affect to believe it presumptuous in man to deprive any animal of six of the joints of the vertebral column which Nature has given him; and no doubt were our horses always idle, especially in summer, when a long tail is of essential service in whisking off flies, the vertebræ ought to be kept entire; but surely there is no greater absurdity in docking the tail, than in driving iron nails into the crust of the hoofs of a horse, and yet without iron shoes to protect it, the horny foot of the horse would be beaten to pieces on hard roads at the pace many kinds of horses are driven along them; and there is no necessary cruelty in the act of docking, for it is an operation of the simplest form when properly done, that is, when effected in a joint where the wound is easily healed. As to *nicking the tail* and *cropping the ears*, such operations are never performed on draught-horses, and at best only serve to disfigure the appearance of the animals subjected to such unnecessary torture.*

19. SOWS FARROWING OR LITTERING.

"Sows ready to farrow this time of the year,
Are for to be made of, and counted full dear,
For now is the loss of a fare of the sow
More great than the loss of two calves of the cow."

Tusser.

(1915.) It should be so managed where there are more than one brood-sow on a farm, as to have one to bring forth pigs early in spring; but, at the same time, it should be borne in mind that young pigs are very susceptible of cold, and if exposed to it, though they may not actually die, their growth will be so stinted as to prevent them attaining to a large size, however fat they may be made. Even the most comfortable housing will not protect them from the influence of the external air, any more than certain constitutional temperaments can be rendered comfortable in any circumstance in spring, when under the influence of the east wind. From March to September may, perhaps, be considered as the period of the year when young pigs thrive best.

[* The reasoning of the author in this case appears not to be conclusive. There is no reason to suppose there is any sensibility in the horn of the hoof, and the nailing of the shoe is intended to prevent, not to give, pain—whereas docking gives much pain at the time, requires care to heal it up, and deprives the horse of the brush which Nature gave him to keep off the flies from a large portion of his body.

The exposure of the tail to be filled with mud, is an inconvenience, but when occasion requires it (which is generally when there are no flies about, in winter,) the hair may be neatly plaited and tied up, as all good teamsters know how to do. We go against all nicking and docking and cropping, and for saving beasts, as well as our fellow-creatures, from every moment of painful sensation that can be avoided. [*Ed. Farm. Lib.*

(1916.) Whenever a brood-sow shows symptoms of approaching parturition; that is, when the vulva is observed to enlarge and become red, it is time to prepare the sty for her reception, for she will keep her reckoning not only to a day but to an hour. The period of gestation of a sow is 112 days, or 16 weeks. The apartments meant to accommodate brood-sows in the steading are marked by the letter *c* in figs. 3 and 4, Plates III. and IV. They consist of an outer-court 18 feet long by 8 feet broad, inclosed by a door, as represented in fig. 23, and described at 5 in (68), and an inner apartment 8 feet by 6, roofed in. This is the usual form of a sty for sows, but others more convenient for overlooking the state of the sow and her pigs is when the outer court and inner apartment are placed under one roof, that is, in a roofed shed, or in a house which may be shut in by a door. The litter allowed to a brood-sow should be rather scanty and of short texture, such as chaff, short straw, or dried leaves of trees, as young pigs are apt at first to be smothered or squeezed to death among long straw, when they get under it. When a sow has liberty before she is about to pig, she will carry straw in her mouth, and collect it in a heap in some retired corner of a shed, and bury herself among it, and the chance is, in such a case, that some of the pigs will be lain down upon unseen and smothered by the sow herself; when seen she will carefully push them aside with her snout before lying down. Some sows have a trick of wandering away to litter in a quiet place, such as in a field of corn, in a plantation among underwood, or in a dry ditch at the root of an old hedge or tree. I remember of a sow being missing for upward of a fortnight, not a person having seen her leave home, or being able to discover where she had gone to; but she was suspected of having disappeared for the purpose of littering. At length she appeared one day craving for food at the kitchen door, bearing evident signs of having littered, and of having suckled pigs. She was cautiously tracked to her hiding-place, though jealous of being discovered; and it was found that she had formed a nest with the straw gathered from the adjoining field of wheat, in a secluded part of a dry ditch at the root of an old thorn-hedge, about 300 yards from the steading. She had subsisted as long as she could upon the corn, but hunger at length drove her to the house in search of food. Had she been allowed, she would, no doubt, have come to the house every day for food; but means, of course, were used to have the pigs conveyed to the steading, and this was a work of some difficulty, as the sow herself was perfectly savage when any one approached her young ones; and these were so wild in their habits that they eluded capture for a long time among the standing corn. At length, by the assistance of the shepherd's dog, which seemed to enjoy the affair as sport, they were all caught, a large litter, and, on being conveyed home in a large basket, the sow naturally followed her captive young ones. I remember of another sow taking up her abode in the bottom of a pea stack, where a small hole was only left as an entrance, but a large chamber was formed in the interior, and it was found impracticable to dislodge her from this stronghold, she keeping every man and the shepherd's dog at bay, and he was too knowing to venture to attack her in single combat; so she was let alone, and she produced her young there, and kept them until they were able to run about, food having been set down for her. I mention these instances of the peculiar habits of some domesticated sows, merely to show you the propriety of securing the brood-sow that is about to farrow, and particularly one that is given to wander abroad in search of a nest, in a proper sty some time before the period of her reckoning.

(1917.) Knowing the day of her reckoning, she should be attended to

pretty frequently, not that she will probably require assistance in the act of parturition, like a cow or a ewe, but merely to see that all the pigs are safe, and to remove any one immediately that may be dead when pigged, or may have died in the pigging. I have heard, however, of a sow in high condition which died because the second pig, on coming by the breech presentation, had a hind-leg folded back, which could not be put right by the sow herself in pressing, and having been neglected, her parts very much swelled. As an attempt to save her life, the Cesarian operation was performed on her, and the obstructing pig was removed; the animal lived, but the others in her womb were dead, and she herself did not survive the operation above an hour, having been completely exhausted before it was attempted. I do not know whether it is generally the case, but I have frequently observed that pigs leave the womb alternately in a reversed order; that is, they are projected by a head and breech presentation alternately, not uniformly so, but most frequently. There is no doubt, however, of the fact that the first-born pigs are the strongest, and the last the smallest and weakest, in a large litter, such as upward of 12, though the difference is less or scarcely observable in smaller litters of 6 or 8. The small, weak pigs are usually nicknamed *wrigs*, or *pock-shakings*, and are scarcely worth bringing up; still, if there is a teat for them to lay hold of, they ought not to be destroyed. Sometimes there are more pigs littered than the sow has teats to give to each. I have seen as many as 19 pigs when there were only 12 teats; and I remember of a sow that never littered fewer than 17, when she had 14 teats, which are two more than the usual number. Extra pigs, can, no doubt, be brought up by hand on cow's milk, but the last ones of a very large litter are usually so small and weak that they generally die off in the course of a day or two to the number of the teats. A young pig soon gets to its feet after birth, and as soon finds its way to the teat; but it can find no sustenance from it until the sow pleases, so that until the entire parturition is accomplished and the sow recovered from it, there is no chance of the pigs getting a suck. Many sows are very sick during parturition, and for some time after—so much so that the skin of their mouth becomes bleached and parched, and the breathing quick. To those unaccustomed to see a sow in that state, it would seem that she must die; but a little rest recovers her, and she betakes herself fondly to her young. It is necessary, as I have said, to remove the pigs as they die, if any die, as some sows evince the abominable propensity of eating their own pigs when they die, whether the death takes place at the birth, or immediately after, or whether it happens on their being smothered or squeezed to death by being lain down upon by the sow herself, when nestled between her and the wall. I remember of a sow that was never sick at pigging, and such was her propensity to eat every pig that died or was smothered, that even during parturition she would get up as every pig was born, to ascertain whether it was dead or alive, and, if dead, would eat it instantly, provided she was not prevented; and even after they were a week old she would eat them, had they died by accident.* There is a peculiarity exhibited by young pigs, different

[* There is much that is superfluous, in this chapter, for American farmers generally. But although the business of hog-breeding is, perhaps, of all stock-breeding the most simple and the one in which Nature may be generally left unassisted and unattended to, still this inattention may be and is often carried to an extreme; for although generally the pigs will *live*, how much better would they thrive if, at the time of farrowing, the sow were treated with a *more liberal allowance of suitable liquid and green food* for keeping the system in a better condition, and expressly for producing a greater flow of milk. The growth and ultimate size of all animals depend greatly

from the young of other domesticated animals, in each choosing a teat for itself, and ever after keeping possession of it; and this compact, as it were, is faithfully maintained. Should there be one pig more than there are teats, it must take its chance of obtaining a teat when the rest are satisfied. It is generally observed that the pigs which are supported at the foremost teats become the strongest; and the fact was noticed long ago by Tusser, who recommends store pigs to be those which are

"Ungelt, of the best keep a couple for store,
One boar pig and sow pig, that *sucketh before*."

Pigs require to use coaxing before the sow will give them milk. They make loud entreaties, and rub the udder with their noses to induce her to lie down; which, when she does, every pig takes its own place right earnestly, and nuzzles away at the udder with the teat held in the mouth, whether situate in the upper or lower row. After a good while of this sort of preparation, the milk begins to flow on the sow emitting a fond-like grunting sound, during which the milk is drawn steadily and quietly till the pigs are all satisfied, and they not unfrequently fall fast asleep with the teat in the mouth. Young pigs are lively, happy creatures, and fond of play as long as they are awake, but they are great sleepers. When a week old, their skins are clean, hair soft and silky, and, with plump bodies and bright eyes, there are few more beautiful young animals to be seen about a farm-yard. Those of a white color look the most delicate and fine.

(1918.) As to the *food of the sow* after she has recovered from parturition—which will be longer or shorter according to her constitutional temperament—she should get a warm drink, consisting of thinnish gruel of oatmeal and lukewarm water, and which serves the double purpose of meat and drink. If she is thirsty—which she is likely to be on recovery from sickness—the gruel may be again offered in a thinner state in an hour or two afterward. The ordinary food may consist of boiled potatoes, with a mixture of barley-meal, among water, administered at a stated hour at morning, noon, and night, with such refuse as may occur from the farm-house. This food will be found to support her well while nursing; and it should be borne in mind that, as long as she is nursing, she should receive abundance of food, if it is desired she should rear *good* pigs. Should the weather be frosty, or otherwise cold, the water may be given a little warmed; but in fresh weather, or in summer, cold water is most acceptable to her. The mess should not be made so thin as to be sloppy and take a long time to drink up, or so thick as to be cloggy in the mouth, but in a state of gruel—meat and drink at the same time. Whatever food is given to her should be *cooked*, and not in a raw state; that is to say, the potatoes should be *boiled* and not given raw, and the barley-meal should first be made into brose with warm water, and then mixed with the potatoes, and the whole mess made like gruel with cold water. The trough out of

---

on their being *well supplied in their infancy with suitable food*. Yet to this it must be confessed that in our country generally too little attention is paid, and in no instance is this the case more than in our neglect to provide properly for the *ewe and the sow* during the period of suckling.

As to the propensity of some sows to eat their pigs, when they *die young*, it is by no means a rare thing—or rather it sometimes happens, as we know, that they will at once devour the whole litter, though farrowed alive and well! They seem to be animated to this horrible and disgusting act of infanticide by a sort of *furor* which is said to proceed from a morbid state of the blood, and to be most apt to happen with sows that are in too high condition. To guard against this monstrous disposition, it was recommended by the late GORHAM PARSONS, of Massachusetts, (whose memory as a personal friend, and able promoter of the cause of agricultural improvement, we shall ever cherish with grateful recollection,) to give, *for* a week or two before farrowing, a spoonfull of sulphur occasionally in their food, to "cool their blood," as he said. *Ed. Farm. Lib.*

which she receives her food should be washed every two or three days in cold, and every day in warm weather. I believe it is the common practice never to give pigs salt among their food, because it is said to encourage the *scab*. A large quantity of salt may have this effect, but I never saw a relish of salt produce such an effect. When a sow leaves any of the food in the trough, it should not be presented to *her* again, but given to the young pigs, who will relish it.

(1919.) Most pigs are usually gelded, both male and female—the few that are kept for breeding forming but a small exception. They should be gelded on the milk at from 10 to 14 days old. The males are castrated on being held between the knees, and the scrotum incised down upon each testicle, which is removed by the pressure of the finger and thumb, and the spermatic chord separated by the knife. The she-pigs are treated in a different manner. Being laid on a chair-bottom or table, on its far side, the pig is there held by an assistant; the operator cuts an upright incision into the flank, of about 2 inches in length, and, introducing a finger, brings out the ovaria of the womb, and separates them by the knife. He then closes the incision by a few stitches with a needle and thread, and the operation is finished. There is very little danger attending the operation to either sex. In the case of rupture or hernia in the male—and some breeds of pigs are very liable to this disease when young—it is necessary to stitch up the incision of the scrotum, and the testicle at castration should, in such a case, be removed with care, in case of producing inflammation in the intestines. The incisions in both the male and female generally heal by the first intention. The gelder should use the precaution of cleaning his knife before every operation. The usual charge for gelding pigs is 2s. 6d. the litter, whatever number it may contain. Young pigs are not gelded when intended to be killed for roasting.

(1920.) It is seldom that any complaint overtakes the sow on littering, though she may be carried off by puerperal fever, and I suspect there is no remedy for this disease in her case. The pigs which she leaves may be very well brought up by hand on cow's milk, as they will soon learn to drink out of a dish, in which the milk should be given them warm from the cow, and as often as the cows are milked. It is surprising how small a quantity of milk a pig will drink at a time; and on this account they should get it frequently, and the dish in which it is served should not be easily upset, because there will be a struggle to get first at the milk, and one or more will be sure to jump into it. The diseases incidental to young pigs are luckily few. Their tails sometimes drop off with a sort of canker, and a red eruption sometimes takes place on their skin, and sometimes one in a litter may take a wasting and die. I believe that if the sow is provided with plenty of wholesome food, the pigs kept clean and warm in their sty and litter, and their sire and dam be not too near a-kin, that few diseases will overtake pigs as long as they are on their mother's milk. A sow is not allowed to take the boar until after the pigs are weaned, but as soon after as possible, in a week or two; and, to bring her into season the sooner, she should be fed with oats or oatmeal until she takes the boar.—The symptoms of season in a sow are a redness and enlargement of the vulva—which, when observed, the boar should have access to her; and, should there be a boar on the spot, the meeting will be easily accomplished, and one embrace, which is usually a protracted one, is quite sufficient for securing a litter of pigs. When there is no boar on the farm, the sow is sent to him, and she remains a few days with him to secure her impregnation. Pigs are weaned at 6 weeks old, and some keep them on the sow for 2 months; but there is little thrift in such management, as the suckling

in the last week of a large litter of large pigs brings a sow very fast down in condition, and which must be made up again with extra feeding and a longer time before she farrows the next time. A sow that can bring up 10 pigs, and has 5 such litters in the course of 2 years, is a profitable animal, and deserves to be well maintained and taken care of. Even at 10s. apiece—which is the lowest sum a farmer should take for a pig, for he should keep it until it is worth that sum, rather than part with it at a lower one—such a sow will return £25 in the course of 2 years.

(1921.) As it is considered by farmers inconvenient to keep beyond a certain number of pigs on the farmstead, it is necessary to determine what that number should be, and as it is difficult to fix its amount for every particular case, a few hints on different modes of managing litters, after they are weaned, may prove acceptable to you. Before investigating this point, a few particulars may be stated which you may regard in the light of *maxims* on this subject. A sow should always be either with young or giving suck, for if allowed to run about in season, or *a-breaming*, as it is termed, she will lose flesh instead of gaining it. A sow should always be kept in good condition, whether with young or supporting young, because a lean sow never brings forth or can nourish strong pigs. Every breeder and feeder of pigs will find his own advantage in never allowing them to go to bed with a hungry belly. A sow that brings forth the greatest number of pigs of the best quality, proves the best nurse, and is most careful of her young, should always be preferred as a brood-sow. When a sow gets old, she is apt to become careless of her pigs, so that 3 or 4 years may be age enough for a brood-sow. Pigs, though on grass during the day in summer, should, nevertheless, receive a drink of water and meal, or potatoes, or of whey at morning and evening.

(1922.) There are just two ways of rearing pigs on a farm—one is to have a large number of sows, and sell the pigs when they are weaned at 6 weeks old; the other is, to have fewer sows, and rear the pigs until they are fit for the pork-curers; and the adoption of either of these plans depends entirely on the nature of the market of the locality. If there is a demand for young pigs immediately after being weaned, supporting the larger number of sows will be the most profitable plan for the farmer, because the pigs have not to be maintained on food independently of their mothers; but it is a plan attended with much trouble, inasmuch as food has to be daily cooked for the sows while supporting their young, and the market for pigs is, moreover, confined to one age. In the latter plan, on the other hand, the sows are only supported on special food as long as they support the pigs, and there is not only the choice of the market for newly weaned pigs, but for pigs of various ages, suited for the tastes of pork-curers. Suppose, then, that 2 sows are maintained, in pursuance of the latter plan, and that they bring forth 20 pigs twice a year. Retaining 4 of these for ham, and other two for pickled pork, for the use of the house, there will be 34 pigs to dispose of every year, and as these meet with a ready market when 4 or 5 stones imperial each, at 6s. a stone, will make them worth each from 24s. to 30s., or from £40 to £50 a year for pigs. It should be borne in mind that these 34 pigs, when running about the courts in winter, eating a few turnips or potatoes, or grazing in the grass-field in summer, do not cost much to rear them to the weight most desiderated by the curers of pork, and they are in that state fat enough for the purpose, and make very wholesome meat. On a farm of 500 acres, 2 brood-sows could thus be easily maintained; on a larger farm 3 might be kept, and on a smaller 1 may suffice; but circumstances must regulate the proper number. Where dairy husbandry is more attended to on one farm than on another, and when the mixed husbandry is practiced on both, more sows may easily be kept in summer than where the dairy husbandry is less attended to. There is a remark of Mr. Henderson on this subject which is worthy of attention, in regard to the timing of sows in bearing their litters of pigs. "Whenever," he says, "farmers have an opportunity of selling pork at all seasons, they do not think it necessary to make the sows bring their litters at a particular season, as they wish to have a lot of a certain age to go off regularly at least every month," in autumn, winter, and spring. "They make them ready for the market," he continues, "with little expense, only giving them close feeding 2 or 3 weeks previous to their being sold." Pigs intended for pickled pork merely, do not require even this feeding, though those sold for making hams are the better for a little extra and hardening feeding. "They have very little trouble in selling them," concludes Mr. Henderson, "as there are jobbers continually traveling through the country, purchasing swine of all descriptions, who receive them and pay the money at the farms."

(1923.) The omnivorous disposition of swine is well known, and it is this disposition which makes them so easily maintained and so serviceable on a farm. "Swine, though exceedingly voracious," remarks Mr. Henderson, "will feed on almost anything. In miry and marshy ground they devour worms, frogs, fern, rush and hedge-roots. In drier and woody countries they feed on haws, sloes, crabs, mast, chestnuts, acorns, &c., and on this food they will grow fleshy and fat. They are a kind of natural scavengers; will thrive on the trash of an orchard, the outcasts of the kitchen, the sweepings of barns and granaries, the offals of a market, and most richly on the refuse of a dairy. If near the sea, they will search the shores for shell-fish, in the fields they eat grass, and in great towns they are supported chiefly by grains. It is evident that the facility of feeding them everywhere at a small expense is a material benefit, more especially in a country where people are accustomed to eat flesh daily, or, on the other hand, where there is so ready a market for bacon and pork as we have. It is no less observable that, notwithstanding the facility of feeding, and the multitude of swine maintained, they seldom fail of coming to a good market. Swine ought to have hard feeding two or three weeks previous to their being killed, to give firmness to the flesh. This practice ought to be particularly attended to by those who feed at distilleries on burnt ale and grains, as the fat of pigs thus fed melts almost wholly away in boiling or roasting. Peas and beans are excellent for the purpose, and acorns are still better.

Where oak plantations are near, they will resort to them in autumn, and there remain until this their favorite food is exhausted. The late Sir James Colquhoun of Luss, I have been told, was in the habit of sending his pigs to one of the islands of Loch Lomond, where there is an oak plantation, that they might pick up the acorns, which is said to have given a surprising degree of delicacy to the flesh. Those who have woods of this kind, and orchards, ought to allow their pigs liberty to range among the trees, to pick up shaken fruit and seeds."* The hogs of Germany enjoy the droppings of the oak and chestnut forests, and it is supposed that it is this species of food that imparts the very superior flavor which the hams of Westphalia are known to possess. That all the hams sold in this country for Westphalian are genuine, I have doubts, after having become acquainted with the true flavor in their own country. I remember of passing through a forest of sweet chestnuts of, I dare say, 3 miles in length, near Bellinzona, in the canton of Ticino, in Switzerland, in autumn, when the fruit was dropping from the trees; and into this forest the peasantry, I was informed, turned their pigs every year to get fattened at the season I allude to.

(1924.) Swine should not be allowed to enter a field of any kind without a ring in the nose. Their propensity to dig for worms and roots makes them turn up the soil with their noses, and when a grass-field is thus treated, it presents a perfect scene of havoc, in so far as the grass is concerned. The best material for making the nose jewels of swine is horse-shoe nails, they being both durable and ductile. As there is no use of retaining the heads of the nails, they are hammered into a point, and the nail is then fit for use. It is inserted into a hole, formed by an awl or other sharp-pointed instrument, through the upper point of the snout, and passing, with a good hold, through the cartilage of the top of the snout to its front, where the points of the nail are twisted firmly together. A new hole can be made in the snout, and another nail substituted, when the old hole and nail have become worn.

---

20. THE HATCHING OF FOWLS.

" . . . . . The careful hen
Calls all her chirping family round,
Fed and defended by the fearless cock,
Whose breast with ardor flames, as on he walks,
Graceful, and crows defiance. In the pond
The finely chequered duck before her train
Rows garrulous. . . . . .
. . . . . The turkey nigh,
Loud threat'ning, reddens; while the peacock spreads
His every-colored glory to the sun,
And swims in radiant majesty along.
O'er the whole homely scene, the cooing dove
Flies thick in am'rous chase, and wanton rolls
The glancing eye, and turns the changeful neck."

THOMSON.

(1925.) Spring is the busy season of the feathered inhabitants of the farm. Thomson well describes the "homely scene," which these happy creatures present while tending their young, and which might be seen at every farmstead in spring, were fowls cared for as they should be. Instead, however, of indulging in unavailing regrets, I shall endeavor, in as few words as the clear elucidation of the subject will admit of, to describe the mode of hatching and rearing every sort of fowl usually domesticated on a farm, and thereby show you that it is not so difficult nor so troublesome an affair as the practice which generally prevails would seem to indicate. Observation of the habits of domesticated birds, and *punctual* attention to their wants, are all that are required to produce and bring up plenty of excellent poultry on a farm.†

[† As no fitter occasion may offer, we think it best to preserve here the following, which appeared in a late number of the Gardeners' Chronicle, and which applies to disorders of poultry of not unfrequent occurrence. The prescriptions appear to be of a practical character and to be founded on experience: [*Ed. Farm. Lib.*

DISEASES OF POULTRY—DISORDERS OF DIGESTION.—1. *Indigestion of, or Turpid (full) Crop.*—This is a very common ailment, arising from taking cold, unsuitable diet, and other causes. The symptoms are moping, little or no disposition to take food, and hardness of the crop when felt. As a remedy, one or two tea-spoonsfull of English gin, according to the size of the fowl, has almost an immediate effect. It appears to act as a solvent, for the crop soon becomes soft,

* Henderson's Treatise on the Breeding of Swine.

(1926.) In my observations on the management of *hens* in winter, I mentioned that the early-hatched chickens of the former spring were the best to treat as laying hens during winter (1473). These same young hens being in fine condition in spring, will prove good layers through the ensuing summer, and should therefore be kindly treated for that purpose, and not encouraged to become sitters on eggs, which they will do, if allowed to wander in search of food, and to find out nests of their own to lay in. I

and maceration soon goes on as usual. Possibly this may be owing to the presence of the essence of the juniper berry, as no other spirit has the same effect, but is, on the contrary, deleterious to birds. This is infallible.

2. *Indigestion of the Gizzard.*—It would be difficult to enumerate all the causes for this, as for the former fatal ailment; but it often arises from confinement, locality, exposure to wet, damp and cold, and most frequently from unskillful treatment in the hands of negligent persons, or those ignorant of the habits or requirements of poultry, such as shelter, wholesome diet, sweet green food, lime, sand, &c., which are quite as necessary as grain. In the farm-yard and fields, the more natural state, birds can procure most of these ingredients for themselves, which in towns, pens, coops, or cages, their perfectly artificial state, must be administered artificially. Rue and fresh butter, or syrup of rue and barley-meal, or soot and fresh butter formed into pellets with barley-meal, with the addition of a little pounded red brick, or pounded dry clay, are excellent remedies; or with the addition of a small pinch of allspice, or a few of the allspice corns. A very few minute grains of Cayenne pepper have been recommended, but with great caution; indeed, I would scarcely advise anything so powerful and irritating. The best and only efficacious remedy, after all, is castor-oil, one or two tea-spoonsfull.

Mechanical Aid, when the crop is overloaded and medicine fails to promote maceration, must be resorted to and be effected by discharging its contents by gentle pressure, with great care and patience, through the mouth.

When, however, the contents swell, and are of a nature impossible to remove in that way without violence, which must never be used on account of the danger of lacerating the throat, an operation by a skillful hand is necessary, but requiring great trouble and attention during the healing process. A small slit must be made in the lower part of the crop, through which the noxious substances can be extracted. One or two sutures should then be neatly made with a needle and thread to hold the sides together, which will soon heal.

More sutures than are absolutely necessary would prevent healthy suppuration, which is requisite, in order to encourage the healing process. Care should be taken to keep the wound clean, but without damaging the sutures. The fowl must be kept within doors very quiet, and upon soft diet until recovered. But this sort of operation is often more curious than useful, if not cruel, unless the patient be one of some value.

3. *Oon, or Lush, or Shelless Eggs.*—When a hen lays this sort of egg, and not habitually, the occurrence is generally accompanied with hard or full crop. In that case, it is owing to indigestion, to be treated as before with one or two tea-spoonsfull of English gin. One cause is said to be overfeeding when fowls are too fat.

These eggs are generally dropped from the roost, and if it is not too high from the floor, or if they fall on straw, may be saved entire and used for puddings. As to symptoms, experience will make known the indications, and the time when a hen is about to pass one of these eggs, by appearing somewhat dull, and uneasy when walking about; when proper precautions should be taken to secure it, and prevent the other hens from gobbling it up. When this occurs from indigestion, the shapes of these eggs are often twofold, either like a funnel, the protuberance being about 2 inches long, ending with a thin thread twisted up at the end, or otherwise twain (two small) eggs, joined by a membrane, about an inch long; one containing the yolk, the other the white. The cause for this curious deviation of shape I have not ascertained. But when this happens habitually, which is not uncommon, the shape is in every respect as usual, and the cause is some derangement or injury of the passages through which the egg has to pass, after the yolk has detached itself (by its own weight, as it grows from the size of a pin's-head) from the pedicle which attaches it to the egg cluster, before the entire egg reaches the sack, just previous to being laid. The writer has a favorite hen, which always regularly drops these eggs from her roost, and never lays any others, and has done so for these five years past, although in perfect health.

This circumstance is attributable to the ignorant and cruel practice of "groping," which cannot be too often denounced and reprobated. When these eggs break within, the yolk and the white will pass off, but the skin will often remain and form a hard "extraneous substance," often becoming putrid. This is the case when the cause is indigestion, of which they often die, if not assisted to get rid of this obstruction. The surest remedy in this case is a dose of castor-oil, which seldom fails to cure the cause and remove the obstruction. But a precaution against this occurrence (when possible) is to assist in removing this skin artificially, before it has time to become a fixture, when it is observed to hang from the fowl. Experience and observation alone can teach the extreme nicety of this operation, so as to lead to success. It often occupies a quarter of an hour of time, and requires great forbearance and patience.

4. *Egg-bound.*—This is a fatality which is not of unfrequent occurrence, arising from an inactive state of the organs, when a fowl does not as usual, in due time, get rid of an egg, which will remain in the egg-bag for some days, often producing very ill consequences. The symptoms are moping, awkward gait, enlarged appearance and hanging down of the abdomen. The causes are various; but generally a cold, and often indigestion. The remedy is sometimes speedy: a few grains of salt put into the entrance, but without using any violence, will excite an immediate disposition to lay, when the fowl will run off instanter to the nest. If caused by indigestion, the cure must be treated accordingly]

also mentioned that there was no great difficulty of bringing up chickens in winter, if it were thought expedient to do it, and should any have been nursed in winter (1474) they will now in spring be in good condition, and be valuable birds, fit to make a handsome dish of roast or boil.

(1927.) As soon as the grass begins to grow in spring, so early will cared-for hens delight to wander into sheltered portions of pasture, in the sunshine, in front of a thorn-hedge, and pick the tender blades, and devour the tiny worms which the genial air may have warmed into life and activity. With such morsels of spring food, and in pleasant temperature, their combs will begin to redden, and their feathers assume a glossy hue; and even by February their chant may be heard, and which is the sure harbinger of the commencement of the laying season. By March a disposition to sit will be evinced by the early laying hens; but every hen should not be allowed to sit; nor can any hen sit at her own discretion where the practice is, as it should be, to gather the eggs every day as they are laid. It is in your option, then, to select the hens you wish to sit to bring out chickens. Those selected should be of a quiet, social disposition, not easily frightened, nor over careful of their brood, nor disposed to wander afar; and they should be large and full feathered, to be able to cover their eggs well and brood their young completely. Those which you may have observed to be good sitters and brooders should be chosen in preference to others; but it is proper to begin one young hen or so every season, to sit for the first time.

(1928.) The *eggs* intended to be set should be carefully selected. If those of a particular hen are desired to be hatched, they should, of course, be kept by themselves, and set after her laying time is finished. In selecting eggs, they should, in the first place, be quite *fresh*, that is, laid within a few days; they should be large, well-shaped, truly ovoidal; neither too thin nor too thick, but smooth in the shell; and their substance should almost entirely fill the shell, and should be perfectly uniform and translucent, when looked through at a candle, which is the best light for their examination. It is said that the position of the cell that contains air in an egg determines the sex of the chick that will spring from the egg, that is, if the cell occupies the exact apex of the end, which is always the large end, the chick will be a male, and if on one side of the apex, it will be a female. I believe there is truth in this observation, but to what extent, and what experiments have been made to determine the point, I have not learned; but there is no doubt of this, that the longer an egg has been kept with access to the air, until it becomes addled or dead, this cell increases in size, by the absorption of air through the shell, and, of course, by absorption also of the substance of the egg, which makes room for the air. The matter of the sex of the egg is of no importance on a farm, as a good chicken of one sex is as valuable, as an article of food, as a good one of the other. Either 11 or 13 eggs are placed under a hen; the former number, 11, is more likely to be successful in being entirely hatched than the latter, as few hens can cover in a sufficient manner so many as 13 large eggs. There is a freak, prevalent even at the present day, of the propriety of setting an *odd* number of eggs under a hen. This may have arisen from the idea that, allowing 1 egg to become rotten, an *even* number, or so many *couples* of chickens, will still be obtained in the hatching, and, accordingly, it is considered a good hatching if 10 chickens are brought out of a setting of 11 eggs, or a dozen of one of 13 eggs. As essential a matter as selecting the hens and eggs, is the making a proper *nest* for the sitting hen. This should consist of a circular hassock of soft straw-ropes, or it may be a box, or a basket. The object of this foundation is to raise the

real nest sufficiently off the ground to keep it dry, and to give the nest such a hollow as that none of the eggs shall roll out by any mischance that may befall the nest. Either a box or a basket is a very convenient thing for the purpose, but in using either it will be requisite to stuff the corners, as well as the bottom, firmly with straw, that the eggs may not drop into the corners, or the young chicks, as they are hatched, fall into them. The nest itself should be made of soft, short straw, sufficiently large to contain the hen, just sufficiently hollow to prevent the eggs rolling out, and sufficiently high above the floor to prevent any draft of air reaching the eggs.

(1929.) Places should be chosen for placing the sitting hens in—for the hen-house, common to all the laying hens, will not answer, the perpetual commotion in it disturbing the sitting hens. A hatching-house should contain one hen at a time, but as many may be accommodated in it as there are partitions to separate the one hen completely from the other, for hens are so jealous of each other, and especially when sitting, that they will sometimes endeavor to take the nest and eggs from one another. Other places can be selected for sitting in, such as an outhouse, a loft, a spare room in the farm-house, or even the back-kitchen. The hen selected for sitting having been accustomed to lay in the hen-house, or elsewhere, will feel annoyed at first on being transferred to her new quarters; she will have to be coaxed to it, and even after all may prove obstreperous, though exhibiting strong symptoms of clucking, in which case she must be dismissed and another chosen, rather than the risk be run of spoiling the whole hatching by her capricious conduct. A couple or so of old eggs should first be put into the nest, upon which she should be induced, by meat and water beside her, to sit for two or three days, to warm the nest thoroughly, before the eggs she is to hatch are placed under her. After she shows a disposition to sit, and the nest has become warm, the eggs are put into the nest, 11, as I said before, being quite enough, and the hen allowed to go upon them in her own way, and to manage the eggs as she chooses, which she will do with her bill and body, spreading herself out fully to cover all the eggs completely. The time chosen for setting the hen should be in the evening, when there is a natural desire for roosting and resting, and by next morning, by daybreak even, it will be found that she has taken to the nest contentedly. It is not an unusual practice to set a hen at any time of the day, even in the daylight, when she is almost certain to come off and desire to wander; and to curb this disposition, a tub, or some such vessl, is placed over her to keep her in the dark, and the consequence is, that the fright consequent upon such treatment prevents her paying any attention to the eggs, and some may even be broken in her attempts to get out of confinement. In such an attempt to keep the creature in the dark, it might suggest itself to a considerate person, one should think, that darkness would be most easily and naturally found at night, and that natural darkness was better than any that could be made artificially. Thus situate, the sitting hen should be looked at occasionally every day, and supplied with fresh food, corn, and clean water. She will not consume much food during the time of incubation, which is 3 weeks. Every 2 or 3 days, the dung, feathers, &c., about the nest or on the floor should be swept and carried away, and the place kept clean and dry. In about 3 weeks a commotion among the eggs may be expected; and should the hen have proved a close sitter, and the weather mild, it is not unlikely that 2 or 3 chickens will be seen peeping out below her feathers before that period. The hen should not be disturbed during the time the chickens are leaving the eggs, or until they are all fairly out and dry. Any attempt to chip an egg infallibly kills the chick; and every attempt to re-

move pieces of a chipped egg causes the chick to bleed. A good plan is to give the chickens, when fairly out, a drink, by taking them one by one and dipping their bills in water. Meat is then set down to them on a flat plate, consisting of crumbled bread and oatmeal, and a flat disk of clean water. The hen's food consists of corn or boiled potatoes and water. The chickens should be visited every 3 hours, and a variety of food presented, so as to induce them to eat it the more frequently and heartily, such as picks of hard porridge, crumbled boiled potatoes, rice, groats, pearl barley —taking care to have their food always fresh, and their water clean, however small the quantity they may consume. The hassock, or box, or basket, should now be removed, and the true nest set down on the floor, with a slope from it, that the chickens may have the means of walking up to the nest to be brooded at night. In the course of 24 hours after all the chickens are on foot, the hen will express a desire to go out, which she should be indulged in, if the weather is dry, and especially when the sun is out; but if it rain, she had better be kept within doors, unless there is a convenient shed near, in which she may remain with her brood for a short time. Visited every 3 hours during the day, and supplied with a change of food such as I have mentioned, and clean water, for about a fortnight, or until the feathers of the tails and the wings begin to sprout, chickens may then be considered out of danger, and, of course, become less of a charge to her who has the care of them. During the remainder of the season the chickens should receive food 3 times a day, consisting of potatoes boiled as they are used at table, as long as they last, and they might last the greater part of the summer, provided means were used to preserve them for the purpose; and the fact of being able to rear poultry cheaper on potatoes than on any other sort of food, is a sufficient inducement to preserve them as long as possible in a useable state. When potatoes fail, or even along with them, hard-made oatmeal porridge is an excellent food for fowls, when administered in small bits at a time. It is not expedient to set a number of hens at one time, but in succession every 3 weeks or a month; for a few chickens, ready in succession, are of greater value than a large number of the same age. As the season advances in summer, hens, as they become fat by picking up plenty of food in the fields, have a predilection to select places for nests in the fields, lay in them, and bring out chickens from their own eggs; and it must be owned that this is the most natural way of obtaining chickens; but no dependence can be placed for a supply of young fowls in this way, as the weather may not suit hens sitting in the open air; and hens may not be in a state for laying a nestfull of eggs in the most desirable part of the year, namely, the early and late periods of the season. In short, it is impossible to depend on a regular supply of either eggs or chickens, unless provision is made for collecting the one and hatching the other in a systematic manner. Chickens go 6 weeks with their mother. A good hen that has brought out an early brood will become so fat while rearing them that she will in time begin again to drop eggs, and of course again become a clucker, and may then be employed to bring out a late brood. Cock-chickens, just out of the egg, are distinguished from hen-chickens by their larger heads and stronger legs.

(1930.) In regard to the hatching and rearing of *turkeys*, it is universally said to be a very difficult matter to accomplish; an opinion I am by no means inclined to acquiesce in, for I am disposed to maintain that they are as easily reared as chickens, as may be seen in the sequel. When a turkey-hen is seen disposed to lay, a nest should be made for her in the hatching-house. It may consist of the same materials as the hen's nest, but, of

course, of a larger size to suit the bird. A box or basket is an excellent thing, with every corner filled up. When once the turkey-hen lays an egg, and a nest-egg is placed in the nest, she will use it regularly every time she requires it, which will be once in about 30 hours. As the eggs are laid, they should be removed and placed gently in a basket in the house, in a *dry* place, and turned with caution every day. When she has done laying, which may not be till she has laid 12 or 13 or even 15 eggs, she will be disposed to sit, when the eggs should be placed under her, to the number of 11 or 13, the former number being the most certain of succeeding, as a turkey cannot cover a greater number of her own eggs than a hen can of hers; and a brood of 10 poults is an excellent hatching. Corn and water should be placed near the nest; but the turkey need not be confined within the apartment she occupies, though she is not disposed to wander, nor is she jealous of another one sitting in the same apartment with her. A turkey sits 4 weeks, and is proverbially a close sitter. During the incubation her food and water should be supplied to her fresh and clean daily, and all dung and dirt removed from her every two or three days. When the poults are expected to make their appearance, the turkey should be frequently looked at, but not disturbed until all the creatures are fairly hatched. It is, I believe, a common practice to put a peppercorn down the throat of every poult a very short time after it is hatched. How this practice originated I cannot say; but as turkeys, when at liberty, have a great relish for ants, and seem to possess an instinctive faculty in discovering their hills, it is possible that the peppercorn may operate as a substitute for the ant. It is known that ants yield a peculiar acid called *formic* acid; and it is not improbable that the pungency of the peppercorn may act as stimulant on the stomach in the same manner as the acid in ants. Dr. Thomson, in speaking of the origin of the formic acid, says that "it is secreted by the *Formica rufa* or red ant, and is the liquid that renders the bites of these insects so painful. It was first publicly noticed by Mr. Ray in the year 1670. . . . Mr. Fisher had stated to Mr. Ray several years before, that 'if you stir a heap of ants so as to rouse them, they will let fall on the instrument you use a liquid which, if you presently smell, will twinge the nose like newly-distilled oil of vitrol.' Mr. Fisher farther stated that 'when ants are distilled by themselves or with water, they yield a spirit like spirit of vinegar, or rather like spirit of *viride æris*. It dissolves iron and lead. When you put the animals into water, you must stir them to make them angry, and then they will spit out their acid juice.' Margraaf obtained this acid in 1749, by distilling ants mixed with water and rectifying the liquid that came over. The acid obtained had a sour taste and smell."* While considering this acid, I may say a few words on the constitution of pepper. "*Piper nigrum* is the name of the plant which produces common pepper. It is a shrub which grows in India. The seeds are berries, round, hard, having an aromatic smell and a *hot acrid taste*. These berries constitute pepper. The unripe berries are the common *black* pepper; while the ripe berries, deprived of their epidermis, constitute *white* pepper. . . . In 1821 M. Pelletier published an elaborate examination of pepper. He showed that it contained the following constituents:

Piperin.	Malic and tartaric acids.
A solid, very acrid oil.	Starch.
A balsamic volatile oil.	Bassorin.
A gummy-colored matter.	Lignin.
Extract similar to that obtained from leguminous seeds.	Earthy and alkaline salts in small quantities.

* Thomson's Chemistry of Animal Bodies.

M. Pelletier showed that piperin did not possess alkaline characters, as Oestedt had supposed, but that it was a peculiar principle. He found, too, that pepper owed its peculiar *taste to a volatile oil.* This I had shown many years before," adds Dr. Thomson.* From this account of it, it is not improbable that the solid and very acrid oil in the pepper may operate on turkeys in a similar manner to the formic acid in ants; and this may form an excuse for an old practice for which a sufficient reason cannot be given by those who follow it. After the peppercorn is given, and it may be given or not at the person who has charge may choose, the poults get a drink of water, and are returned into the warm nest, where the mother receives them with characteristic fondness. But before leaving the turkey for that night, the box or basket in which the nest is formed should be taken away, and the nest brought down upon the floor, with a sloping face toward the floor to enable the young poults to gain the nest. For 24 hours the poults will eat nothing, though the turkey herself should be provided with corn or potatoes and water. Next morning the young creatures will be quite astir and ready to eat food, which should now be given them. It should consist *solely of hard-boiled eggs, yolks and white shredded down very small,* and put on a flat plate or small square board. In one respect turkey-poults differ in their nature from chickens, inasmuch as they are more apt to purge for about the first fortnight of their existence, and when purging does overtake them it is difficult of cure, and indeed generally proves fatal; but hard-boiled eggs, forming an astringent and nourishing food, entirely *prevent* purging, and are better for them than some other things I have seen tried. For instance, for the sake of experiment, hard-made oatmeal-porridge was given instead of hard-boiled eggs, and in a short time two poults took the flux and died, the rest having been saved by a return to the egg. With egg, not a single death has occurred among one to two hatchings every year for upward of 20 years, and that is surely sufficient experience to justify the recommendation of any practice. Let the poults be visited every 3 or 4 hours, supplied with hard-boiled egg and clean water. Let their food be removed after the poults are served, otherwise the turkey-hen will devour it, for she is a keen feeder, and not so disinterested a bird as a hen. Let them remain 2 nights and a day in the house, and after that let them go into the open air and enjoy the sun and warmth, of which, it is hoped, there will be a plenty in the month of May. In wet weather, however, they should either be confined to their house, or allowed to go into a shed. When the birds become strong and active, in the course of a few days let the turkey be placed in a coop on the green to curb her wandering propensity, until the poults can follow her, which they will be able to do after they have partaken of the hard-boiled egg for a fortnight. Their meat can be put down on a plate on the green beyond the reach of the coop, and where the poults can help themselves, while the food of the turkey is placed within reach of the coop, consisting of corn, and potatoes, and water. After the feathers in the tails and wings of the poults are beginning to sprout, the egg may be gradually withdrawn, and hard-boiled picks of porridge, with a little sweet milk in the dish, to facilitate the swallowing of the porridge, should be given them at least 4 or 5 times a day at stated hours, and will make wholesome food, until the mother can provide insects and other natural food for them, which will form a desirable variety with the food given them, and then they will thrive apace, and grow amazingly fast as the weather becomes warm. Should the grass be damp, let the coop be placed on the gravel of the road or walk, as dampness is injurious to all young birds of the gallinaceous tribe. After the egg

* Thomson's Chemistry of Vegetables.

the poults are fond of a little shredded cress and mustard, and when at full liberty, they will pick the leaves of nettles with avidity. These predilections for ants, cress, and nettles, show that turkeys enjoy stimulating condiments with their food.

(1931.) Turkeys are sometimes extraordinary layers. One season a hen-turkey of my own, after bringing up 11 poults till they were 8 weeks old, made a nest in the middle of a large bush of nettles at the edge of a young plantation which she visited, and contrived to slip away unnoticed from her brood to lay an egg in *every day*. The nest was soon discovered, the egg taken away every day as it was laid, and a nest-egg left in it, and thus she continued to visit it daily until she had laid the extraordinary number of 90 eggs. The consequence of this oviparous fecundity was, that the turkey did not moult till the depth of winter, and the moulting was so very bare that she had to be confined to the house; and whether the catastrophe which befell her before spring was owing to the severity of the late moulting I do not know, but an inflammation and a consequent swelling seized one of her eyes, and she was deprived of its sight. By spring, however, she recovered from the moulting, was furnished with a complete set of new feathers, the wound on the eye healed, but somehow she died in a very short time after. Turkey-hens are most watchful protectors of their young, and are particularly wary of birds of prey, which, whenever observed, even at the greatest hight in the air, they will utter a peculiar cry, and every poult will instantly hide itself among the longest grass and other plants within reach. There is another peculiarity in regard to the turkey-hen; one impregnation from the cock fecundates all the eggs of the ovarium; and on account of this property, I am told it is not uncommon in spring in Ireland to see people carrying about a turkey-cock and offering his services at farmsteads as those of a stallion are proffered. It is perhaps owing to this peculiar constitutional habit of the turkey that makes the cock so regardless of his own progeny; and, indeed, the hen voluntarily shuns his attention when in charge of her brood. The brood goes with her for an indefinite length of time.

(1932.) In regard to *geese*, they make early preparation for incubation. There are couplets in existence indicative of the period of commencement of their laying, namely,

"By Candlemas day,
Good goose will lay."

And,

"By St. Valentine's day,
Good and bad goose will lay."

Geese, however, seldom lay in Scotland till the end of February. The goose and gander cannot embrace but in water, and if the pond which they frequent be covered with ice, it should be broken to allow them to get to the water, and every egg requires a separate impregnation. An attentive observer will know when a goose is desirous of laying, by her picking among straws and placing one on this side and one on that of her, as if making a nest. Whenever this is noticed, or an embrace on the water, a nest should be made for the goose to lay in in the hatching-house, and to which she should have easy access, for she cannot jump up with the nimbleness of either a hen or a turkey, though her nest may be made in a box or basket, in the same manner as that of the hen, but of a size to suit the bird intended to occupy it. It is not proper to confine a goose a long time before laying her first egg; but when symptoms of being with egg are observed, she should be caught in the morning, when let out, and the lower portion of the soft part of the abdomen felt, where the egg may be easily ascertained to be in a state or not, for being immediately laid, and if it feel hard, the goose should be shown her nest and confined to it until she

lays in the course of the day, after which she is of course let out, the egg taken away and kept dry in a basket, and turned every day, until the whole are placed under her. Every other day after this the goose will visit her nest and lay an egg, and the number she may lay will seldom exceed 12, though 18 have been known to be laid; so, by the time she is done laying, it will be about the end of March. There is, however, considerable difference in this respect with geese, on some farms they being considerably earlier in hatching than on others. This may arise from the nature of the soil, for it is probable that a dry, sharp, early soil for grass and grain, will also early promote the functions of the animals that live upon it. After the goose has finished laying her eggs she will incline to sit, and then is the time for her to receive the eggs; and the best time for placing her upon them in the nest, as I have said before, is in the evening, that, by the arrival of the morning, the nest being warm and comfortable, the goose will have no inducement to leave it. The number of eggs given to be hatched should be 11, which is as many as a goose can conveniently and easily cover. The goose plucks the down off her body to furnish her nest with the means of its increasing its heat; and one great use of the down is, that when she leaves her nest at any time it serves the double purpose of retaining the heat about the eggs and of preventing the external cold affecting them. A little clean water and a few oats are put beside a goose when she is sitting; but she will eat very little food all the time of her incubation. A feed of good oats, such as is given to a horse, will serve a sitting goose for a month, yet this little handfull is actually grudged the goose, and instead of good corn, only little better than chaff, the lightest corn that is blown from the fanners, is only allowed by many farmers who consider themselves very good managers. Some hen-wives will not allow the goose to go abroad as long as she is sitting; but this is an unnecessary constraint upon her. Let her go off whenever *she pleases*, and there is no fear but that she will return to her nest in time to retain the heat of the eggs; for she makes it a point to cover every egg with down before leaving the nest. Most people will not allow her to go to the water at all, alleging that if she return wet upon her eggs they will become addled, but this is a mistake. Let her go to the pond if she wills it, and wash herself in it, and, depend upon it, she will not continue long there; she will be cooled and much refreshed by it. The feathers will not become *wet;* it is not their nature to become so; and after such a relaxation, which she much enjoys, she will sit the closer. Geese are liable to become costive while sitting, and to counteract this tendency, they should be supplied now and then with a little boiled potato in a dry state, which they will relish much, and feel much the better for; and, indeed, every fowl, while sitting, should receive a little of this useful succedaneum at that peculiar juncture. The gander usually takes up with one mate, but if there are only two geese, he will pay attention to both; and his regard for his mate is so strong that he will remain at the door of the hatching-house like a watch-dog, guarding her from every danger, and ready to attack all and sundry who approach her sanctuary. At the end of a calendar month the eggs may be expected to be hatched; and during this process the goose should be left undisturbed, but not unobserved. After the goslings are all fairly out of the shell, and before they are even dry, they may be taken in a basket with straw to a sheltered dry spot in a grass-field, the goose carried by the wings, and the gander will follow the goslings' soft whistle. Here they may remain for an hour or two, provided the sun shines, for in sunshine goslings will pick up more strength in one hour than all the brooding they can receive even from their mother for a day. The goose will rest on the

grass, the goslings will endeavor to balance themselves on their feet to pluck it, and the gander will proudly protect the whole. Water should be placed beside them to drink. Should the sky overcast, and rain likely to fall, the goslings should be collected, and they and goose carried instantly to their nest; for if goslings get their backs wetted with rain or snow in the first two days of their existence, they will lose the use of their legs, never recover their strength, and inevitably die. Should the weather be wet, a sod of good grass should be cut and placed within their house, with a shallow plate of water. In setting down a common plate to goslings, it should be prevented from upsetting, as they are apt to put their foot upon its edge, and spill the water. After two days' strength, and especially in sunny weather, the goslings may venture to the pond to swim; but the horse-pond is a rather dangerous place for them as yet, so many creatures frequenting it. Some water, or a pond, in a grass-field, would be a better place for them. For the first two or three days after goslings go about, they should be particularly observed, for should they in that time happen to fall upon their backs, or even into a hardened hoof-print of a horse, they cannot recover their legs, will be deserted by their dam and the rest of the flock, and will perish. After three or four days, however, in dry sunny weather, and on good grass, they will become strong, grow fast, and be past all danger. It is surprising how rapidly a young gosling grows in the first month of its life. After that time they begin to tire of grass, and go in search of other food; and this is the time to supply them daily with a few good oats, if you wish to have a flock of fine birds by Michaelmas; any other grain will answer the purpose, as rice and Indian corn, let it be but corn, though oats are their favorite food. Even ordinary light corn will be better for them than none; and if they get corn only till harvest, they will have passed the most growing period of their life, and will then be able to shift for themselves, first in the stack-yard and afterward in the stubbles. The sex of the gosling may easily be ascertained after the feathers begin to sprout, the ganders being white, and strong in the leg, head, and neck; the geese are gray and gentler-looking. Goslings go with their parents for an indefinite length of time.

(1933.) Geese are in general close sitters; but sometimes they become so capricious as to forsake some of their eggs after a number of them have been hatched. An instance of this sort of desertion I have witnessed. A goose after hatching 5 goslings, deserted her nest and would no longer sit on the other 6 eggs to bring them out, though one of them was chipped. Fearing that the deserted eggs would perish from cold, my housekeeper —who took the charge of all the poultry, cows, and calves, besides the duties of the house—brought the eggs into the house, put them in a basket among flannel and wool, caused the oven to be gently heated, placed the basket with the eggs in the oven, and continued the heat in it night and day until all the goslings were hatched, which they were one by one, excepting one in which the bird had died. The young creatures occupied some days in leaving their eggs, and longer than they would have done under the goose. They were carefully attended to and were taken out to the grass in the best part of the day, kept warm in the house at night, and, when the weather was such that they could not get out, a grass-sod was brought to them into the house. The goose refused to take her own broken brood when offered to her, after they had gained sufficient strength to go about; and this being the case, they were brought up without her aid, and became as strong birds as those of her own out-bringing. I consider this a remarkable instance of the resources of a ready mind, and of disregard of personal trouble; and it is an encouraging example of perseverance in an

attempt to preserve the lives of useful animals under very inauspicious and even provoking circumstances.

(1934.) *Ducks* begin to lay eggs early in the season, as early as February, so it is possible to obtain an early hatching of ducklings, if desired; but early ducklings are not desirable, for, during that unnatural period for them, they do not acquire much flesh, even with the utmost care; their bills and bones grow disproportionately large, and altogether the experiment does not succeed. It is early enough to set duck-eggs in Scotland by May, and by April in England. It is customary to place duck-eggs under hens, owing I believe, to the great difficulty of making a duck take to a nest which she has not herself made. Hens make pretty good foster-mothers to ducklings, though in becoming so, the task is imposed upon them of a week's longer sitting than is *natural* to them, and, after all, the natural plan is for ducks to bring out their own kind; and there is no doubt that when a duck does choose a nest for herself, lines it with her own down, and brings out a brood, the ducklings are better than any reared under the auspices of a hen; the instinct of the duck being more congenial to ducklings in leading them to places in search of food peculiar to their tastes, as well upon land as upon water. Still the entire production of ducklings on a farm should not be left to the chance of ducks setting themselves on eggs, for they are proverbially careless of where they deposit their eggs, and on that account hens must be employed to hatch at least a few broods.

(1935.) As in the case of her own eggs, a hen can only cover 11 duck-eggs with ease, and, of course, she requires the same treatment when sitting on them as she receives with her own eggs. A calendar month is required to bring out ducklings; and the hen should be left undisturbed until all the brood comes out. Ducklings should be kept from water for a couple of days, until their navel-string is healed; and the food which they receive should be of a soft nature, quite the opposite of that given to turkey-poults, such as bits of oatmeal porridge, boiled potatoes, bread steeped in water, barley-meal brose, and clean water to drink in a flat dish in which they cannot swim. On this treatment, 3 or 4 times at least every day, they will thrive apace, and become soon fledged in the body, when they are fit for use; but their quill-feathers do not appear for some time after. In this state wild ducklings, under the name of *flaffers*, make good sport, and are an excellent dish with green peas, when stuffed with onion and sage shred small, and a little pepper and salt among them, and roasted, and served up in a hot sauce of Port wine seasoned with pepper and mace.

(1936.) A great number of ducklings are bred and reared every year at Aylesbury in Buckinghamshire, for the London market, by people of the poorer class. The eggs are hatched by hens, and 3 or 4 broods are put together into one division; while other divisions contain them in a different state of growth, some half grown, others full fledged, and all are fed alike. In this way one person has 300 or 400 ducklings feeding about his house, and perhaps under the same roof with his own family. A great many are housed in little space, and never allowed to go at large; but are permitted to wash themselves every day in a pond made on purpose near the house. They are fed three times a day on potatoes, barley-meal, bran, greaves, &c., and receive as much as they can eat; and it is said that they can eat an incredible quantity of food while thus forced for the market. When full-feathered they are sent to London, where they find a ready sale, at from 6s. 6d. to 8s. a pair. As the season advances, prices fall, till they reach 3s. a pair, when the breeding is given up for the season. These poo-

ple allege that they are not remunerated for their trouble even at the highest prices.

(1937.) *Pea-hens*, in their hatching, cannot be subjected to control. The hen selects a secluded spot for her nest, not unlikely in the garden, where she feels herself secure from the attentions of the cock, whom she seems to avoid at this season, with marked assiduity. She takes care that he shall not know, not only where her nest is, but when the pea-fowls come out, because, as is alleged, the cock would destroy them. A pea-hen in this country seldom brings out more than 3 or 4 birds, though usually laying 5 eggs; and these she tends with great care, taking them to places where wild food can be found in greatest abundance, such as insects of various kinds and in different states, and grain, while they are fed as young turkeys; and she continues her attentions to them for the greater part of the year.

(1938.) *Pigeons*, when their dove-cot is favorably situated for heat, begin to lay in February, and will continue to do so until December. They make their own nests, which are of the simplest and rudest construction, and, indeed, the same nest will be used by the same pair season after season, even after it has been much elevated with dung. A fine nest is not required by pigeons, which only laying 2 eggs at a time, one of each sex, the hen can easily cover them; and to secure them still more, she pushes them below her with her bill, among the feathers, to keep them warm. A supply of young pigeons might be found at the farmer's table all summer. To vary their cookery, they can be stewed, roasted, broiled, and made into pies, one and all of which, when properly seasoned with pepper, salt, onions shred small, and butter, makes a savory appendent to any dinner. While touching on cookery, I may remark, in regard to other poultry, that a young chicken roasted or broiled, when in perfection, at 14 weeks old—a young cock especially, or boiled—a young hen being the more delicate—with a slice of ham, is a standing delicacy at a farmer's table. Ducklings and green peas are seen for a short season in the early part of summer, but a roast duck may be had all autumn and the early part of winter. Turkey-poults are never indulged in by the Scottish farmer, probably from the idea that they have too little flesh upon them, and are too similar to boiled chickens; and as chickens are more plentiful, and can be used with less scruple, the poults are spared until they attain full size. Young geese are never seen at a Scottish farmer's table, though a stubble-goose at Michaelmas seems to be prized in England. With regard to the means of supplying young fowls on a farm, 2 turkey-hens and 2 geese will rear as many turkeys and geese as will be required by a large family; 3 or 4 broods of ducks will suffice; a brood or broods of chickens may be brought out from March to November; and as to pigeons, it is the farmer's own fault if he has not a supply of them from March to December. Those who do not care for the flesh of fowls may send their poultry to market; and those who breed for the market should provide a person well versed in rearing poultry to undertake the duty.

(1939.) With regard to the feeding of fowls in summer, boiled potatoes and hard-made oatmeal porridge should be their staple food; and so fond are all sorts of birds of potatoes, that there should some pains be taken by farmers to preserve a few of the best of them over the summer, for the express purpose of feeding poultry. I have described a plan of keeping them over a year in a former paragraph (1871). Food, when distributed for poultry, should not be laid down in a large heap in one place, when birds of different natures partake of it, and are therefore almost certain of quarreling and fighting; but it should be scattered thinly along a bare

piece of ground, or, what is better, upon grass, which keeps it clean, and from which it can easily be picked up, but it should not be laid among straw, as it is easily lost sight of among it. As different sorts of birds have different habits, and frequent different places, the food should be scattered for each kind as near their usual habitats as their natures indicate, and which the person who has charge of the matter can devise—scattering some near water for geese and ducks, upon the margin of grass on the side of the road near the steading, for hens, and at a more retired place, though still upon grass, for the turkeys; and the food should be thus be laid down for the different sorts of fowls at a fixed hour of morning and afternoon. Cleanliness, attention, regularity, and good food, constitute the grand secret of rearing poultry to the highest perfection.

(1940.) What I have described of hatching the different sorts of fowls usually reared, is suitable to every sort of farm, and may be acquired by any domestic of the farm-house: and that it is a practicable scheme my own experience has demonstrated. Other schemes are recommended in books, and large establishments, consisting of buildings and ponds, and spare ground, are erected in the parks and farm-courts of country gentlemen; but let any other plan be what it may, and the erections and other appliances of whatever magnitude, there is none, I feel confident, will afford poultry at all times in a higher degree of perfection than the simple one I have been describing, and recommending for your adoption—and experience is the true test to which every plan should be subjected. I do not hold it out as a peculiarly cheap plan, that is, that it will supply *good* poultry for the table at *little or no cost*, though that is the idea of cheapness entertained by farmers, when they condescend to cast a thought on the poultry of their farms. I will not say, because I do not believe it, that fowls can be reared for nothing, or upon the *refuse* of the products of a farm; because, when I see that it requires the best oats, the best turnips, and the best grass that a farm can raise, to rear such horses, cattle, and sheep, as purchasers desire to have, I cannot believe that the *best* poultry can be reared but on the *best* sort of food suited for them; but this I will say for the plan as a practicable one for an ordinary farm, that it requires no costly buildings, and that it will assuredly yield poultry in good condition at all times in return for the food and trouble bestowed upon them, and what more can any reasonable farmer desire?

(1941.) Fowls are kept in towns in places quite unsuited to their habits; most frequently in a small court, surrounded by a high rail, except on the side in which the hen-house is situated; and this consists of a flattish-roofed outhouse, pervious to rain and redolent of moisture—a condition the very worst for fowls. The floor of the court is generally covered with dirt, and the small vessel which is intended to contain water is as often dry as plenished with *clean* water, while the food is thrown upon the dirty court-floor. Add to these sources of discomfort, the sun, probably, never shines upon the town hen-house, or only for a few minutes in the afternoon, when the fowls are about to retire to roost. Ducks are treated in even a less ceremonious manner than hens; having no water, their feathers become begrimed with dirt, and their food is given them in a state little else than a puddle. It is, of course, impossible that fowls can *thrive* in such circumstances, and, indeed, a sight of the poor creatures excites nothing but commiseration for their fate. What can induce people to keep animals in such a state of filth and suffering is what I cannot conceive. One cause of suffering to hens in such situations is the want of sand or gravel to assist the trituration of food in the stomach. It is found that gallinaceous birds require a supply of quartzy substances, and these they find on any farm, as also calcareous matter, such as lime, to assist in the formation of the shell of the egg, without which hens will lay what are called *wind* eggs, that is, eggs without a *hardened* shell. In the case of the fowls on board a certain East Indiaman getting unwell in their coops, notwithstanding the attention daily bestowed, and the good food allowed them, it was discovered by the surgeon, on dissection of some of the birds which had died, that the cause of death was the want of gravel to assist the digestion of food. A supply of stones to beat down small was obtained at a convenient port, and the fowls became healthy and continued so afterward. Another source of suffering of a similar nature to hens, is the want of dust to flutter among their feathers in order to destroy the vermin that annoy their skin; and the want of water for the ducks to wash in and clean themselves.

(1942.) With the diseases of chickens or other young fowls, such as the *pip* or *chip*, I am not acquainted, not having seen any such disease after an experience of many years in rearing every

species of fowl that is found on a farm, and, of course, I am inclined to maintain that, were others to follow a similar course to the one I have so successfully pursued, they would have equal success, and witness as few diseases among their poultry as I have. I am corroborated by a writer on the rearing of domestic poultry, whose experience I know is considerable—whose attention I am sure is unremitting—and whose good sense is evident. "Of the diseases to which poultry are liable we are practically ignorant," says the writer, a lady of my acquaintance, "having been for many years here so fortunate as to experience few or no instances of disease among our stock; and we attribute the health of our various animals in the farm-yard *entirely to strict attention to cleanliness, diet, and rational treatment.* Those who listen to advice of the ignorant and the prejudiced, nay, they who seek from books remedies for disorders which may appear among their live-stock, will have to contend with monstrous absurdities, excessive ignorance, and barbarous cruelty, in the quackeries recommended. Nature will generally effect a cure, if her efforts are seconded by simple means on our own part. Calomel, sulphur, rue, pepper, and gin, are all absurdities, though all recommended for the ailments of poultry." Another writer thus expresses himself on the same subject: "With regard to medical treatment applied to the diseases of poultry, but little regarding its efficacy is known. The nostrums and mode of treatment adopted throughout the country, together with the greater part that has been written upon the subject, is a farrago of nonsense and absurdity. *If shelter, warmth, food, and cleanliness, congenial to their habits, will not preserve them in health, but little reliance can be placed upon medicine.* Most good wives, however possess an insatiable itching to be considered skillful doctors. From among some thousand birds that have come under my observation, *I never could discover that common and universal disease* called the '*pip*.' Yet show any farmer's wife a sickly chicken, and she immediately opens its mouth, and with her needle tears off the cartilage from the under part of the bird's tongue, to show it is afflicted with it! When will the light of knowledge banish these absurdities?"* The former writer, however, alludes to an ailment among chickens which I have never seen, arising, it would appear, from their being hatched at a particular period of the year. After adverting to the tender state of chickens superinduced by both early and late hatching, the writer particularizes the period of the year when the disease alluded to makes its appearance: "There is yet another time, during which it is *absolutely indispensable that hens be prevented from sitting, and that is the month of June.* Close observation (after having suffered at that season numerous failures most unaccountably) enabled us to discover the cause, and thereby verify the truth of an old saying, which we have since met with—

'Between the sickle and the scythe,
What you rear will seldom thrive.'

We had noticed that chickens which were hatched during the month of July were almost all attacked about the time of their first moulting (a period always attended with much suffering to them) with a fatal disorder, the symptoms of which are unvarying. The chickens appeared to collapse, and moved about with difficulty, as if their joints were stiffened, or rather as if the skin had become tight and tender; their feathers became rough and stood out; their wings drooped and dragged on the ground; they refused sustenance; and becoming more and more weak and torpid, they in a day or two, died off in great numbers. Every rational means was resorted to in order to arrest, or even account for the disorder; at length it was discovered that they were in a high state of fever, and that the extreme redness of the skin was caused by the irritation of hundreds of that minute pest the harvest bug. Some—very few—were recovered by anointing them all over with oil and vinegar (which is also the best, nay the only remedy for the annoyance which human beings experience from the same source); but the receipt is too rough for little delicate creatures already enduring the pain attendant on the season of moulting. It became obvious that the period during which harvest-bugs are most numerous and tormenting must be inimical to the rearing of chickens; and that if hens were not allowed to sit in June, or rather, if the chickens were either strong enough to cope with the evil, or were not hatched until the season for the pest had passed by, the destruction might be prevented, and so it has proved." †

(1943.) On considering the hatching of fowls, the mind is naturally led to the curious artificial system of hatching which the ancient Egyptians practiced, and which afforded them an immense supply of poultry every year. It is unnecessary to detail the ancient mode of hatching, as it is unsuited to this country, our climate being much too unsteady for the purpose; but particular accounts of it may be found detailed by authors.‡ The modern Egyptians still practice the system, and as the results exhibit some extraordinary facts, I am tempted to give the following account of it from Mr. Mowbray. "Sicard," he says, "gives an idea of the immense quantities of chickens hatched in his time in Egypt. The number of ovens for hatching the eggs, dispersed in the several cantons of the country, was no less than 386. The business seems to be monopolized by the Agas or Government, and therefore cannot be varied in extent but by their permission. Each *mamal* or oven has one managing Bermean, a native of the village of Bermé in the Delta, by whom the art of managing it has been retained, and is taught to his children. These managers cannot absent themselves from duty but with leave obtained from the Aga of Bermé, never obtained but at the expense of 6 to 10 crowns. The Aga constantly keeps a register of these fees, which to him is a sort of rent-roll. The above number of ovens is kept at work in Egypt annually during 4 to 6 months, allowing more time than is necessary to hatch 8 successive broods of chickens, ducks, and turkeys, making in the whole, yearly, 3,088 broods. The number in each hatching is not always equal, from the occasional difficulty of obtaining a sufficient number of eggs, which may be stated at a medium between the two extremes of 40,000 and 80,000 to each oven. The Bermean contracts to return, in a living brood to his employer, ⅓ of the number of eggs set in the oven—all above being his own perquisite in addition to his salary for the season, which is 30 to 40 crowns, exclusive of his board. According to report, the crop of poul

* Bucknell's Ecealeobion. † Quarterly Journal of Agriculture, vol. viii.
‡ Wilkinson's Manners and Customs of the Ancient Egyptians, vol. i., New Series.

try thus artificially raised in Egypt was seldom or never below that ratio, making the enormous annual amount of 92,640,000. It is obvious that the apparent grand difficulty of obtaining a sufficient number of eggs must subsist chiefly or entirely in the infancy of such an undertaking, and that its progress must infinitely extend that supply, as has been the case in Egypt, where the breeding stock has been so multiplied, and where, in consequence, the commodity is so cheap from its superabundance, that in the time of Sicard 1,000 eggs were sold for 30 or 40 medims, making 3s. or 4s. English money. Indeed, the chickens were not sold from the stores by tale but by measure; according to Reaumur, by the bushel! And it appears from travelers of the present day, to be the custom in Egypt to purchase chickens by the basketfull."* M. Reaumur, under the French Academy, instituted experiments to prove that eggs could be hatched in France as well as in Egypt; but it was soon discovered that the two countries were placed in different circumstances in regard to climate, and the project was abandoned as being impracticable. Plans of artificial hatching were tried with better success by M. Bonnemain, by a system of supplying heat from hot water in pipes; but the French Revolution put an end to the experiment. It is worth observing, in passing, how strange it is to hear of the circulation of hot water in pipes, as a steady source of heat, recommended at the present day as a *novelty*.† To supply the inhabitants of Great Britain and Ireland with fowls as the Egyptians are, namely, at the rate of 46 1-5 fowls to each person every year, the number that would require to be hatched in the relative proportions of the two countries, would be 1,109,000,000 of fowls!

(1944.) A remarkable machine, exhibited in London some years ago, which I saw in the summer of 1839, was said to have attained the power of supplying the requisite degree of temperature for hatching for any length of time. It was the invention of Mr. William Bucknell, and named the Eccaleobion, derived from two Greek words meaning "I give forth life." "Rationally to hope for success in the artificial hatching of eggs," says Mr. Bucknell, "it becomes necessary to be in possession of a power completely to control temperature, independent of climate, seasons, or changes in the atmosphere, and also uninfluenced by them. These invaluable properties the Eccaleobion possesses, in a perfect and absolute command over temperature, from 300° Fahr. to that of cold water; so that any substance submitted to its influence shall uniformly be acted upon over its whole surface, at any required intermediate degree within the above range, and such heat maintained unaltered, without trouble and difficulty, for any length of time. By means, then, of this absolute and complete control over temperature, obtained by this machine, the impregnated egg of any bird, not stale, placed within its influence at the proper degree of warmth is, at the expiration of its natural time, elicited into life without the possibility of failure, which is sometimes the case with eggs subjected to the caprice of their natural parent."‡ Without attempting to describe the machine, I may mention that it is capable of containing 2,000 eggs, which are open to the sight through glazed doors, in different states of incubation, from the day the egg is inserted into it, until the bird is seen to leave it in the act of being hatched. It may be interesting, however, to relate a few of the facts regarding the condition of eggs in different states, as to their vitality, observed by Mr. Bucknell in his experience of the machine.

(1945.) Few eggs are worth the trial of hatching if more than a month old; their condition, however, is greatly influenced by the season and the state of the weather. An egg retains its freshness longest in moderately cool weather; very hot weather destroys vitality in a few days; and an egg having been frozen is also worthless. Failures in hatching arise from want of impregnation in the egg—from age, commonly called staleness, whereby life has become extinct—from weakness of the vital energy of the eggs, produced by age, lowness of keep, or ill health of the parent, in which cases the chick partially develops itself, but dies before the full period of incubation. Eggs may be brought to life, but unless the process of incubation be properly executed, the birds will be weakly, ill-conditioned, and die in a short time afterward. To prevent the yolk of weak eggs from settling by its specific gravity, and adhering to the shell, it is useful to pass the hand over them, so as to change their position every 24 hours. The egg of a strong, healthy bird, at the time of its protrusion from the body, is completely filled with yolk and albumen. If examined a few days after, by holding it toward the light, a small cell of air will be discoverable at the larger end, which increases with the age of the egg. This waste of its internal substance is occasioned by absorption of the atmosphere, through the pores of the shell, of the more volatile parts of its contents. When the cell is large in any egg, it is unfit for incubation; nevertheless, in a good egg, as incubation proceeds, this cell becomes considerable, produced probably both from evaporation by heat and the vital action going on within the shell. It also serves an important purpose in the economy of this mysterious process. An egg will not hatch in vacuo.

(1946.) The progressive series of phenomena daily observable during the process of incubation, in the egg of a common fowl, are curious and instructive. In an impregnated egg, previous to the commencement of incubation, a small spot is discernible upon the yolk, composed of a membranous sack containing fluid matter in which the embryo of the future chick swims. 1st Day: At the expiration of 12 or 14 hours after incubation has commenced, the matter within the embryo evidently bears a resemblance to a head—vesicles assume the shape of the vertebral bones of the back. 2d Day: In 39 hours the eyes make their appearance—vessels joined together indicate the navel—the brain, spinal marrow, rudiments of the wings, and principal muscles—the heart is evidently proceeding. 3d Day: At its commencement the beating of the heart is visible—some hours after, two vesicles containing blood appear, one forming the left ventricle and the other the great artery—the auricle of the heart is next seen, and pulsation is evident. 4th Day: Wings assume a defined form—the brain, the beak, the front and hind parts of the head visible. 5th Day: Liver seen—circulation of the blood evident. 6th Day: Lungs and stomach distin-

* Mowbray's Practical Treatise on Domestic Poultry.
† Ure's Dictionary of the Arts and Manufactures, art. *Incubation, Artificial.*
‡ Bucknell's Eccaleobion.

guishable—full gush of blood from the heart distinct. 7th Day: Intestines, veins, and upper mandible visible—brain becomes consistent. 8th Day: Beak opens—formation of flesh on the breast. 9th Day: Ribs formed—gall-bladder perceptible. 10th Day: Bill formed—first voluntary motion of the chick seen. 11th Day: Skull becomes cartilaginous—protrusion of feathers evident. 12th Day: Orbits of sight appear—ribs perfected. 13th Day: Spleen in its proper position in the abdomen. 14th Day: Lungs inclosed within the breast. 15th, 16th, and 17th Days: Mature state approached—yolk of the egg still outside of the body. 18th Day: Audible sign of life outside the shell—piping of the chick heard. 19th, 20th and 21st Days: Increase of size and strength—yolk inclosed within the body—chick liberates itself by repeated efforts made by the bill, seconded by muscular exertion of the limbs.

(1947.) The embryo of the chick is not in every egg placed precisely in the same situation, but varies considerably. Generally it develops itself within the circumference of the broadest part of the egg: sometimes it is found higher, sometimes lower; and when held before a strong light has an appearance, when a few days old, somewhat resembling the meshes of a spider's web, with the spider in the center. As it increases in size, the bulk of the contents of the egg decreases, so that when the bird is completely matured, it has ample space to move, and to use its limbs with sufficient effect to insure its liberation. The position of the chick in the shell is such as to occupy the least space. The head, which is large and heavy in proportion to the rest of the body, is placed in front of the belly, with its beak under the right wing; the feet are gathered up like a bird dressed for the spit, yet, in this singular manner and apparently uncomfortable position, the bird is by no means cramped or confined, but performs all the necessary motions and efforts required for its liberation with the most perfect ease, and with that consummate skill which instinct renders almost infallible. The chicken, when it breaks the shell, is heavier than the whole egg was at first.

(1948.) "If chickens about 2 months old and upward," says Mr. Bucknell, "are turned in among a brood of young birds that have no mother, they will sometimes take to brooding and tending them with the delight of natural parents. The gratification being quite mutual, the young chicks run after and strive with each other for their favors with the most untiring perseverance. Although, probably, it is simply the pleasurable sensation derived from the genial warmth communicated by the young birds nestling under them which induces them to do it, it is nevertheless a striking and highly interesting picture to witness these mimic mothers acting the part of foster parents with so much apparent satisfaction, yet with the awkwardness with which a girl, in similar circumstances, fondles her doll." I never witnessed such an instance of affectionate regard, possibly because I never saw a brood of chickens deprived of their mother, but the sentiments conveyed in the following sentence I have frequently seen realized, and can testify to the accuracy of observation and the correctness of the conclusions of Mr. Bucknell: "There is no difficulty," he says, "in teaching the young of the various tribes of gallinaceous fowl to eat and to drink; they perform these operations spontaneously, or from observation, as appetite prompts them. Are not the facts of the extraordinary fecundity of these tribes, their requiring no assistance in hatching, and their being self-instructed in the manner of taking their food, abundant evidence that an All-wise Providence ordained these peculiarities expressly for man's advantage; as in all those families of birds not so fitted for his use, they do not exist, and consequently cannot be rendered by artificial means available for his benefit? Food is not necessary for the chick until 12 or 24 hours after leaving the shell. Sickly and badly hatched birds seldom can be induced to eat, and die from inanition. Birds but a few hours old recognize the person who feeds them, and in a few days evince so many and such pleasing traits of confidence in her as their protector and friend, following her steps, and clamorously repining at her absence, as must induce in the most callous breast a delightful sensation of regard for their welfare."

(1949.) It is of some importance to farmers to have the question answered in a practical sense, Whether the hatching and rearing of *chickens* is profitable? Hear Mr. Bucknell's answer to this question, as it affects artificial hatching: "Mr. Mowbray, in his standard work," says Mr. Bucknell, "gives the consumption of food by birds in the highest state of condition as follows: 'By an experiment made in July, 1806, a measured peck of good barley kept in a high style of condition the following stock, confined, and having no other provision: 1 cock, 3 hens, 3 March chickens, 6 April and 6 May chickens, during 8 clear days, and one feed left.' Here, then, are 19 birds, varying in age from 2 months to their full size, consuming 1 peck of corn in 8 days, which, at 1s. per peck, gives a cost of 1½ halfpenny per head, which, however, is considerably above the cost of *chickens* for the first 8 weeks of their existence. But taking it at this high average, it gives an expense of each bird of 9d. all but a fraction, for 14 weeks' keep, at which age they are in the highest perfection, being the most delicate and easy to digest of all other animal food. Where they can enjoy the advantage of a good run, the expense would still be lessened perhaps ¼. Now, what is the price at a poulterer's, or in the London markets, of a fine fat chicken 14 weeks old, or nearly its full size? Never less than 2s., and for 6 months in the year, or during the dear season, 4s. or 5s.—which, adding to 9d. an additional 3d. for the value of the egg and extras, gives the enormous profit of from 100 to 500 per cent. dividend between the trader, the middleman and the retailer. It need not be wondered at that such is the case, nor can it be otherwise while the present system continues. A poulterer whose sale is not more than 10 dozen per week, must keep a man and a horse and cart, and attend the different markets for his purchases. All these things, with incidental expenses, will amount at least to 2 guineas per week, which 2 guineas must be spread over the 10 dozen birds before he derives any profit for himself. Upon any artificial system, these expenses would be saved, and the 2 guineas thus thrown away would keep 1,000 birds, averaging all ages, 1 whole week. Buildings and machinery, and other necessary apparatus being provided, no objection exists as to the expenses of hatching. An Eccaleobion machine might be constructed, only requiring regulation once in 24 hours, capable of hatching throughout the year 10,000 eggs per month, (a week being allowed for removing and re-fitting,) while the cost for hatching during the month would probably be ¼ caldron of coke at £1 per caldron, which would be the 1-20 part of 1 farthing per bird. The expense for artificial warmth

during the time the birds might require it, would be somewhat more—perhaps 1 farthing per bird."*

(1950.) I mentioned, in an extract from another writer, that the harvest-bug annoys fowls. This short account of that animal may prove interesting. "You have already, perhaps, been satiated with the account given of our enemies of the *Acarus* or *mite* tribe," says Mr. Kirby or Mr. Spence; "there are a few, however, which I could not with propriety introduce here, as they do not take up their abode and breed in us, which nevertheless annoy us considerably. One of these is a hexapod so minute that, were it not for the uncommon brilliancy of its color, which is the most vivid crimson that can be conceived, it would be quite invisible. It is known by the name of the harvest-bug (*Acarus autumnalis*, Shaw), and is so called, I imagine, from its attacking the legs of laborers employed in the harvest, in the flesh of which it buries itself at the roots of the hairs, producing intolerable itching, attended by inflammation and considerable tumors, and sometimes even occasioning fevers." †

(1951.) In regard to the original formation of feathers in the chick of a bird, M. Raspail has the following observations: "If we examine," he says, "the epidermis of a *sparrow*, as it comes from the egg, we shall find that we can isolate each of the small bottles, which the vesicles that form the rudiments of hairs assume the shape of, as well as the nerve of which it seems to be the terminal development. It might almost be supposed that the object viewed was the eye of a *mollusca*, with its long optic nerve. The summit of this vesicle is open, even at its early period, to afford a passage for a cylindrical bundle of small fibres, which are also cylindrical, and which are nothing else than the barbs, as yet single, of the feather. If, afterward, we examine a feather at a more advanced period, we may, by a little address, satisfy ourselves that its tube is formed and grows by means of spathæ, one within another, of which the external ones project over the inner ones, so that the tube seems as if divided by so many diaphragms. The interstices of these diaphragms are filled with a fatty liquid, which condenses in them gradually, as the summits of the spathæ approximate and adhere to each other." ‡

(1952.) *Capons* of the common fowl are formed both of the cock and hen chickens, when they are fit to leave the hen, at about 6 weeks old. Chickens are transmuted into capons by destroying the testicles of the male and the ovaries of the female. The testicles are attached by a membrane to what is called the *back bone* of the carved fowl. They are destroyed by laying the bird on its near side, keeping it down, removing a few feathers, and making an incision through the skin of the abdomen, and, on introducing the fore-finger through the incision, first the one and then the other testicle is obliterated or removed altogether by it. In the case of the hen, the ovary is nipped off by the thumb-nail, or cut off by a knife. The incision is stitched up with thread, and little danger is apprehended of the result. The effect of castration is enlargement of the body of the fowl, an increased delicacy of its flesh, but its flavor is in no way improved, at least in none of the capons I have tasted. Time was when capons were more plentiful at the table than chickens, so that even kain-rent was paid in them; but the conversion of fowls into capons is now abandoned as an unnecessary and troublesome operation, and will not probably be resumed as long as a well-fed delicate chicken can be procured with little trouble. ‖

[‖ Our poulterers seem to make very slow progress in the art and mystery of caponizing. We are not aware that it is now practiced or understood in Maryland at all, although 50 years ago capons were made by a few old women in Calvert County for carrying chickens. It begins to be done for improving fowls for the table in the neighborhood of Philadelphia, and in New-York it is so little practiced that the hotel keepers have "CAPON CHICKENS" announced in large letters on their bills of fare, and some of these probably never felt the knife until it was applied to their throats. It is to be lamented that the practice of caponizing were not more general—surely he who pleases, ought to be able to command what a benevolent monarch said he would have all his subjects enjoy, *a fat capon*. SUMMER.

"The season now is all delight,
Sweet smile the passing hours,
And SUMMER'S pleasures, at their hight,
Are sweet as are her flowers;
The purple morning wakened soon,
The mid-day's gleaming din,
Gray Evening with her silver moon,
Are sweet to mingle in.

"How sweet the fanning breeze is felt
Breathed through the dancing boughs,
How sweet the rural voices melt
From distant sheep and cows.
The lovely green of wood and hill,
The hummings in the air,
Serenely in my breast instil,
The rapture reigning there."

CLARE.

I HAVE represented Winter, in the agricultural sense, as the season of dormancy, in which everything remains in a state of quiescence. In the same sense I have said that Spring is the season of restoration to life, in which everything again stirs and becomes active. SUMMER, on the same principle, is the season of *progress*, in which nothing is begun or ended—none of the greater operations of the field are either commenced or terminated, but only advanced a step toward the consummation of all things in Autumn; and, therefore, the mere advancement of the greater operations involves no change of principle, while the smaller ones present so varied an aspect as to excite considerable interest.

The astronomical cause of Summer, as one of the seasons, and the safety in which every living thing—whether animal or vegetable—progresses or grows under its influence, are thus succinctly and well described by Mr. Mudie. "Summer is the bloom of the year—the period during which all the growing and living children of Nature, which wax and wane with the revolving seasons, are in the spring-tide of their activity, and when all those general agencies by which they are stimulated are working to the very top of their bent. Summer is, both in the literal and the metaphorical sense, the season of blossoms; and as the blossoms make the fruit, the time of them is really the most important of the whole. In our middle latitudes, there is a very beautiful instance of design and adaptation in this. The grand stimulating agent in all is terrestrial action, at least in a natural view of it on the surface of the earth, and the intensity of this action is made up of two elements—the position of the twenty-four hours during which the sun is above the horizon, and the altitude of the sun above that horizon. Both of them, in either hemisphere, increase as the sun declines toward that hemisphere, or rather as the hemisphere inclines to the sun; though, as the first of these is the apparent result of the second as a reality, our using an expression on the other does not affect the result. The increase or decrease of altitude is the same, with the same change of declination, in all latitudes; but the variation in time above the horizon increases with the latitude: consequently the higher the latitude the greater the change of solar action with the same change of declination. The change in declination increases from the solstice to the equinox, and diminishes from the equinox to the solstice. Thus the increase of solar action begins to slacken at the vernal equinox in March, and gradually diminishes till it becomes 0 at midsummer; after this the decrease commences. This, however, only in so far as depends on the altitude of the sun; for the other element, the

time which the sun is above the horizon, goes on increasing till the longest day, or day of the solstice. Thus, in the advanced part of the summer, there is a diminished increase of the momentary intensity of the solar action, and a lengthening of its daily duration. What is given to the presence of the sun above the horizon is taken from its absence below it; and thus, as the summer advances toward the longest day, all that works by the action of the sun works with his increase of intensity and for a longer time. After the longest day is past, both elements of the solar action diminish, slowly at first, and more rapidly afterward, until the summer merges in the autumn. Near the Equator the changes are comparatively small, and they increase with the latitude; and the differences in this respect are what may be called the celestial differences of the character of summer in different latitudes; but terrestrial causes modify them so much, that the practical results as observed are very different from what the celestial theory would give. Still, any one who thinks but for a moment will not fail to discover how beautifully the season of bloom is secured from violent action either in the one way or the other. This is enough to convince us that the action which goes on in the production of Nature during the summer is really the most important of the whole year; for it is performed with the maximum of power in the agents, and the minimum of disturbance in their operation. That resistance of winter, which but too often shrivels the young leaf and blights the early blossom in the spring, is vanquished and completely stayed from making any inroad till the seasonal purposes of Nature are accomplished; and the ardor of the stimulating causes which have vanquished the destructive one, are slackened, so that they may not injure that which during the struggle of the early part of the year they have preserved. All this, too, is accomplished by means so very simple that their simplicity proves the most wonderful part of the whole, for it is nothing more than the planes of the annual and daily motions of the earth intersecting each other at an angle of about 23° 28′; and the line of intersection passing through the equinoctial points of the diurnal orbit."*

The atmospherical phenomena of summer are of the most varied and complicated nature. At one time the air is highly elastic, and feels balmy and bracing, indicated by the high position of the mercury in the barometer; at another the mercury descends, and almost always suddenly, to the lowest point, accompanied with gusts of wind and a deluge of rain, forming what is callled a tornado in the tropics. The heat of the air at one time is so scorching as to cause us to seek the shade, and the thermometer marks its intensity; at another, a chilling gust, accompanied with a heavy shower of hail, suddenly brings down the thermometer many degrees. The air to-day is so calm and breathless that not a ripple is visible even on the bosom of the great ocean; to-morrow a hurricane raises the waves of the sea to a state of agitation dangerous to the safety of the mariner. Not a cloud is seen at times to stain the purity of the blue vault of Heaven; at others the thunder-cloud hovers over the earth, and blackens its surface with a portentous shadow. These changes, in summer, are usually sudden and of short duration, and they are requisite to preserve the healthy state of the air. Did rain not fall in quantities, the vapor absorbed by the great capacity of heated air for moisture would accumulate beyond due bonds. Were there no colder strata of air moving about to condense the warmer, the warmer portion containing a large quantity of vapor in solution would always be elevated beyond the reach of the earth, and there waste its latent heat. The thunder-storm of sheet-lightning passing from cloud to cloud, the most common display of electric action in summer, re-

* Mudie's Seminer.

stores the electric equilibrium of the air, and the forked lightning relieves both earth and air. Did not the hurricane at times force its way through the calm and inert air, the same portion of the atmosphere would always remain over the same locality, and become vitiated by the breath of animals and the exhalations of vegetables. If the dews failed to descend upon the grass, the pasture would soon become parched by the meridian fervor of the summer sun. Thus, all the agencies of Nature are required to keep the air in a healthy state for animals and vegetables, and these operate in the most beneficial manner in summer—the season of the intensest action of the solar rays.

As I have already entered very fully into the state of the weather in winter, in Section 18, p. 163 to 197 of the 1st volume, I have less occasion to revert to the subject here; but the consideration of a few of the atmospherical phenomena which only occur in summer was purposely reserved until the arrival at that season; and these phenomena were, thunder and lightning, dew, hail, and easterly winds. The origin of the electricity of the air was indicated at sufficient length from (299) to (312). The presence of electric matter being accounted for, the *rationale* of a *thunder-storm* is simple, and it is this: The electric fluid, as the agency of electricity is called, for want of a better name, derived from sources enumerated in the above paragraphs, accumulates in the clouds of vapor. When two clouds, thus provided with electric matter beyond their usual state, are not far from each other, the electricity of the one becomes *positive*, that is, in an active state; and that of the other, as a necessary consequence, becomes *negative*, that is, in a passive state. Why these opposite states of electricity always coëxist when near each other, it is impossible to say; but the fact is established as an unvarying law of electric matter. When two clouds thus in these opposite states are near each other, they attract and approach, and when the approach comes within the distance in which the force of the positive electricity is able to overcome the resistance of the air between the positive and negative clouds, the fluid leaves the positive and enters into the negative cloud in such quantity as to restore the equilibrium of both. The forcible passage of the electric fluid causes a concussion in the air between the two clouds, and the vibrations occasioned by the concussion striking against the earth and mountains, cause the noise which is heard in thunder. The time taken by the electric fluid in passing from one cloud to another is inappreciable, but the velocity of sound is calculable. For every 4½ seconds of time which elapse after seeing the lightning to hearing the thunder, the clouds are situate as many miles from the auditor.—Far at sea, where there are no objects for sound to be reflected from, thunder is never heard; whereas, in a mountainous country, it inspires terror, though it is obvious that thunder, a mere sound, can do no harm, and lightning, which can do harm, does all the mischief it can do before we are made aware of its danger.

The phenomenon of *dew* is familiar to every person who lives in the country. In the hottest day of summer the shoes become wet in walking over a grass-field at sunset, and they may then become as effectually wetted as in wading through water. The late Dr. Wells investigated the phenomena of dew more closely than any other person; and his experiments, as detailed in his instructive essay on that subject, appear to have been very satisfactorily conducted; and the theory which he established on these experiments is the one now embraced by philosophers. From that essay I shall first relate a few of the circumstances which influence the production of dew; and then give Dr. Wells's theory of its formation, in contradistinction to those of other philosophers. "Aristotle and many other writers," says

)r. Wells, "have remarked that dew appears only in calm and serene ights. This remark of Aristotle, however, is not to be received in its trictest sense, as I have frequently found a small quantity of dew on rass, both in windy nights, if the sky was clear or nearly so, and in loudy nights, if there was no wind. If, indeed, the clouds were high and he weather calm, I have sometimes seen on grass, though the sky was ntirely hidden, no very inconsiderable quantity of dew. Again, according o my observation, entire stillness of the atmosphere is so far from being ecessary for the formation of this fluid, that its quantity has seemed to ie to be increased by a very gentle motion of the air. Dew, however, as never been seen by me on nights both cloudy and windy. If, in the ourse of the night, the weather, from being calm and serene, should beome windy and cloudy, not only will dew cease to form, but that which vas formed will either disappear or diminish considerably. In calm veather, if the sky be partially covered with clouds, more dew will apear than if it were entirely covered, but less than if it were entirely lear. Dew probably begins in the country to appear upon grass, in laces shaded from the sun during calm and clear weather, soon after the eat of the atmosphere has declined; and I have frequently felt grass noist in dry weather several hours before sunset. On the other hand, I ave scarcely ever known dew to be present in such quantity upon grass s to exhibit visible drops before the sun was very near the horizon, or to e very copious till some time after sunset. It also continues to form in haded places after sunrise; and if the weather be favorable, more dew orms a little before, and, in shaded places, a little after sunrise, than at ny other time. The formation of dew, after it has once commenced, coninues during the whole night, if the weather remain still and serene.)uring nights that are equally clear and calm, dew often appears in very nequal quantities, even after allowance has been made for any difference n their lengths. One great source of their difference is very obvious, for, : being manifest, whatever theory be adopted concerning the immediate ause of dew, that the more replete the atmosphere is with moisture, preiously to the operation of that cause, the more copious will be the preipitation of moisture in the atmosphere, must likewise tend to increase he production of dew. Thus dew, in equally calm and clear nights, is nore abundant shortly after rain than during a long tract of dry weather. t is more abundant during S. and W. winds, than during those which low from the N. and the E. Dew is commonly more plentiful in spring nd autumn than in summer; the reason is that a greater difference is enerally found between the temperature of the day and the night in the)rmer seasons of the year than in the latter. Dew is always very copiis on those clear and calm nights which are followed by misty or foggy nornings; the turbidness of the air in the morning showing that it must ave contained, during the preceding night, a considerable quantity of noisture. I have observed dew to be unusually plentiful on a clear morng which had succeeded a cloudy night. For the air having, in the ourse of the night, lost little or no moisture, was in the morning charged 'ith more watery vapor than it would have been if the night had also been lear. Heat of the atmosphere, if other circumstances are favorable, 'hich, according to my experience, they seldom are in this country, occaons a great formation of dew. For, as the power of the air to retain 'atery vapor in a pellucid state increases considerably faster while its mperature is rising than in proportion to the heat acquired, a decrease f its heat in any small given quantity during the night must bring it, if ie temperature be high, much nearer to the point of repletion before it

be acted upon by the immediate cause of dew, than if the temperature were low. I always found when the clearness and stillness of the atmosphere were the same, that more dew was found between midnight and sunrise, than between sunset and midnight, though the positive quantity of moisture in the air must have been less in the former than in the latter time, in consequence of a previous precipitation of part of it. The reason, no doubt, is the cold of the atmosphere being greater in the latter than in the prior part of the night."

Theories of the formation of dew have been proffered by many philosophers, from the days of Aristotle to the time of Dr. Wells. "Dew, according to Aristotle," remarks Dr. Wells, is "a species of rain formed in the lower atmosphere, in consequence of its moisture being condensed by the cold of the night into minute drops. Opinions of this kind, respecting the cause of dew, are still entertained by many persons, among whom is the very ingenious Mr. Leslie, of Edinburgh." This view is erroneous, because "bodies a little elevated in the air become moist with dew, while similar bodies, lying on the ground, remain dry, though necessarily from their position as liable to be wetted by whatever falls from the heavens, as the former." Dufay concluded that dew is an electric phenomenon, but it leaves untouched bodies which conduct electricity, while it appears upon those which cannot transmit that influence. All the theories on dew, to the time of Dr. Wells, omitted the important part that the production of dew is attended with cold, and this is a very important omission, since no explanation of a natural phenomenon can be well founded which has been built without a knowledge of one of its principal circumstances. "It may seem strange to many," continues Dr. Wells, "that neither Mr. Wilson nor Mr. Six applied the fact of the existence of cold to its production, to the improvement of the theory of dew. But, according to their view of the subject, no such use could have been made of it by them, as they held *the formation of that fluid* to be *the cause* of the cold observed with it. I had many years held the same opinion, but I began to see reason, not long after the regular course of my experiments commenced, to doubt its truth, as I found that bodies would sometimes become colder than the air without being dewed; and that when dew was found, if different times were compared, its quantity and the degree of cold which appeared with it were very far from being always in the same proportion to each other. The frequent recurrence of such observation at length corrected the doubt of the justness of my ancient opinion into a conviction of its error, and at the same time occasioned me to conclude that dew is the production of *a preceding cold in the substance* upon which it appears." Dr. Wells's theory, therefore, is "that the cold observed with dew is the previous occurrence, and, consequently, that the formation of this fluid has precisely the same immediate cause as the presence of moisture upon the outside of a glass or metallic vessel, where a liquid considerably colder than the air has been poured into it shortly before." As an obvious application of this theory, the experiments of Dr. Wells, which led to its establishment, evince that of all natural substances grass is peculiarly adapted to the exhibition of dew, inasmuch as it becomes, under ordinary circumstances, colder than the air above it, by the radiation of more heat toward the heavens than it receives in any way, and, accordingly, whenever the air is calm and serene, dew may be seen on grass, when it may not be observed on other substances.

But it has been alleged by Dufay that dew is the condensation of vapor *rising* out of the earth upon the grass on it, because objects removed higher from the surface of the earth, as trees, are exempt from dew; and this is

a very popular opinion; but it is an erroneous one, and the phenomenon can be explained on other principles, because the lower air in a clear and calm evening is colder than the upper, and it contains more moisture than the upper; and hence, on all these considerations, it will sooner deposit a part of its moisture. At the same time, it is true that vapor does rise from the earth, and it may be condensed as dew; for we find the grass first becoming moist with dew, then the substances raised above it, while both indicate an equal degree of cold; but all the quantity of dew from this cause can never be great, because until the air be cooled by the substances attractive of dew with which it comes in contact below its point of repletion with moisture, it will always be in a condition to take up that which has been deposited upon grass, or other low bodies, by warm vapor emitted by the earth, just as the moisture formed on a mirror by our breath is, in temperate weather, almost immediately carried away by the surrounding air. Agreeably to another opinion, the dew found on growing vegetables is the condensed vapor of the very plants on which it appears; but this also is erroneous, because dew forms as copiously upon dead as upon living vegetable substances; and "if a plant," as Dr. Wells observes, "has become, by radiating its heat to the heavens, so cold as to be enabled to bring the air in contact with it below the point of repletion with moisture, that which forms upon it from its own transpiration will not then indeed evaporate. But although moisture will at the same time be communicated to it by the atmosphere, and when the difference in the copiousness of these two sources is considered, it may, I think, be safely concluded that almost the whole of the dew which will afterward form upon the plant must be derived from the air; more especially when the coldness of a clear night, and the general inactivity of plants in the absence of light, both lessening their transpiration, are taken into account." Hoarfrost is just frozen dew, but as it only appears when the surface of the earth is sealed with frost, the vapor of which *it* is formed cannot, of course, at the time, perspire from the earth.*

Another remarkable phenomenon in summer is *hail*. "The difficulty for accounting for the retention of masses of ice in the free atmosphere," observes Professor Forbes, "is certainly very great. Perhaps no hypothesis more satisfactory, certainly none more ingenious, has followed that of Volta, who conceived, from the highly electric condition of the atmosphere, almost universally attending the production of hail, that the frozen masses were kept in a state of reciprocating motion between two clouds oppositely charged with electricity, until the increase of the mass rendered the force of gravity predominant, or the electric tension of the clouds was exhausted by mutual reaction."† As hail is a very curious and highly interesting phenomenon, a few facts regarding its occurrence and the forms of hailstones may prove instructive. "Hail generally falls in the hottest hours of the day in Spain, Italy and France. It falls in Europe generally in the day, and seldom in the night. It seldom falls in winter, though at Plymouth, according to Mr. Giddy, there seems to be an exception. Thus, in the course of 21 years, the recurrence in each month was, in

ance of hail-clouds seems to be distinguished from other stormy clouds by a remarkable shading; their edges present a multitude of indentations, and their surfaces disclose here and there immense irregular protuberances. Hail seldom falls on mountains, which indicates lowness of clouds, which Arago has seen cover the valley with fog, while the mountains were clear above. The form of hailstones varies. They are nearly uniform when they fall on the same level; and in the same storm they have fallen smaller on the tops of mountains than on the plains. Change of temperature or wind changes the form of hail. On 7th July, 1769, M. Adanson observed 6-sided pyramids fall, but the wind changing to N.E., changed them to convex lenses, and so transparent as to transfer objects without distortion. Hail is sometimes attended with spongy snow, which may have formed the interior of the hailstone, while its exterior was transparent ice. It has been supposed from this, that the different portions have been formed under different circumstances. Leslie imagines the spongy texture to result from an atom of water having been suddenly frozen, and particles of perhaps rarefied air suddenly driven into the center. The pyramidal form fell at Aberdeen on 29th November, 1823. The usual form of hail is a concentric lamellar structure, with a stellular fibrous arrangement. There is great difficulty in accounting for large masses of ice in the atmosphere, as hail cannot take above 1 minute in falling from low clouds."*

The forms of the *clouds* in summer are very distinctly marked. When a deposition of vapor is taking place in the highest part of the atmosphere, the *cirrus*, or curl-cloud, appears (283), and it sometimes soon disappears, which is a sign of fine weather; but instead of disappearing, it may descend a little lower, and be converted into the *cirro-cumulus* (287), which is the form of that elegant, light, flocculent cloud so often seen in a fine summer day. A farther deposition changes the small cloud into the larger *cumulus*, called the day-cloud in summer, because it disappears into another form in the evening. The *cumulus* or heap may may be seen distinctly represented in the plate of the Liecester tup, both above the animal and above the horizon, where it frequently takes up its position for the greater part of the day, resting on the vapor plane. When a large cumulus rises from the horizon in the daytime, and shows white towering heads, it is a sign of a storm or a fall of rain from that quarter; and the wind will change to that direction in the course of the next 24 hours. This threatening cloud, is called *cumulo-stratus*. In calm, serene evenings in summer, the day-cloud or cumulus descends and spreads itself along the bottom of valleys, or in hollows of the open country, covering the ground like a lake as seen in moonlight, or with a partial sheet of snow. This is the true *stratus* cloud. Tall objects, such as trees, steeples, and even elevated ground, jut through it like rocks and islands in a lake. The air is then perfectly calm, the temperature is delightfully warm, and the intenseness of the silence is broken only by the snipe drumming in its curious somersets in the air—by the harsh ventriloquous cry of the corn-craik among the grass—or by the occasional barking of the watch-dog at some distant homestead. The morning after such a night is sure to usher in a bright and peerless sun, whose steady heat will soon evaporate the sheet-like stratus-cloud from the valley and hollows, and elevate it, in the form of the beautiful day-cloud, above the mountain-top or the horizon.

The direction of the *wind* forms an important item in the consideration

*Encyclopedia Metropolitana, art. Meteorology.

of the weather in summer; for in no other season does the slightest variation of the wind make so decided changes on the weather. If we assent to the general conclusion in regard to the cause of winds, that it is the partial changes of temperature which are their chief general cause, we may expect the winds to be most variable in summer, since changes of temperature are most likely to occur at that season; and the change of the wind is the most ready indication of the change of temperature, especially in the upper portion of the atmosphere. In the torrid zone, while the barometer seldom varies but in a trifling degree, in the temperate zone it is not less fickle than the wind. This indication of a loss of weight in the atmosphere can arise only from a local diminution of its elasticity, most likely from changes of temperature. But the most remarkable effect in relation to the wind in summer, is the constancy with which it blows from the east in the early part of that season; and so invariable is this phenomenon, that every person who dwells on the east coast of Great Britain is quite familiar with it, as every one feels the keenness of the east wind, and every one knows the aptitude with which catarrhal affections are produced by it. An explanation of this remarkable phenomenon cannot fail to prove interesting; and as a very rational solution of its recurrence has been given by Mr. Samuel Marshall, I shall copy his succinct but satisfactory account of it. After stating that the east winds in early summer usually prevail from the middle of April to the 7th or 8th of May, or even to the 18th of May, and I may add that it continued all June in 1843, Mr. Marshall then proceeds to account for the cause of the phenomenon. "In Sweden and Norway, the face of the country is covered with snow to the middle of May or longer. This frozen covering, which has been formed during winter, grows gradually shallower to the 15th or 16th of May, or until the sun has acquired 17° or 18° N. declination; while, on the other hand, the valleys and mountains of England have received an accession of 24° or 25°. On this account, when the temperature of Sweden and Norway is cooled down by snow to 32°, that of Britain is 24° or 25° higher than that of the preceding countries. Because, while the ground is covered with snow, the rays of the sun are incapable of heating the air above 32°, the freezing point. For this reason, the air of England is 24° or 25° more heated than that of the before-mentioned countries. The air of Sweden and Norway will then, of course, by the laws of comparative specific gravity, displace that of England, and, from the relative situation of those countries with this country, will produce a N.E. wind. The current is in common stronger by day than by night, because the variation of temperature is at that time the greatest, being frequently from 50° to 60° about noon, and sinking to 32° in the night."* Some of the most obvious prognostics of the wind in summer are, when the wind is variable, rain is not far distant; when it blows low, and raises the dust much, it has the same effect; but when there are small whirlwinds raising the dust along the road or corn-fields, it is a sign of dry weather. I remember of seeing a beautiful whirlwind, in a calm hot day, in the neighborhood of Berlin, raise the sand of a field, the soil being mostly composed of that substance, in a perpendicular direction to a great hight in the air. When currents of air are seen to move in different directions, that which the upper current takes will ultimately prevail. At times in summer, and particularly in the evening, it is hard to say from which quarter the current comes, when a wetted finger held up will tell the quarter, from the cold produced on it by consequent evaporation of the moisture. The pleasant phenomena of the

* Brewster's Journal of Science, vol. viii.

land and sea breezes are distinctly marked in fine warm weather in summer. When winds blow strongly from any quarter, even from the warm west, for two or three days in succession, the temperature of the air is much diminished, sometimes as much as 20°, and seldom less than 10°.

So much for the aërial speculations of summer. Let us now notice the humbler toils of the field. These, as I have already observed, require to be advanced a stage toward their completion in autumn. The first operation which calls for the plowman's attention in summer is the turnip-land, which is now drilled up, dunged, and sown. The culture of the turnip is a most important and stirring operation, affording much interesting work in singling and hoeing the plants for the greater part of the season. In the hight of summer, young stock luxuriate on the riches of the pasture-field, while forage plants, consisting of vetches, rape, or broad clover, are allowed to grow until the general season of want, between the failure of pasture and the premature consumption of turnip. Before stock take possession of the pasture-fields, the hedger makes it a point to put the fences in a complete state of repair, and to second his exertions, the carpenter and smith make the field-gates secure for the season. Fattened stock are seldom allowed to taste the pasture, they being disposed of off the turnips to the butcher or dealer. The fat cattle are almost always then sold. Young cattle and cows are sent to the grazing field of the farm, though turnip sheep are not unfrequently retained on grass until the fleece is clipped from their backs (the season being nigh at hand,) and after that they also are disposed of. The separation of ewe and lamb is now effected; and the respective marks of age, sex, and ownership, are put on each. Horses now live entirely another sort of life, being transferred from the confinement of the collar in the stable to the perfect liberty of the field, and heartily do they enjoy themselves there. The brood mare now brings forth her foal, and receives immunity from labor for a time. Hay-making is represented by poets as a scene of unalloyed pleasure. No doubt lads and lasses are then as merry and chirping as grasshoppers, but, nevertheless, in spite of buoyant spirits, hay-making, in sober truth, is a labor of much heat and great toil—the constant use of the hay-rake and pitch-fork, in hot weather, being no sinecure. Early as the season is, preparations are made in summer for the next year's crop. The bare fallow is worked and dunged, and it may be limed too, in readiness for the seed in autumn.—Summer is of all others the season in which the farmer most seriously makes his attacks on those spoilers of his clean fields, and contaminators of the samples of his grain—the weeds. Whether in stocked pastures, upon tilled ground, along drills of green crops, among growing corn, or in hedges, young and old, weeds are daily exterminated, and the extermination is most effectually accomplished by the minute and pains-taking exertions of female field-workers. For these purposes they are provided with appropriate cleaning instruments. This is the season, too, in which his stock and crops are sometimes seriously affected by the attacks of insects. Where building-stones are plentiful, and the risk great from the overflowings of rivulets in winter, summer is also the season for the erection of stone dykes as fences between fields, and of embankments along the margins of rivers. The former afford a substantial fence at once, the latter form insuperable barriers against an element powerful alike whether exerted for or against Man's operations.

Every operation requires constant attention in summer, for, the season being active in its influences, farmers must then put forth their energies to meet its rapid effects, whether these tend to forward or retard his efforts.

The long hours of a summer day, of which at least ten are spent in the fields—the ordinary high temperature of the air, which suffuses the body of the working man in constant perspiration—and the fatiguing nature of all field-work in summer, bear hard as well on the mental as the physical energies of the laborer, and cause him to seek for rest at a comparatively early hour of the evening. None but those who have experienced the fatigue of working in the fields in hot weather, and for long hours, can truly appreciate the luxury of rest—a feeling truly described in these simple lines:

"Night is the time for rest.
How sweet when labors close
To gather round the aching breast
The curtain of repose—
Stretch the tired limbs, and lay the head
Upon one's own delightful bed!"
MONTGOMERY.

The hours devoted to field-work vary in summer in different parts of the country. On the borders it is the practice to go very early to the morning yoke, as early as 4 o'clock, that the forenoon's work may be over by 9, and that there may be time to rest in the heat of the day; the afternoon's yoking commences at 1 o'clock, and continues till 6 o'clock. There are thus 10 hours spent in the fields. But in most parts of the country, the morning yoking does not commence till 6 o'clock, and, on terminating at 11, there are only 2 hours for rest and dinner till 1 o'clock, when the afternoon's yoking begins. In other parts, only 4 hours are spent in the morning yoking, when the horses loose at 10 o'clock, and yoking again from 2 to 6 in the afternoon, only eight hours are spent in the fields, and the men are employed elsewhere by themselves for 2 hours. This is practiced where the plowmen are made to do the work of field-workers, and where a large numbers of draughts are kept. Perhaps the best division of time is to begin the yoking at 5 o'clock in the morning, loose at 10, yoke again at 1, and loose at 6 in the evening, affording 3 hours for rest to man and horse at the hight of the day, and 10 hours in the field. Day-laborers, when not dependent on the horses, as well as field-workers, usually work from 7 to 12, and from 1 to 6 o'clock in the evening, having 1 hour for rest and dinner. When laborers take their dinner with them to the field of their operations, this may be a good enough division of time; but when they have to go home to dinner, 1 hour is too little for the purpose, and affords no time for rest between yokings, which is to be deprecated, as neither men nor women are able to work 10 hours without an interval of quiet rest. It would, therefore, be a better arrangement for field-workers to go to work at 6 instead of 7, and loose at 11 instead of 12, when they have to go home to dinner; but if they took their dinners with them to the field, then 1 hour is sufficient for rest and dinner at the same time.

Summer is the only season in which the farmer has liberty to leave home without incurring the blame of neglecting his business, and even then the time which he has to spare is very limited. There is only about a fortnight between finishing the fallow, the turnip and potato culture, and haymaking, and the commencement of harvest, in which the farmer has leisure to travel. This limitation of time is to be regretted, because it is proper that he should take a journey every year, and see how farm operations are conducted in other parts of the kingdom. An excursion of this nature is seldom undertaken by a farmer, who is generally a man capable of observation, without acquiring some hints which may induce the adoption of a pratice that seems good, or the rejection of one which is bad. Such a journey exhibits mar' ind in various aspects,

and elevates the mind above local prejudices; and as husbandry is a progressive art, a ramble of a week or two, through different parts of the country, cannot fail to enlighten the mind of the most experienced farmer much beyond anything he can observe by always remaining at home.

---

21. THE SOWING OF TURNIPS, MANGEL-WURZEL, RAPE, CARROTS AND PARSNIPS.

"They require the land to be well broken by frequent plowings and harrowings, and also to be well dunged; this is of great importance, not only as the crop of these roots is thereby rendered larger, but as the land is thereby prepared for carrying good crops of corn." COLUMELLA.

(1953.) The first great field operation in summer is the completion of the preparation of the soil for the sowing of the turnip crop. This crop commences the rotation of crops, is a substitute of bare-fallowing, and is of the same nature, as regards the amelioration and working of the soil, as the potato crop, and therefore admits of the soil being manured; and, indeed, on account of all these properties, it is regarded and denominated a *fallow* crop. Being thus a renovator of the condition of the soil, the turnip crop necessarily succeeds the crop which terminates the rotation, and beyond which the exhaustion of the soil is not permitted; and, being a fallow crop, the preparation of the soil for it requires much labor, and should therefore be begun as early as the breaking up of the stubble in the beginning of winter. This fact is indicated in (916); and the different modes of plowing stubble for fallow, according to the nature of the soil, are mentioned in (917), and the due precautions to be used to keep the soil in a dry state all winter are stated in (918). These constitute the winter preparations for the turnip crop; and those in spring are begun by cross-plowing, fig. 312. Should potatoes have been planted in the same field intended for turnips, the cross-plowing for the potato land should be extended across the turnip land, if there is time for it; but should the time required for this extended cross-plowing encroach upon that which is devoted to potato-planting, the turnip land should be let alone, until there is leisure. From the cross-plowing to the drilling of the land for the reception of the dung, the turnip culture is exactly the same as for potatoes, with perhaps the exception that as there is more time for working and cleaning turnip-land, it receives one or more plowings or stirrings with the grubber than the potato land; and in this cleansing process the grubber will be found a most efficient implement, and will save a plowing, while it keeps the upper soil uppermost and in a fine loose state. When turnip land is manured with farm-yard dung, the drilling is best and most expeditiously done in the single mode, fig. 313; but as the drills have to be kept in exact proportions, for the sake of the better operation of the sowing-machine that is to follow, the best plowman should be desired to make them. The position of the plow which makes the single drills is shown at *a*, fig. 344; the ground occupied by one feering in drilling is shown from *a* to *e*; and the process of dunging, both in carting out and spreading the dung, and in splitting the drills in the double way, are conducted in the manner described for that figure, with the exception of the potato planters at *r* and *s*. So far, then, the culture of potatoes and

turnips correspond, but after this point a considerable difference ensues, which arises from the difference in the nature of the seed. After the soil on the top of the drills has become a little browned with the sun, or *rizzared*, as it is technically phrased in some, or with a proper *tid* in other places, the turnip sowing-machine, which sows 2 rows at a time, such as the one described below by Mr. Slight, is then used, with one horse, for sowing the seed. The soil should be dry at the top of the drills before the seed is sown, because damp soil clings to the rollers of the machine, and causes them to make bad work. One of these machines could sow a great breadth of land in a day, but it is seldom that it can be employed throughout a whole day, for two reasons: One is, that the soil is seldom in a dry enough state in the morning to be thus sown; and the other reason is, that a sufficient quantity of land will not be dunged and split in the course of a day to keep a machine going constantly, because one plow can only split ¼ more land in a day than it can plow, so that 3 plows will only split 5 acres at most of drills over dung in a day, and thus 1 machine could hold 4 plows splitting drills; and as the dunging is carried on at the same time, there are few farms so large as to employ 4 plows splitting drills.

(1954.) The quantity of seed sown need not exceed 3 lbs. to the English acre, nor should the quantity be much less, as thick sowing insures a quick braird of the turnip plant, and the seed is not a costly article, being usually from 9d. to 1s. per lb. Fortunately, that the land may receive its due labor, the different kinds of turnips cultivated require to be sown at different times. Swedes, for instance, should be sown by the 15th of May at latest, and if the land is ready to receive the seed by the 10th, so much the better. Swedes will grow on any kind of soil, except, perhaps, what is *in a state of pure peat;* but they grow best in rich alluvial sandy loam —best, because largest, and in that state this particular turnip is firmest too. The yellow turnip follows the Swedes, and then the white, which may be sown any time in June. In England, white turnips are sown as late as July, because, if sown earlier, they would come too soon to maturity. The seeds of Swedish turnips are much larger than those of yellow or white, and require to be sown through a larger hole in the canister of the machine. They will retain their freshness for several years, and may be confidently sown though kept for 3 years; but it would be hazardous to sow yellow or white turnip-seed after the first year; they somehow lose their vitality after that time. The reason why I give the preference to the purple-top Swedish, the Aberdeenshire yellow bullock, and the white globe turnips, will be found in paragraphs from (1022) to (1031) inclusive, and these turnips are figured in fig. 214, at the same place. At the same time, you should partly be guided by the practice of the district in which your farm is situate, what sorts you should sow on your first coming into the district; but you should hear very satisfactory reasons why those kinds will not thrive in that particular district, and should even experience their failure before you determine on preferring the culture of other kinds. When I began to farm in Forfarshire, I was told that the Swedish turnip would not thrive on such soil as my farm, a light turnip soil, and that I would find the red-topped white the best; but a very short trial showed every one that Swedes and the white or green-topped globe throve much better than the favorite red-topped, which is an early turnip, no doubt, but a very spongy one on that soil. For my part, I would have no fears of raising a good crop of Swedes on any ordinary soil by proper culture, that is by giving them plenty of old well-made dung, and sowing them early. Give Swedes 15 tons, or 20 good cart-loads, of dung in that

state to the imperial acre, and sow them *before* the 15th of May, and little fear need be entertained of the crop on the most ordinary soil; 12 tons of well-made dung will suffice for yellow turnips, and 10 tons of the same for white globes; but, of course, the more dung each of the kinds receive, the larger crop may be expected.

(1955.) It is not an unusual practice in England to sow turnips *broadcast on the flat ground*, instead of in rows, and on ridglets or drills, as in Scotland; and the reason I have heard stated in vindication of the broadcast method is, that it resisted the bad effects of drouth on the land in summer. No doubt excessive drouth in summer is inimical to the full development of the turnip, and it is on this account that the turnip crop fails so frequently in Germany; but, for my part, I cannot see how a broadcast crop can escape drouth more certainly than one in rows, since the plants have to grow and be thinned out to proper distances in both cases; and should the ground be foul with weeds it must be stirred to get rid of them in both cases; and as the work of weeding is done by hand instruments in the case of the broadcast crop, it is, of course, not so *effectually* done as with horse-hoes, in the case with the crop in rows; while I can see, that as the dung must be spread broadcast for a broadcast crop, it will not have the same opportunity of promoting the growth of the crop at its early stage as when it is deposited in rows, so that the means employed defeat its own purpose; because I think it cannot admit of doubt that the same quantity of manure placed in bulk immediately under the seed should promote the growth of the plant more rapidly than when it is spread over a larger surface of ground, and there can be no doubt, also, in regard to the turnip plant itself, that the more rapidly it grows in its early stage, the more certainly it will be free of danger from drouth and from some insects, at least; for it is well known, in regard to the habits of some of those which attack the turnip, that they become innocuous to its leaves after the development of the rough ones. I do not aver that the sowing of turnips in drills will render them invulnerable to the attacks of insects or to the effects of drouth, but these evils being merely seasonal, the drill system places the crop more immediately under the management of the cultivator, inasmuch as it enables him to apply the whole powers of the manure at once, and of cleaning the soil quickly with the assistance of horse-power. Besides all this, the period of sowing the crop should be suited to the climate of the locality. If drouth is too great in July, or the insects too powerful, the crop should be sown earlier, and though it should reach maturity sooner than desired, it can be drawn and stored until the season of its consumption arrives; or it should be sown later, such as in August, when the genial climate of the South of England—where the nights are warm as well as the day, thereby affording every day the growth of two ordinary days in Scotland, where the nights are always cold—is sufficient to mature the crop before the end of October, which is as early as the turnip crop is required for consumption in that part of the country, and where till then the grass continues good. And were the soil properly cleaned before the crop is sown, comparatively little labor would be required to keep it so in the hight of summer, and of course the drouth would not then much affect it. Or, a part of the turnip crop could be taken after winter vetches, which, on being cleared off the ground in time by feeding sheep, or by cutting, would enable the land to receive a short fallowing for turnips before the end of July.

(1956.) Nor is a much earlier fallowing and cleaning of the turnip land an impracticable thing in England, since the corn crop is frequently cleared from the fields by the end of August, when the stubble could be broken

up, harrowed, cross-plowed, cleaned, drilled, and even dunged, before the arrival of winter, as has been proved in Scotland, by the practice of Mr. James Scougall, at Balgone, East-Lothian, the seat of Sir George Grant Suttie, Bart., in the autumn of 1841, when he drilled and dunged good turnip land, at 32 inches apart in the drill, and otherwise finished its tillage. Purple-top Swedes were sown on the 10th of May, 1842, the plants thinned to 15 inches apart, and the matured crop was drawn and stored by the middle of September following, when the ground was sown with wheat. On comparing the produce of this mode of culture with the usual one of laboring the turnip land in spring, and at the usual distance of 28 inches between the drills and 12 inches between the plants, the ground prepared in autumn yielded, in 429 links measured along one drill, 82 stones of turnips, whereas that worked in spring yielded only 58 stones, though the number of turnips in the former weight was only 238, while that in the latter was 276, thus giving to each turnip a weight of 4 lbs. 13 oz. in the former, and of only 2 lbs. 15 oz. in the latter case. A single horse-load of turnips selected from the ground prepared in autumn only numbered 141 roots, and weighed as much as 109 stones, showing the weight of each root to be 10 lbs. 13 oz.* This instance proves that land for Swedish turnips may be prepared in autumn, and a heavy crop obtained on drills as wide as 32 inches, and from plants 15 inches apart. A somewhat similar success attended the trial of raising turnips on strong clay land, at ordinary distances, by Mr. Peter Thomson, Peffermill, near Edinburgh. So soon as the ground was cleared of tares, he cross-plowed it with a deep furrow, well worked it with harrows and grubber early in October, drilled it in the single way at 28 inches asunder, but, owing to the unfavorable state of the weather, was prevented applying the dung until December and January, which consisted of 32 single horse-loads of street-manure per imperial acre, and which was covered in with the common plow. In March the soil was found in a fine state, but as it was rather foul with weeds, the drills were harrowed a double tine, the ground stirred between them with the single-horse grubber, and set up with the double mould-board plow, and again set up just before sowing the seed of the green-top yellow turnip on the 15th, and of the white globe on the 25th and 26th of May. The yield was 32 tons of turnips per imperial acre, including tops, and quite free of mildew. The field had been dunged 5 years before, and twice since top-dressed with 8 bags of 4 bushels each of soot to the imperial acre.† Were such modes of culture adopted in the South of England, I have no doubt certain and abundant crops of turnips would be raised in spite of drouth and insects, and the slovenly practice of broadcast culture would then give way to the more scientific mode of the drill system.

(1957.) Besides farm-yard dung, a great breadth of turnips is raised every year with *bone-dust*. This manure is not only cheap, but insures a good crop of turnips in ordinary circumstances, and its use expedites field-labor very much. When the land is ready to be drilled up from the flat, the drills are made in the double way (1741); and that is all the preparation the land requires for bone-dust, which is then applied by the bone-dust sowing-machine, represented in Plate XXXI., and described below by Mr. Slight. This machine deposits the bone-dust and turnip-seed at the same time, and finishes the sowing of the turnip crop. The quantity of bone-dust used is commonly 16 bushels or 2 quarters to the imperial acre. There is something in the action of bone-dust on the soil, and its consequent power to produce a turnip crop, which I do not understand, the

* Mark-Lane Express, 17th October, 1842. † Ibid., 21st November, 1842.

means being apparently so inadequate to produce the results obtained. What I mean is, that up to a certain quantity used, this manure has evidently a beneficial effect, but, beyond that quantity, there is derived from its use no apparent benefit, in as far, at least, as the crop is concerned. I have tried to raise turnips with different quantities of bone-dust, varying from 12, 16, 20, and 24 bushels to the imperial acre, and have found the crop improved up to 16 bushels, but any quantity beyond that, even to 24 bushels, produced no greater effect on the turnips in the same field, and on the same sort of soil, than 16 bushels. Nay, more than this, my late agricultural preceptor, Mr. George Brown, when he farmed Hetton Steads, in Northumberland, raised as good crops of turnips as 16 bushels of bone-dust, with only 8 bushels of bone-dust, combined with an indefinite quantity of sifted dry coal-ashes; and yet 8 bushels of bone-dust, or an indefinite quantity of coal-ashes applied separately, produced a very poor crop of turnips. It is, therefore, unnecessary, in so far as the crop of turnips is concerned, to sow more than 16 bushels of bone-dust alone, or 8 bushels with coal-ashes, or perhaps street-manure. Both coal-ashes and street-manure, when proposed to be used with bone-dust, should be kept dry under cover and sifted free of large lumps. It is truly surprising what an effect on the soil so small a quantity of bone-dust produces. I have raised a portion of the manured soil of a drill with my hand before the turnip-seed had germinated, and found it agglutinated together in a lump with a greasy matter, and the lump interspersed partly with white mouldiness, and partly with minute fibres of plants. When the turnip-seed germinates, which it will do in 8 or 10 days, according to the state of the weather, its radicle strikes into the greasy mass of earth, and sends out an immense number of white fibres around and through it. Its cotyledons then expand upward into two rudimentary, smooth leaves, and immediately thereafter two true or rough leaves appear, and these last are called *rough* leaves, because they feel rough by reason of the small spiculæ which may be observed to occupy the surface of every leaf of the common turnip. The rudimentary leaves of the Swedish turnip are not rough but smooth, because the plant is not a true *turnip*, but a species of cabbage, which are all smooth-leaved. The smaller bone-dust is ground the more effective it is as a manure, because it then mixes more intimately with the soil, though its action upon it continues for a shorter time; and, on the other hand, large or *drilled*, or *inch-bones*, as they are called, remain longer in the soil undecomposed, but produce less immediate effect. On these accounts, bone-dust is the more valuable manure for turnips, and inch-bones for wheat. But even *bone-dust* has effect beyond the turnip crop; it extends its influence over all the crops of the rotation. I pulled off 4 acres of turnips raised with bone-dust, and 4 acres adjoining these in the same field that had been raised with 15 loads of farm-yard dung; and the crop of turnips was not only better after the bone-dust than after the dung, but all the crops that followed in the rotation, namely, barley, hay, pasture, and oats, were also better in their respective years. *Bone-dust*, when purchased in that state on shipboard, is almost always adulterated with old plaster, brick-dust, ashes, &c., and should therefore be purchased direct from the grinder, one who is on the spot. There are now many bone-mills scattered over the country. To avoid adulteration, an association of farmers was formed a few years ago in Perthshire to import bones, rape-cake, &c., and grind them at their own mills under the superintendence of a manager in whom they have confidence, and in this way they continue to supply themselves with genuine manures. Bone-dust is best conveyed in sacks, and 40 bushels will fill a double-horse cart and sow 2½ acres impe-

rial. It weighs 47 lbs. per bushel. It should be immediately emptied out of the sacks and kept in small heaps in a cool shed until it is used, as it is very apt to heat, and one consequence of *recent* heating is to become lumpy and troublesome to sow by the machine, though otherwise it is not injured, but rather improved by it. In some parts of the country, particularly on the Borders, bone-dust is sown by hand either along drills made up in the single way, which are then split in the double way, while this plan imposes the trouble of a second drilling, or it is sown on the flat ground and covered by drilling in the double way. In both cases, the seed is sown afterward by itself with the common turnip-sowing machine. The only reason I have heard in favor of sowing bone-dust by hand instead of machinery is saving the cost of the machine; but whatever advantage is gained by this saving, it is, I think, evident that the machine must deposit the bone-dust much more regularly than the hand; and as to the cost of a machine the saving must be trifling, as hoppers for containing bone-dust can be attached and made to remove at pleasure from an ordinary sowing-machine. I always used a machine of this form myself. But in a case of this kind accuracy of work is a more potent consideration than the cost of a small machine, even though it should be used but for a few weeks every year. There is another consideration, too, of even greater import, that the nearer bone-dust is placed to the turnip-seed the quicker will the seed vegetate, and experience has proved that turnip-seed may safely be placed among bone-dust. In sowing by hand, the manure is not placed near the seed in as far as the sower knows, and when the seed is sown by itself after the bone-dust has been covered up by the drill, the sowing-machine is as likely to deposit it away from, as near to, the manure, and hence a regular braird cannot be insured by the practice. The ordinary bone-dust sowing-machine, as well as sowing by the hand, deposits the bone-dust in a continuous line along the drill; but a sowing-machine has been lately invented, and is partially in use in Perthshire, which deposits the bone-dust in small portions at regular intervals. The argument in favor of this mode of depositing manure is the comparatively small quantity required by it to produce a full crop; and certainly when bone-dust is either very scarce or very dear, this is a fair argument to use in its favor. If by depositing as much bone-dust at given distances of 12 inches as would be deposited at those distances were 16 bushels per acre sown in a continuous line, and if the quantities so deposited at intervals of 12 inches are found to produce as well-grown turnips as a continuous sowing, then the saving of manure must be as great as from $\frac{1}{2}$ to $\frac{2}{3}$, because the intervals between the distances are not manured at all; and even if a greater quantity than usual were sown on the spots at intervals, still a saving would be effected upon the whole; and if these greater quantities are found to produce a greater crop than the usual mode, then the *plumping* mode, as this method of sowing by intervals is termed, may be regarded as a valuable discovery. Still more experience of its results is required before implicit faith can be placed in it as a practice fit for general adoption; although it must be owned that the anomalous circumstance regarding the action of bone-dust already noticed, namely, of its maximum effect being produced by a given quantity, and not by indefinite quantities—favors the pretensions of the plumping mode, and renders it deserving of experiment. The very best method of using bone-dust in small quantity, both for increasing the fertility of the soil and rearing a good crop, is to sow the seed along with it in drills already manured with farm-yard dung. The bone-dust secures a good and quick braird of the plant, and the dung supports it powerfully afterward. This plan I would

recommend to be pursued, particularly in England, on the land prepared for turnips in autumn, and were it practiced we need not despair of raising heavy crops of turnips, especially Swedes, on the strongest soils, and most certainly they would be obtained after thorough-draining. On using bone-dust, it should be measured from the heaps in the shed in bushels, and put into the bodies of close carts, which should be left at stated distances upon the head-ridge; it being exceedingly inconvenient to take bone-dust out of sacks. A field-worker should take the charge of replenishing the hoppers of the machine as the steward returns with it to the head-ridge at every bout, with a rusky, fig. 315, filled by the frying-pan shovel, fig. 176. As bone-dust is apt to heat in heap, and although it is improbable that you will keep bone-dust over the year, it being more profitable to put it into the ground, yet in case you should have any left over, or in case you should purchase a lot cheap out of season, it may be proper to let you know how to keep it in the best state until it is used for turnips or for any other purpose. The mode of keeping it is this: Whenever you get it you should put it on a dry pavement floor, as a damp one rots it fast away. It will heat again, but not so violently as at first after being made, and would heat again every time it is turned, which it should not be. It should not be kept in bags, as it will soon rot them, as I have experienced, nor should it be kept upon or under a wooden floor, as it will rot them both; nor should it be kept near horses and cattle, as they evince a strong dislike to its smell, on feeling which, horses actually become restive and troublesome. If new bone-dust obtained from the mill is desired to be heated at once, which it should be when it is to be kept, the process is much accelerated by the addition of a little sifted coal-ashes or earth, and as much water as will make the whole mass only damp, and turning it over several times until the entire mass is incorporated; and in 48 hours the heat will be so great as that you cannot hold your hand in it. The heat will gradually subside, the mass become dry and in a good state for passing through the sowing-machine. Heating has the effect of increasing the weight of bone-dust from 47 lbs. to 49 lbs. per bushel, and this increase is no doubt effected by the heating having taken off the angles of the particles, and allowing them to come closer together in the bushel. The color is also changed to blue and yellow, and on examination by the microscope, the mass will be found full of mites.*

(1958.) The established manures for raising turnips are farm-yard dung, street-manure in the neighborhood of towns, and bone-dust. There are many other substances which have been recommended for the same purpose, such as guano, animalized carbon, &c.; but as they are only of comparatively recent introduction, and cannot be said to have yet established their characters, I shall decline entertaining their pretensions here, and shall rather notice what promise they hold out when I come to mention the subject of making experiments in Agriculture.

Bone-dust.—The specific gravity of bone, as determined by Dr. Thomson, is as follows:

Os femoris of a sheep.....2·0345	Ilium of an ox.....1·8353
Tibia of a sheep.....2·0329	Human os humeri.....1·7479
Vertebræ of haddock.....1.6350	

The nature of this remarkable substance, as a manure, demands attention. Bone consists of organic and inorganic matter, and these are found in the following proportion in the bones of those animals which supply the largest quantity for manure, namely, the ox and sheep:

* Quarterly Journal of Agriculture, vol. xiii.

		Ilium of a Sheep.	Ilium of an Ox.	Tibia of a Sheep.	Vertebræ of Haddock.	Snout of saw fish, deprived of Teeth.
Organic matter or cartilage		43·30	48·05	51·97	39·49	46·310
Inorganic	Phosphate of lime	50·58	45·02	40·42	56·08	42·550
	Carbonate of lime	4·49	6·10	7·03	3·57	2·638
	Magnesia	0·86	0·24	0·22	0·79	0·101
	Soda	0·31	0·20	0·19	0·79	0·141
	Potash	0·19	0·11	trace.		water 6·920
		99·73	100·35	99·83	100·72	98·66*

In an analysis made by Dr. Henry R. Madden, to ascertain the relative component parts of bones and farm-yard dung, the following results were obtained, the bone being used in the state it is applied to the soil, and the dung consisting of a proportion of both stable and byre manure:

BONE-DUST.		FARM-YARD DUNG.	
Water	11·5	Water	45·535
Organic matter with some saline materials. Soluble in cold water	4·7	Organic matter. Soluble in water	10·750
.. .. hot water	5·5	.. .. potass	14·250
.. .. weak potass	26·0	Destroyed by heat	18·565
.. .. in strong potass	15·5	Salts of potass	7·900
Destroyed by heat	6·0	.. of soda	
		.. of lime	
Phosphate of lime	28·0	Silica	
Carbonate of lime	2·8	Earthy phosphates	3·000
	100·0		100·00

Another analysis gave of azote in bone-dust 1·77 per cent., in farm-yard dung ·45; so that in this respect these substances stand comparatively thus:

	Bone-dust.	Farm-yard dung.		Bone-dust.	Farm-yard dung
Soluble matter	10·20	10·750	Azote	1·77	.450
Easily rendered soluble	41·50	14·250	Total organic matter	38·50	33·565
Saline matter				55·00	10·900

Hence 1 ton bone-dust equals, as regards organic matter ..... 1 ton farm-yard dung.

..	..	..	..	..	soluble matter	1	..	..	..
..	..	..	..	..	easily dissolved matter	2·9	..	..	..
..	..	..	..	..	azote	3·9	..	..	..
..	..	..	..	..	saline matter	5	..	..	..
..	..	..	..	..	earthy phosphates	18·3	..	..	..

If all the various degrees in which bone-dust is superior to farm-yard dung be added together, 1 ton of it equals 30 tons of dung, but as only 16 bushels of bone-dust are applied to the acre, which at 47 lbs. per bushel, weighs 7 cwt., this quantity is equal to 10½ tons of dung.* It is still a question whether the organic or the inorganic portion of bone-manure bestows the greatest benefit on the land, and from its effects extending over more than one crop, some are of opinion, among whom are Liebig and Sprengel, that its principal efficacy is in all cases to be ascribed to the earthy ingredients, and especially to the phosphate of lime; but it has been brought to light that bones do not lose their organic matter entirely, though they should have been buried for years under ground. Thus the bones of a bear and a stag, after being long buried, were found by Marchand to consist of

	Bones of the bear buried.		Femur of a Stag.
	Deep.	Shallow.	
Animal matter	16·2	4·2	7·3
Phosphate of lime	56·0	62·1	54·1
Carbonate of lime	13·1	13·3	19·3
Sulphate of lime	7·1	12·3	12·2
Phosphate of magnesia	0·3	0·5	2·1
Fluoride of calcium	2·0	2·1	2·1
Oxides of iron and manganese	2·0	2·1	2·9
Soda	1·1	1·3	
Silica	2·2	2·1	
	100·	100·	100·

"The most striking change," as Professor Johnston observes, "undergone by these bones, was the large loss of organic or animal matter they had suffered. The relative proportions of the phosphate and carbonate of lime had been comparatively little altered. The *main* effect, therefore, produced by bones, when buried at the roots of trees, and their first effect, in all cases, must be owing to the animal matter they contain—the elements of the animal matter, as it decomposes, being absorbed by the roots with which the bones are in contact." Still, it is found that bones, after

* Thomson's Animal Chemistry. † Prize Essays of the Highland and Agricultural Society, vol. xiv.

having been boiled, and of course deprived of the greater part of their animal matter, make excellent manure; but as they at the same time take up a considerable quantity of water, which will cause them to decompose more rapidly when mixed with the soil, they will appear to act as beneficially, Professor Johnston conjectures, as unboiled bones. "He who candidly weighs the considerations above presented, will, I think, conclude," says the Professor, "that the whole effect of bones cannot in any case be ascribed exclusively either to the one or the other of the principal constituents. He will believe, indeed, that in the turnip husbandry, the organic part performs the most permanent and most immediately useful office, but that the earthy part, nevertheless, affords a ready supply of certain inorganic kinds of food, which in many soils the plants could not otherwise easily obtain. He will assign to each constituent its separate and important function, being constrained at the same time to confess that, while in very many cases the *earthy part of bones applied alone* would fail to benefit the land, there are few cultivated fields in which the *organic part applied alone* would not materially promote the growth of most of our artificial crops."* When bones are heated to redness in the open air, the organic part burns away, and leaves the white earthy matter, in the form and nearly of the bulk of the original bone. It is very brittle, and consists chiefly of phosphate of lime, and is sold at the chemical works at 9s. per cwt. Bones of cattle and other animals, and of fish, except whale-fins, whether burnt or not, or as animal charcoal, pay a duty by the new Tariff of 6d. per ton. The declared value of bones imported into this country in 1832 was £91,755 5s. 5d.; and the duty paid thereon was £940 5s. 9d.† I should suppose there has been a considerable increase in the import since that period. The price of bones at Hull, the great mart of their import, in 1843, was from £3 15s. to £4 per ton.

(1960.) *Turnip-drills*, like the other members of the class of implements employed under the drill system of cultivation, mark an improved state of the art, for in the early history of the turnip culture, we find the broadcast method of sowing generally adopted, and in some parts of England at the present day, where farming is otherwise well understood, we yet see the broadcast system of sowing turnips not only practiced, but advocated as the most productive. That great aggregate weight of turnip may be produced in broadcast in particular soils and seasons, may be true, but doubtless a greater certainty of success is to be obtained from the drill practice; and it appears now, from the latest English authorities,‡ that the former practice will soon be rooted out by the unflinching hand of experience. In the early stages of the drill practice of turnip culture, the breadth of land sown being but small, a single row hand-drill or barrow seems to have been generally used, but a simpler implement than even this has been employed—the hand flask sower. As the practice extended, machines of two rows were introduced, drawn by one horse, and this in various forms continues to be the chief instrument employed in sowing the seed of this important root.

(1961.) The varieties of the turnip-drill are too numerous to be detailed here in full, nor would it be profitable to follow all the fancies of machine makers, some of which have produced but cumbrous and inconvenient vehicles, which, when their purpose is considered, are cumbrous not only in their bulk, but in the multiplicity of their parts, and hence are complicated and tender, liable to derangement and failure, and are marked by an absence of that simplicity of construction so desirable in agricultural *mechanics*. In many of our more modern turnip-drills, however, there is to be seen a marked simplicity of construction, that accords well with the objects in view, and this holds especially with those machines which are employed for sowing the seed alone; and in none more so than the machine now very generally known as the East Lothian drill, which I shall have occasion more particularly to notice. The recent introduction of numerous granulated manures has called forth a new class of machines, whose object is to deposit the manure along with the seed either in immediate contact, or in close contiguity, and these compound machines have again involved a degree of complexity of construction; for whenever a machine is required to perform compound functions, a necessarily increased complication of structure is entailed upon it to a greater or less extent, proportionate, perhaps, to the mechanical talents of the fabricator. An additional cause of complication in the compound drills has arisen within the last few years, from a desire to economize the distribution of the modern expensive manures, by depositing small portions of it at the points only where the future root is intended to grow, leaving the intervals destitute of manure. The propriety of thus dealing so niggardly with the soil in withholding those substances in abundance by which it is enabled to continue its fertility, is at least questionable; but the experiment has effected what I am at present endeavoring to establish—the farther complication of structure in the machines employed. The drill-sowing machines adapted to this purpose are designated in Scotland *plumpers*, from their dropping their gifts on one point. In England they are better known by the name of dibbling-machines, or drop-drills.

[Of turnip and other drills and complicated machinery used in England, they have either been excluded from use in this country on account of their cost and complexity, or they have been greatly simplified if not improved. The agricultural warehouses everywhere abound in drills of various forms adapted to various purposes.

Although the cheapness of Indian corn and the dryness of our climate will prevent the general introduction of turnip husbandry on a large scale in this country, the dearness of labor adding another objection, we are strongly persuaded that through all the mountainous ranges of the Southern States, where morning fogs prevails through the summer so favorable to the grasses, they might profitably cultivate the Swedish turnip, to be employed in feeding their cattle, intended to be fatted on grass the next summer. Turnip crops and sheds for sheltering and feeding their cattle in

* Johnston's Lectures on Agricultural Chemistry.

winter, would, we think, on trial be found a great improvement on their present system. The extent of the country referred to, the value of its industry, and our partiality for that branch of husbandry, and some of those who pursue it, induce us to give what otherwise might have been omitted with prejudice to the mass of American farmers. *Ed. Farm. Lib.*]

---

22. REPAIRING THE FENCES OF GRASS-FIELDS, AND THE PROPER CONSTRUCTION OF FIELD-GATES.

"At neglected gaps
Burst scrambling through, and widen every breach.
A stake put timely in, or whinny bush,
Until the season come when living plants
May fill the vacant space, much harm prevents."
GRAHAM.

(1962.) The season being almost arrived when the grass is able to support stock, and of course, when the cattle are permitted to leave their winter quarters in the steading, it is necessary to ascertain, in the first place, whether the fences of the grass-fields are in such a state of repair as will offer no temptation to stock to scramble through neglected gaps, much to the injury not only of the fence, but perhaps of themselves, or at least much to their disquietude; and in the next place, to watch the period when the grass is in a fit state to receive them. Sometimes a good deal of work is required to put grass-fields in a proper state for the reception of stock, owing principally to the nature of the soil, and partly to the state of the weather. On every kind of land the small stones lying on its surface should be gathered by the field-workers and carted off for the use of drains, or be broken into metal for roads. It may happen that the throng of other work may prevent the assistance of horses and carts being given for this purpose, in which case the stones should be gathered together in small heaps on the furrow-brow of every other single ridge; but in doing this, it should be remembered that these heaps occupy so much of the ground, and, of course, prevent the growth of so much grass, that, on this account, it is a much better practice to cart them away at once if practicable. When carts are used the stones are thrown directly into them; whereas in making heaps, the stones require some care to be put together, and, of course, waste time, and they have to be removed after all. Some farmers are regardless of gathering the stones from any of their fields, even from grass-fields which are to be in pasture; while all acknowledge that fields of grass which are to be made into hay ought to be cleared of stones to save the scythes at hay-time. On clay soils there are very few, or perhaps no stones to clear off, and in wet weather no cart should be allowed to go on new grass. As every field, whether of new or of old grass, should be rolled some time before the stock enter them, it is clear that the ground cannot receive all the benefits of rolling as long as stones are allowed to remain on its surface. The best time for rolling is when the surface is *dry*—mark you, not when *hard* and dry—for when grass, especially young grass, is rolled in a wet state, it is very apt to become bruised and blackened. When dry, grass is elastic and able to bear the pressure of the roller without injury. Light land will bear rolling at any time when the surface is dry; but plants are very liable to be bruised by the roller against the hard clods of clay land, and in a soft state, on the other hand, clay land

is apt to become hardened or encrusted by rolling. The rolling of heavy land is thus a ticklish matter; but a good criterion to judge of its being in a fit state for the roller, is when clods crumble down easily with the pressure of the foot, and not press flat, or enter whole into the soil. The rolling is always given *across* the ridges. The stones should be gathered, and the land rolled at least a fortnight before the stock are put on grass, to allow the grass time to grow after these operations, when it will be found to grow rapidly, if the weather is at all favorable.

(1963.) Besides the fences, the *gates* of grass-fields require inspection and repairs, so as they may be put in a useable state for the season. When any of the timbers, posts, or bars, are broken or wanting, or the fastenings loose, the carpenter or smith should be made to repair them; and the posts on which the gates hang should be made firm in the ground when loose, or renewed when decayed. In putting up new gate-posts, the firmest mode I have found, is to dig as narrow a hole as practicable 3 feet deep for the hanging-post, and then to ram the earth, by little and little, firmly around the post without any stones. Charring or pitching the part under ground is a pretty good prevention from rot for some time. The simplest mode I have seen of fastening field-gates is with a small chain attached to the fore stile of the gate, to link on to a hook on the receiving-post. The most convenient position for field-gates is at the ends of head-ridges, which may be regarded as the roads of fields. Field-gates should be made to fold back upon a fence; to open beyond the square; and not to shut of themselves. When they shut of themselves, and are not properly set when opened, and which requires greater care than is usually bestowed on these matters, they are apt to catch a wheel of the cart which is passing, and, of course, to be shivered to atoms, or the post to be snapped asunder; and more than this, self-shutting gates are apt to be left unfastened by most people who pass through them, and are therefore unavailing as a fence to stock, especially to horses when idle, which seem to take delight to loiter about gates, and they not unfrequently find out the mode of opening them. One reason, perhaps, for horses loitering about the gates is to rub themselves, to prevent which, thorns are wattled into the bars: but independent of this casual safety, every pasture-field should be provided with one good *rubbing-post* at least, standing 6 feet in hight. The proper construction of field-gates is generally very little attended to, if one may judge by those usually to be seen in the country. Some judicious remarks by Mr. Slight, with appropriate figures, in reference to this much neglected subject, will be found below, and which I hope will tend to the diffusion of an improved form in this necessary portion of farm furniture.

(1964.) The importance of field-gates, whether viewed as the means of security to crops and live stock, or as a portion of the peri hable stock in trade of the farm, is an object deserving of grave consideration. Hitherto, it may safely be averred that very little attention has been paid to principle in the construction of field-gates; and for the truth of this, we have only to look around us, where the eye of the constructive student will detect probably not more than one in a hundred of our field-gates that are not glaringly defective as pieces of extremely simple constructive carpentry. Defects in point of construction are not even confined to the field gate: we find them in many of those gates of much higher pretensions, and where the hand of a master having been at work, we might be led to expect something like an approach to the true and simple principle: yet how seldom does the eye, experienced in directing those geometrical and dynamial principles, on which alone a just and permanent system of construction depends, light upon a form that satisfies its discriminating glance. We do, indeed, occasionally meet with examples wherein is evinced a correct knowledge of those arrangements of the parts, in a rectangular frame, whether of wood or iron, that at once secures permanency of form, and stability in the entire structure. In such cases we are sure to find that the proprietor possesses not only an educated mind, but one that has not disdained to stoop to the drudgery of acquiring a competent knowledge of practical mechanics, leading him also to see the advantage of securing the assistance of mechanics whose education qualifies them to perform their duties in accordance with the laws of that science. It may seem trivial to apply remarks of this kind to such a simple matter as the construction of a field-gate; but assuredly there is no part of our agricultural economy that points out so broadly the

ignorance of our artizans in those important branches of their education, the elementary truths of Geometry and Mechanics.

(1965.) A gate, generally speaking, may be described as a rectangular frame; there are exceptions to this definition applicable to gates as a whole, but to *field-gates* there are none. A gate, to be permanent, should be immutable or unchangeable in its form; a simple rectangular frame without upfillings, if they are placed at right angles to each other, is the most liable to change of any connected structure of frame-work. The triangle, on the other hand, is the most immutable or least liable to change; it is, in short, so long as the materials remain unchanged, perfectly immutable, but a gate in a form of a triangle would, in most cases, be very unserviceable, though a combination of triangles may produce the requisite figure for a serviceable gate. If then we take the rectangular frame so essential to a field-gate, and apply a bar in the position of the diagonal of the parallelogram, we immediately convert the original rectangular figure into two triangles, applied to each other by their hypothenuse, and this gives us the true elements of a properly constructed gate, all the other parts being subordinate to these, and adapted solely to the practical purposes of the gate as a defence or for ornament. In many cases depending upon the material employed, an opposite diagonal may be applied, dividing the gate into four triangles; but, in general, this is only necessary where flexible rods of iron are applied as the diagonals.

(1966.) In looking at the construction generally of field-gates, we observe traces of an incipient knowledge of the usefulness of a diagonal bar, but in very many cases it is applied with that uncertainty of purpose that marks a doubtful and hesitating knowledge of the subject; we see it, in short, applied in all the possible positions that may be conceived to deviate from the one, true, and simple position—extending from an angle to its opposite—which is the simple and universal rule applicable to gates. Let it, then, be borne in mind that the essentials of a field-gate, whether of wood or iron, are a rectangular frame, consisting of the heel and head-posts, and a top and bottom bar or rail, which four parts, properly connected at the angles, are rendered of an unchangeable figure, by the application of one or more diagonal bars, and these diagonals should in *no case* be applied short of the whole length between any two of the opposite angles. The upfilling, whether of rails or otherwise, as may be desired to attain any particular object, are mere accessories, and not in any way tending to the stability or durability of the fabric.

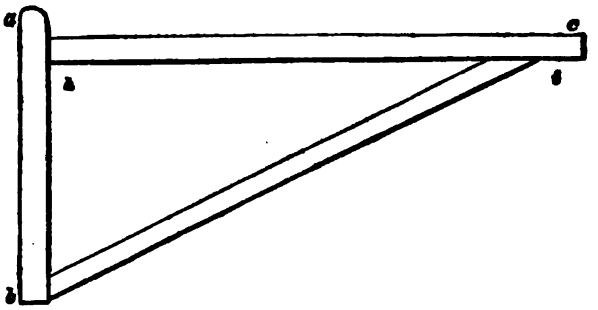
(1967.) The choice of the material for the diagonal is of some importance, and here the maxim of universal application in mechanical construction: "*Tie with iron and strut with wood*," is especially applicable. The field-gates constructed entirely of wood, the diagonal should invariably be applied as a strut; that is to say, it should *rise* from the *foot* of the heel-post, and terminate at the *top* of the head-post. Placed in this position, the diagonal supports the head or swinging end of the gate, by its resistance to compression, a duty which, from the *area* of its cross section being considerable, and hence capable of resisting lateral flexure, it is well adapted to perform; while, at the same time, the above sectional property gives it a broad terminal resistance, where it abuts upon the angles of the external frame. The same diagonal bar, if applied in the opposite position, and performing a duty of a tie or stay, its great sectional area would avail but little, for, though woody fibre is capable of resisting very considerable tension, larch-wood having, with equal sectional areas, a power of resistance to tension equal to about ½ that of malleable iron of medium quality: and though this wooden tie might be found to possess in its aggregate section a cohesive force greatly beyond that of an iron bar applied in the same position, for the wooden bar would have a sectional area at least twelve times greater than could be requisite for an iron tie, thus yielding an aggregate force double of the iron; yet as the wooden *tie* must depend for its connection in the structure, upon nails or bolts only, its ultimate power of resistance to tension depends not on its own sectional area, but on that of the nails or bolts by which it is fastened, and these again, may be very greatly reduced by the rending of the extremities of the wooden tie.

(1968.) The advantages of iron as a tie, and its disadvantages as a strut, are just the converse of the foregoing. From the smallness of sectional area requisite in an iron bar applied in this construction, as compared with its length, it is not capable of withstanding compression even to the smallest extent without suffering lateral flexure, and this defect unfits it entirely for the purpose of a strut. Applied as a tie the iron bar is perfect; the cohesion is such that a very small sectional area is sufficient for the purpose under consideration; thus, a rod of ½ inch square even of inferior iron will bear a tension, with safety, of two or three tons, while the best quality will bear six tons; a rod of half this sectional area may, therefore, be held as sufficient for the diagonal *tie* of a gate, and as it can be fixed by bolts without risk of fracturing its ends, as in the case of wood, its application in principle becomes as perfect as it is possible to approach. But though this construction is in principle completely supported by the *tie* from any force tending to depress the head-post of the gate, there is yet a defect in practice; for a gate is liable, from various causes, to be forced upward at the head-post. We have seen that a slender and flexible iron rod cannot resist compression without flexure, and, therefore, a gate with only one iron diagonal tie will still be practically imperfect, and it becomes necessary to apply an antagonist placed in the position of a strut, but virtually performing the duties of a *tie* arising from the antagonist effects of the two, the tendency of the one being to hold the head of the gate up, while the other exerts an equal force to keep it down, whereby a perfect equilibrium is preserved within the structure.

(1969.) In treating of the *practical* construction of field-gates, it is, perhaps, unnecessary to dwell upon the strains that occur in the individual horizontal bars, because, if the principles inculcated above are attended to, all cross strains in the principal joinings are avoided; and, except when any extraneous force is applied, the strains are resolved by construction into those of direct compression or of tension. Thus, in fig. 352, which may represent the elements of a fly-gate, applicable to a drive or thoroughfare, and opening either way; if we take the heel-post *a b* and the bar *a c* alone, and hinged in any manner at *a* and *b*; and if the bar *a c* is 10 feet long, the breadth of the heel-post at *a* 5 inches, and the parts being joined by mortise and tenon: suppose, then, a load applied to the bar at *c*, the mechanical effect of the load would be a cross strain at *b*, tending to break the bar directly across with a force equal to 24 times the load, exclusive of the effect of

the bar itself, the bar *a c* forming here a lever of the first order, whose arm *b c* is to the arm *b a*, or the breadth of the heel post, as 24 to 1. By increasing the number of bars we do not alter the

Fig. 352.



THE ELEMENTS OF THE TRUSS IN A WOODEN FIELD-GATE.

total effect of the load, but simply divide it equally over the superinduced bars, supposing them to be connected with a head-post at *i*. But reverting again to the single bar *a c*, and applying to it the diagonal *b c*, we have now the triangular figure *a b c*, the parts of which being firmly connected at their points of junction, the form becomes unchangeable, and the effect of the load at *c* is instantly altered. The effect of the load at *c* is now resolvable by the parallelogram of forces into two others, the one of tension on the bar *a c*, the other of compression on the diagonal *b c*, and taking the length *a b* as a representative of the gravitating or direct effect of that load, then the tension on *a c* will be to the absolute load as the length of *a b* is to that of *a c*, and the compression on the diagonal will be as *b c* to *b a*. In this example the hinges of the gate are not shown, but in actual practice the tails of the upper hinge stretch along part of the top bar, binding it securely to the heel-post, while the bottom hinge may be made to form an abutment to the foot of the diagonal.

(1970.) The practical insertion of the diagonal is also of some importance. Fig. 353 exhibits one mode of performing this, where *a b* is the strut half lapped upon the heel-post at bottom and upon the head-post at top: it is not an elegant mode of insertion, but it is efficient, in so far that while it acts as a strut, it binds the top of the head-post to the top-bar, and prevents it from flying off by the thrust of the diagonal.

(1971.) Fig. 354 exhibits another mode of insertion of the diagonal, which is perhaps preferable to the former; here the head of the diagonal is attached to the top bar, half lapped upon it at *b*, and notched into the lower edge as an abutment, forming a very efficient strut, the tension strain being brought entirely upon the top-rail, which is always securely tied to the heel-post by the tails of the hinges at *c*. These examples are applicable to field-gates where the bars are always much thinner than the heel and head-posts, the latter being generally about 2½ to 3 inches thick, and the former only 1½ inches. In such cases the diagonal is slightly notched upon all the bars, and deeper upon the heel and head-posts, where the method fig. 353, is adopted; but in no case should the bars be notched except in the edge of the top bar, where it receives the head of the diagonal.

Fig. 353.

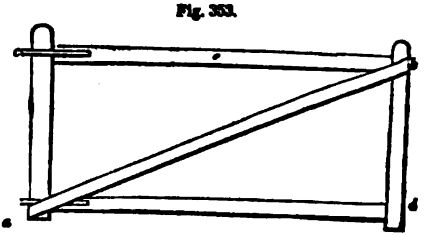


Fig. 354.

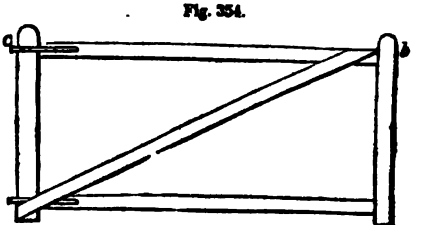


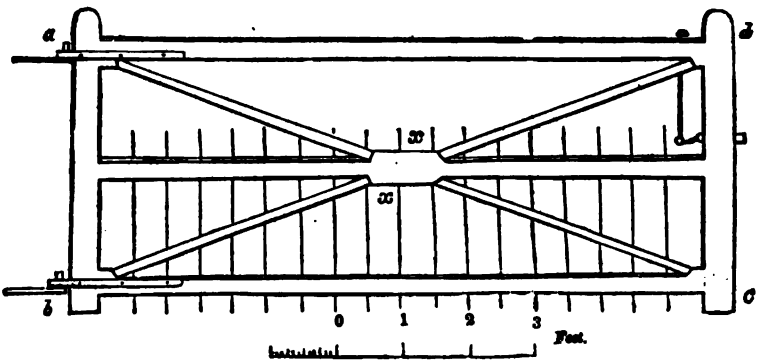
EXAMPLES OF THE APPLICATION OF THE DIAGONAL.

(1972.) I have hitherto alluded only to the simplest efficient form of wooden field-gates, in the construction of which cheapness is always an object, and I have, in order to avoid confusion of ideas, restricted the description to the essential parts, the number of bars, or other means of rendering the gate a sufficient fence, is left to be filled up at discretion. In making these upfillings the maker should studiously keep in mind that no curved bars or timbers, of any description, should enter into the construction, either for ornament or ostensibly for use.

(1973.) In the construction of wooden gates for drives or approaches, where utility is still the chief object, strict attention should still be paid to the principles of construction, but a little more latitude may be admissible in point of finish and expense. For such purposes, the rails and posts of the gate should be all of one thickness, or at most, the only difference should be a gradual diminution in thickness toward the head, to lessen the effect of gravity on the hinges and gate-post; and for pleasant effect, there should not be more than three horizontal rails, with two diag-

ginals; and if it is necessary to have a closer upfilling, it should be of an upright light balustrade form. Fig. 355 is an example of this form of gate, which I adopted 26 years ago, and the ori-

Fig. 355.



WOODEN GATE SUITED FOR THE APPROACH TO A VILLA.

ginals then constructed are still good and serviceable, but it is considerably more expensive than the common field-gate. The heel-post *a b* is 5 inches broad and 3 inches thick, while the head-post *c d* may be reduced to 2½ inches if thought advisable. The top and bottom bars are formed with abutment pieces at both ends, which are 5 inches broad, the intermediate parts being reduced to 3½ inches; the middle bar has the same breadth, but is made up in the middle with corresponding abutments, and the two diagonals, of 2 inches in breadth, are inserted in four pieces, exactly fitted between the abutments of the bars. The hinges are of the common double-tailed form, binding the top and bottom rails firmly to the heel-post, and the gate may be hung upon pillars of stone, or of wood well secured. The best balustrade for a gate of this kind is rods of iron ½ inch diameter, as in the figure, passed up through the bottom and middle bars and the diagonals, the holes for these being easily bored with an auger after the gate is formed; but a simple and cheaper balustrade is formed of light wooden spars sunk into the bars and diagonals.

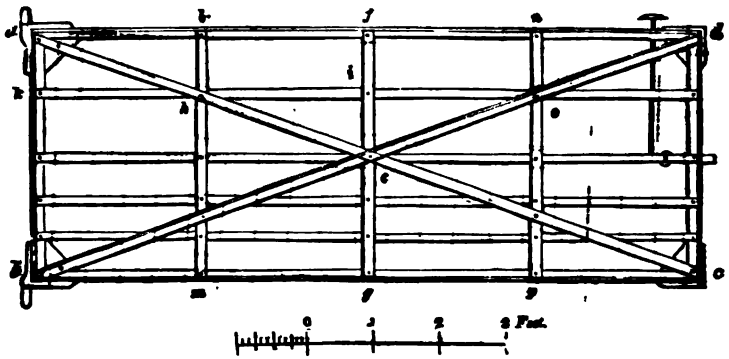
(1974.) For all wooden gates, the method of bracing with light iron diagonals is to be preferred to wooden struts, but to be effective two diagonals must always be applied. In some cases, they may pass from one angle to its opposite in one length, but in others it is necessary to apply them in four pieces, the connection at the center of the gate being effected either by a ring of iron, in which the four ends are screwed, or by bolting the palmated ends of the four parts, two and two together, through the middle bar, as applied at *x x* fig. 355, one bolt securing the four ends, and in either case the rods pass through the top and bottom of the heel and head-posts of the gate, and are there secured by screw-nuts. It is obvious that iron diagonals would apply in this manner to the gate, fig. 355, instead of wooden braces.

(1975.) Field-gates of wood, from the cheapness with which they may be furnished when imperfectly constructed, have been long in use, and in many localities continue to be more extensively used than any other; but *malleable iron* is gradually taking the place of wood, and, from its greater durability, may be expected to supersede wood entirely. In the construction of malleable iron gates, we as frequently find malformations as in those of wood, such as placing all the bars on edge except the heel and head-post, misplacing the diagonal, if single, and not unfrequently applying bars variously formed in curves and fanciful figures, to serve the purpose of the diagonals. The field-gate maker should be instructed to hold steadily in view that there is but *one position* and form for that member of the structure that can be fully efficient, and these are, the straight bar extending from the upper angle at the heel to its opposite angle at the head-post, and, if the materials of the gate are light, to apply an antagonist diagonal crossing the first. In framing the gate, also, the top and bottom bars should be set flat-ways, to enable the structure to resist lateral strain from animals rubbing or pushing against it.

(1976.) One of the latest improvements in iron field-gates is the introduction of *angle iron*, now so extensively used in boiler-making, ship-building and other purposes. In the application of the angle-iron to the construction of gates, the fabric acquires the rigidity of a massive wooden gate, with all the tenacity and strength of the iron, while its weight is little more than that of wood. Fig. 356 is a form of gate of this construction, which I have lately adopted, with some alteration, from a design of Mr. William Dunlop, Edinburgh, and is manufactured by James Slight & Co., Edinburgh. The external form is composed of four bars of angle-iron, measuring 1½ inches on each side, and to give security to the joinings at the four angles of the truss, the ends of the bars are riveted upon cast-iron corner-plates, those of the heel-post *a b* being formed with strong projecting pivots, by which the gate is hinged. Any number of interior bars may be applied to suit the objects of the gate. The figure exhibits the arrangement adapted to retain sheep and lambs. The diagonal *b d* is contrary to the general rule, for it is apparently a strut, but being a bar of angle-iron, of the same breadth as before, it possesses the stiffness of wood, to resist lateral strains—and is hence properly adapted for a strut: to render the bracing complete, the antagonist diagonal *a c* is applied, and this, acting as a tie, is only a flat bar 1 inch by ¼ inch. The external frame is thus rendered unchangeable in figure by any force that may be applied to the

head-post in a vertical direction, either upward or downward, short of what will fracture the gate; and the point *e*, where the diagonals cross each other at the center of the gate, becomes also immovable in the plane of the truss; hence the perpendicular bar *f e g*, being riveted to the

Fig. 356.



THE FIELD-GATE WITH ANGLE-IRON FRAME-WORK.

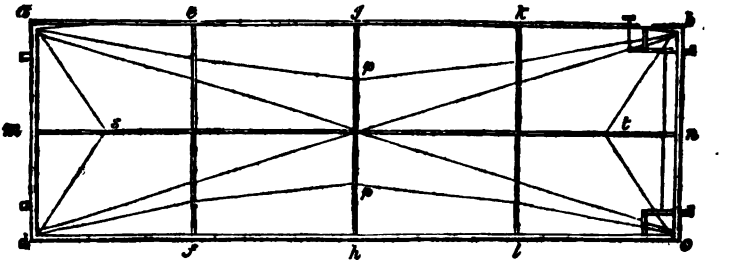
diagonal at *e*, acquires the same property, and by attaching all the horizontal bars to *f e g* at their several crossings, each of them is rendered permanent in its position at that point, and no force short of breaking down the gate can bend any of the parts upward or downward in the direction of the bar *f e g*, so long as this last remains attached to the crossing of the diagonals at *e*. In order to give farther support to the horizontal bars by the *principle* of construction, we have only to take a point where a diagonal crosses a bar, as at *k*, forming the opposite triangles *e k i* and *a k k*, which, when the bar and diagonal have been connected, become also immutable, and the perpendicular bar *l k m* being secured to the point *k*, and again to the different bars at their intersection with *l k m*, the whole are again rendered immovable as in the middle. The support given to the horizontal bars in the line *l k m*, would have been still more complete if there had been only one intermediate bar below the middle one, as the three parts would then have met in one point, as they do at *k*, but two bars are introduced to render the gate fencible for sheep of all ages. The perpendicular bar *n o p* is applied on the same principle as laid down for *l k m*, the point of support in this case being *o*.

(1977.) In this construction of gates, the greatest possible amount of mutual support among the parts is obtained with a given quantity of materials; hence gates of this construction may be made lighter than any other form where iron is the material employed, and yet have a greater amount of strength. In this example, the dimensions of the angle-iron are 1¼ inches each way, and about ¼ inch thick; all the other parts are 1¼ inches broad by ¼ inch thick, the cast-iron corner plates being, of course, stouter, and the entire weight of the gate is 112 lbs. It may be of use to those who make iron gates, but who have not taken time to study the first principles of their construction, to notice this farther remark. Any number whatever of additional upright bars to those shown in fig. 356 would add strength or support to the horizontal bars only on the principle of superposition, or adding bar to bar, without the advantages which arise from the principle of unchangeableness in the triangle when applied in the construction of frame-work, whether in a simple field-gate, or in the highest branches of constructive carpentry in wood or in iron. In the one case, the stress on the parts continue to act at right angles to the bars, the direction in which they are weakest, while in the other—the principle of throwing the frame into triangles—the whole stress is thrown upon one or more parts in the direction of their length, in which position all bars and beams are strongest.

(1978.) An example of an ingenious construction of iron gate is given in Parnell's work on Road-Making, which has been improved upon by Mr. Buist, now of Bombay, and described in the Prize Essays of the Highland and Agricultural Society. These gates consist of a wrought-iron external frame, which is supported by a very perfect system of bracing, with diagonal ties of iron wire, and filled up in a variety of forms with the same material. Fig. 357 represents Mr. Buist's gate with the fundamental braces and ties, which he thus describes: "The framing *a b c d* is fashioned like that of an ordinary gate; *e f*, *g h*, and *k l* are three light slips of iron parallel to the ends of the gate, and riveted to the upper and lower rails; *a p b* is a wire about the thickness of a goose-quill, fastened by a rivet at one end, and a screw and nut at the other; it passes through holes in the slips *e f*, *g h*, and *k l*, and serves as a brace to support the bar *a b*. In the same manner *d p c* serves as a brace to *d c*, while the two sides of the gate being coupled together by the slips *e f*, *g h*, and *k l*, the lower and upper rails have severally the benefit of both braces. The diagonals *a c* and *d b* keep the frame in shape, while *a s d* and *b t c* are braces to *a d* and *b c*, by means of the light bar *m n*. It will be seen that all the wires and straps which act as fills-up, are either braces or supports, so that nothing can be more stiff than the gate thus completed. It weighs about 80 lbs., and costs £1 8s. Its dimensions are 9 feet by 3½ feet, but may be made of any size, the price varying in proportion. It may be observed that a gate with one bolt, when shut suddenly, vibrates for some time at the fore-foot; this is obviated by two bolts coupled together, as in the figure, near *b* and *c*, and acting simultaneously. It is also convenient for gates opening into policy grounds, getting bolted when thrown back by means of a short stump driven into the ground, with a catch at the height of the lower bolt *a*."

(1979.) Fig. 358 represents a gate of this construction filled up with wires in the form of rays from a center. "The horizontal bar *m n*, and the braces *a s d*, and *b t c*, of fig. 357 are here omitted as superfluous. The rays consist of wires of the same thickness as before, and about 9 inches

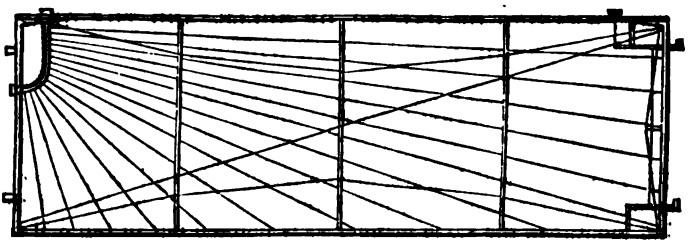
Fig. 357.



THE ELEMENTS OF THE BRACING OF A WIRE FIELD-GATE.

from each other. Their lower extremities are upset as nail heads or rivets, and their upper ends are fastened with a nut and screw. For the admission of the screws a strong iron arch is placed in the corner of the gate, and fastened at each end with screw-nuts; its range down the heel-post

Fig. 358.



THE WIRE FIELD-GATE WITH RAYED UPFILLINGS.

as compared with that along the upper rail, should be as the length of the gate is to its hight, which in this example, is 18 inches down the heel-post, and 6 inches along the upper rail. A gate of this form, and 9 feet by 3½ feet, costs £1 15s."*

(1980.) The wire-gates above described are admirable examples of the principles of trussed frames, and for gates. So far as that principle gives them firmness and support, they can hardly be excelled; but there is one defect attendant upon the wire upfilling, its too great tenuity, which renders the wires liable to derangement on being loaded with any cross-strain, such as a person attempting to climb over the gate, and setting foot on the wires. A diagonal wire undergoing such treatment will be liable to stretch, and thereby lose its effect. Could such accidents be effectually guarded against, these gates might be regarded as almost perfect. In regard to the expense of the gates first described, the common wooden field-gates may be considered to range from 15s. to 25s. The gate, fig. 355, about £1 15s.; and the selling price of the angle-iron-gate, fig. 356, is about £1 5s.

(1981.) *Gate-pillars and fastenings.*—For field-gates where hedges form the inclosures, the simplest kind of gate-posts are those of larch or common Scots fir. They may be set in their natural state, or peeled or dressed in any form to the taste and means of the farmer; but in whatever form the body of the post may be, the top should be cut off either in form of a cone or pyramid, or a hemisphere, to prevent the lodgment of water on it. The simplest means of fastening wooden gate-posts is by beating or *pinning* in the earth around them as described (1963), but the most effectual and permanent mode is to form a pit of at least 2½ feet square, and of the same depth, and the post being set in it, the pit is filled up with rubble masonry in mortar packed firmly, and grouted round the post. This an expensive mode, but is more permanent, and a greater durability of the timber is effected by contact with the lime.

(1982.) In the Isle of Man, though its agriculturists cannot boast more than ourselves of the perfection of their gates, Nature has supplied them with an admirable material for gate-posts. The transition-slate with which the island abounds is found in one locality, Spanish-head, of a nature that serves all the purposes of beams and planks of wood, and of this many, indeed, most of the gate-posts are formed. In Scotland we have now in abundance a material equally suitable for the same purpose, in the Caithness pavement, which is now applied for gate-pillars, and for which no material can surpass it. They are built into the ground in the same manner as wooden posts, and look very much like a plank of wood, but possessing strength, and especially durability, far beyond wood. The crook-hinges are either fixed into them by passing through them as bolts through a jumper hole, or they may be put in the form of a hoop, and secured with wedges. For

* Prize Essays of the Highland and Agricultural Society, vol. xiv.

field-gates built pillars of stone are seldom used, and only when the inclosures are formed of stone-dykes; and these forms are so various, that it is out of place to describe them here.

(1983.) The *hanging of gates* has already been slightly adverted to: the crook and band hinges are those chiefly employed, and of them it is only necessary to say that the hinge should be always double-tailed. The fastenings of gates are still more various, and many of them so simple and efficient that it were difficult to point out which is the superior.—J. S.]

(1984.) While treating of fences and iron gates, I may mention a simple plan by which grass-lawns, or the small plats usually formed in front of farm-houses, may be kept short without the use of scythes, or incurring much trouble and expense. Let a bught be made of wire hurdles of the form of the gate fig. 357: and, that it may be movable, let the hurdles be fixed together. If the plat is very small, one inclosure composed of 4 hurdles, forming a square of 9 feet, will suffice; if it is larger, any number of such bughts may be be employed. The use of these inclosures is to fence 1 or 2 sheep within each, so that when they have eaten down the inclosed grass, the bughts may be moved forward, or backward, or sideways to a fresh division of grass, until the whole grass-plat is eaten bare. The sheep may then be removed for a time till the grass grows, and again brought back. Or, since such bughts would be rather ornamental as otherwise, only as many sheep may be inclosed within them as will just suffice to keep the grass in good order, and where they may constantly grace the lawn. A few Leicester tups or tup-lambs may thus be kept separate all the summer from the rest of the flock, and be pretty objects on the lawn, while, at the same time, they may be doing good in keeping the grass in order, and top-dressing it.

23. THE WEANING OF CALVES, OF BULLS, AND THE GRAZING OF CATTLE TILL WINTER.

"Dissolved in pleasure, crowned with buds of May,
They, for a time, in their fat pastures play."
FLAVEL.

(1985.) The cattle which were accommodated in their respective places in the steading at the beginning of winter, continue to be treated through the spring months in the same manner as is pointed out in the 32d section, p. 495 of the first volume. In fact, their treatment is throughout the same until turned out to grass, which is usually some time in May; unless variety of food may be regarded as difference of treatment. It is found that cattle in a state of confinement in a steading, thrive better on a variety than on the same food; and yet when on grass they require no variety of food, and thrive the better the longer they are kept upon it, except that a change of pasture is desirable when it becomes bare. Grass is thus evidently the natural food of the ox, and his anatomical structure is peculiarly suited for it. Whatever kind of food he is supplied with in winter partakes of an artificial character, and that being only a succedaneum for grass when it cannot be obtained, the food he receives should be made as palatable to him as circumstances will allow, whether by variety or in in superior quality.

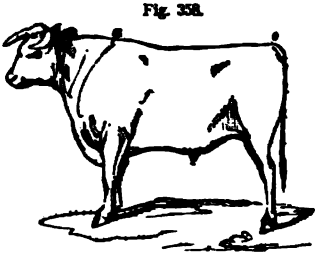
(1986.) The grass should be ready to afford a bite for cattle whenever the turnips are all exhausted; at which time the cattle will be found to be in this state: The 2-year-olds, now 3-year-olds, will be full fat, and ready to be disposed of to the butcher or dealer. The 1-year-olds and calves will have grown much to bone, and their condition will have improved in proportion to the quantity of nourishing food they have received during the feeding season. The cows will all have calved, or should all have calved, for a May calf is too late to bring up and form a part of the herd; they will be in milk, and in fresh condition to put to grass. The early calves will have just been weaned, and in excellent order to put on grass; and the remainder will be in rapid progress toward weaning. These cattle, in their respective states, are treated in summer in a different manner from each other, and different from the way they were treated in winter, and they are treated thus.

(1987.) The *fat* cattle are seldom put on grass, being disposed of to the butcher or dealer, either at home or in markets held for the purpose. Breeders of their own stock seldom dispose of their fat cattle until the turnips are nearly consumed, being anxious to keep them as long as possible for the sake of the excellent manure which the turnips afford. Those who purchase oxen to fatten usually buy a larger lot than can be maintained on full turnips till the grass is ready, in order to dispose of them before the season arrives when fat oxen are usually sold. Such fatteners of cattle dispose of their lots in whole, or in part, from the end of the year to April, whenever the market offers them the most profit. As you are supposed to breed and feed your own stock, you are supposed to retain your fat oxen to the end of May, when Swedish turnips are still fresh, sweet and nutritious, though perhaps a little shriveled and even sprouted. There are then plenty of opportunities to dispose of them, such as the weekly markets of large towns, fairs for fat stock, butchers from the neighboring towns, dealers from a distance, and shipment by sea to London, under consignment to a respectable salesman. Before disposing of your oxen, however, you should be acquainted with their weight; otherwise you will not know what to ask for them at the current market prices. Experience will teach you to estimate the weight of an ox by the eye, not the actual live-weight of the animal, but the weight of beef it will yield after deducting the weight of what is called the *offal*, that is, the weight of every part but the beef and bones, such as the skin, head, entrails, and loose tallow. It is understood that the farmer is entitled to the value of the entire weight of the beef at the current prices, and these are always understood to relate to the prices of the meat alone; and that the profit of the purchaser consists of the value of the offal, subject to the deduction of incidental expenses before the animals are slaughtered. The available parts of the offals are supposed to be equal to the value of $\frac{1}{5}$ of that of the animal, so that an ox of £20 value should leave the purchaser £4 profit, subject to incidental expenses. But if the buyer is a good judge of cattle, and knows their exact available weight of beef, which he will know to within a very small fraction, he may make such a bargain with the farmer as will not only cover his expenses, but leave a profit on the carcass over and above the value of the offals; and as dealers are constantly in practice, they generally contrive to make pretty good bargains for themselves, in as far as their judgment is concerned, at the time the bargain is made, but their purchases are subject to fluctuation of price, which may fall without an adequate cause, and occasion them serious loss; or they may rise and leave them a handsomer profit than was anticipated, so that the profession of dealers resolves itself into a speculation, which, if prolonged in its issue, is involved in uncertainty. Dealers formerly made large fortunes when breeders and feeders of stock could estimate the value of even their own stock but indifferently; but nowadays I believe few dealers make fortunes, owing partly to competition, and partly to greater skill on the part of the farmer, and partly to the great expense incurred on driving their purchases to suitable markets, and in leading a roving sort of life.

(1988.) But assistance may be afforded you in ascertaining the weight of your cattle until you are better taught by experience, and this consists in *measuring their bulk, or in weighing their live-weight.* The live-weight of cattle is easily ascertained by placing the animals upon a steel-yard, of which convenient forms have been recommended for the special purpose; but I am not aware that any of those which have been specially recommended are as accurate or convenient as might be. The rule to determine the quantity of beef by the live-weight is to multiply the gross weight by

·605 of a decimal, if the ox is ripe fat, but if not so, by ·5 of a decimal; that is to say, that the offals of an ox in ordinary condition weighs about as much as its beef and bones. An ox should not be weighed immediately after it has fed, as it will weigh too heavy, but after it has chewed the cud, and is ready again to feed. Ascertaining the weight by measurement is a more convenient method than by weighing; and when the measurement is properly taken, and the ox of an ordinary size, it is about as accurate, though every person cannot measure an ox, that process requiring judgment to do it properly and accurately. Suppose fig. 358 to represent an ox whose weight, sinking offals, is desired to be ascertained by measurement. The mode is, measure with a tape-line from the top of the shoulder *a* to the tail-head *c*, and mark this for the *length*, then measure round the body at *f*, immediately behind the shoulder, and mark this for the *girth*, and on consulting the tables calculated for the purpose of affording the results, the weight of beef will be found. Upon what principle this rule for measurement is founded I cannot say, and suspect that it is entirely empirical. The rules by which the tables are calculated seem to be these two, namely: multiply the *square* of the *girth* in *inches* by the *length* in *inches*, and divide the product by 7344, and the quotient is the weight in imperial stones. Or, square the girth in *feet* and multiply it by the length in *feet*, and multiply again by the decimal ·238, and the sum is the weight in imperial stones. For example: Suppose the girth is 7 feet, or 84 inches, and the length 5 feet, or 60 inches, the weight of beef in imperial stones, according to Strachan's Tables, which are the most recent, is 57 sts. 10 lbs. by the former rule, and by the latter it is 56 sts. 4 lbs. These results show that there is no fixed principle upon which either rule is founded.

Fig. 358.



HOW TO MEASURE A FAT OX IN ORDER TO ASCERTAIN HIS WEIGHT, SINKING THE OFFALS.

(1989.) This seems a very simple process, and so it would always be, were the form of the ox always perfect, which is very seldom the case, the fore and hind-quarters, instead of being equal, being more frequently otherwise; and were the condition always the same. Therefore, the judgment is called into exercise to make allowance for those differences. When the fore-quarter seems heavier of the two, the line should be stretched nearer the head than *a*, the exact top of the shoulder; and so in like manner, when the hind-quarter seems heavier than the fore, the line should be stretched beyond *c*. In regard to the girth, it is no uncommon fault in an ox to have the carcass gripped small behind the shoulder, so that the exact girth of such a shoulder would be below the truth. It is very rare to find the girth too much filled out. You thus see that judgment is required to apply the tape-line to an ox; and as an illustration of the practical effects of misapplying the tape-line, I may state that 1 inch only added to the girth and length given in the above example, makes a difference in the above weight of upward of 2 sts. The addition of 1 inch in the length is a mistake which may easily be made by the ox merely standing with his head down and back up; and a similar position may may as easily cause an error in the girth. Experience alone can make you proficient in measuring. I knew a steward in Berwickshire who had so much practice in measuring and so frequent opportunities of verifying his measurements, that he measured any ordinary sized ox, whether fat or half lean, from 1 st. to ½ st. of its true weight.

(1990.) To an ox from 40 to 70 stones the rule of measurement applies pretty near, if it is applied with judgment, and it is but fair to the principle that it should be so applied; but in weights both below and above these figures the rule is usually at fault. I have no instances of error in very small weights to adduce, but many of large ones, and shall adduce only two. A Short-Horn white ox belonging to Mr. Boswell of Kingcausie was exhibited at the Highland and Agricultural Society's Show at Aberdeen in October, 1834. Its measurement was 9 feet 3 inches in girth, and 6 feet 2 inches in length. According to Renton's Tables, the farmer of Dykegatehead, in Berwickshire, the weight should be 126 sts. 9 lbs.; Strachan's Tables, 124 sts. 2 lbs.; Ainslie's Tables, 122 sts.; and Stewart's Tables, 117 sts. The actual weight of beef yielded by it was 136 sts. 10 lbs., after being slaughtered by Deacon Sparks of Aberdeen, being 10 sts. 1 lb. more than the heaviest weight indicated by all these tables. This difference of weight, at 6s. per stone, would make a loss to the feeder of £3 upon a single animal! A 2-year-old light-red ox, also belonging to Mr. Boswell, and exhibited at the same time, measured 7 feet 10 inches in girth, and 5 feet in length. Stewart's Tables give a weight of 80 sts. 3 lbs.; Renton's, 73 sts. 8 lbs.; Ainslie's, 73 sts.; and Strachan's, 72 sts. The actual weight obtained by Deacon Sparks was 89 sts. 10 lbs., showing the enormous difference of 17 sts. 10 lbs. between the real weight obtained and the lowest weight indicated by Strachan's Tables, and which, estimated at 6s. per stone, would cause a loss to the feeder of £5 6s. 3d. The rule derived from live weight is also liable to err, or when applied to oxen of inordinate weights. Thus, Lord Kintore's black ox, 7 years off, exhibited on the above occasion at Aberdeen, weighed 28 cwt., or 224 stones. By the rule of multiplying the live weight by the decimal ·605, the dead weight should have been 135 sts. 7 lbs.; but when the ox was slaughtered by Mr. Roger, Crown Street, Aberdeen, his 4 quarters weighed 173 sts. 4 lbs., or 37 sts. 11 lbs. more than anticipated, which, at 6s. per stone, made him worth more by £11 6s. 8d.! On the other hand, a small spayed heifer, belonging to Mr. Boswell, weighed 88 sts. live weight, and should have yielded 53 sts. 3 lbs., but her 4 quarters only weighed 49 stones.* In consequence of such discrepancies, it would certainly be desirable were means used to render the rules of measurement, as well as of weight, more correct than they are; and I see no way of effecting this desirable end except by collecting data, by instituting a set of experiments in different parts of the country, to measure and weigh every animal before slaughtering, be it ox, sheep, or pig, be it large or small, for a given period, say 12 months, and see how far the results coincide or differ from the actual weight of meat afforded by the 4 quarters.

(1991.) The fat cattle being disposed of, the pasture should be judiciously distributed among the remaining stock; and first, as to the *cows*, they should be supplied with the best pasture, the object of keeping them being to breed calves and to afford plenty of milk to bring them up; the more milk they yield the better will the calves prove, and the more profitable they will themselves prove after the calves are weaned. Cows in summer are treated in a different manner by different people, some taking them into the byre at night, and even at all times of milking, whereas others allow them to lie out all night, and milk them in the field. Whichsoever mode is adopted, it should be kept in mind that cows are peculiarly susceptible of sudden changes of temperature, especially from heat to cold and from drouth to rain, so that whenever cold or rain, or both together, which is the most common circumstance, occur, they should be brought

* See paper by me on this subject in the Quarterly Journal of Agriculture, vol. v.

into the byre. For some time after they are put out to grass they should be brought into the byre at night, where they are milked, and again in the morning before they are let out to the field, and milked in the field at mid-day. After the nights become warm I have found it conducive to health, and it is both a rational and a natural plan to allow them to lie out in the field all night, and to milk them there at stated hours, three times every day, the shepherd or cattle-man taking it as a part of his duty to bring them to a certain spot of the field to be milked, and which is usually named the *milking loan*. This mode of allowing them to lie out always in a sheltered field, no doubt imposes a good deal of labor on the dairy-maid and her assistant in carrying the milk to the dairy after the calves have been weaned; but I am persuaded it is an excellent system for the health of the cows. Under it cows rise from their lair at daybreak and feed while the dew is still on the grass, and by the time of milking arrives, say 6 o'clock, they are already partially filled with food, and stand contented, chewing the cud, while the milking proceeds. They then roam and fill themselves, and by 9 o'clock lie down in a shady part of the field and chew their cud until milking time arrives at mid-day, when they are again brought to the loan and milked. Again they roam for food, and, when the afternoon is hot, will stand in the coolest part of the field whisking away the flies with their tail and ears. The evening milking takes place about 7, after which they feed industriously, and take up their lair about sunset, and from which they rouse themselves in the morning before being milked. Some people are apprehensive that cows must injure themselves by eating grass which is wet with dew in the morning; but it is a fact, which I believe is not so sufficiently known as it should be, that bedewed grass before sunrise, and grass after it is dried by the sun, are alike uninjurious to animals, and it is only when the dew is in the act of being evaporated, immediately after sunrise, that grass proves injurious to animals. Why it should be injurious at that particular state I do not precisely know, but imagine it to be so, because the grass then becomes suddenly cold by evaporation of the dew. When cows lie out, they have nearly filled themselves by the time the dew is evaporated, and therefore feel less impelled to eat much of the grass in the dangerous state; whereas, cows that are housed in the byre all night are usually milked about sunrise, and put out to grass just at the very time the dew on it is being evaporated, and is, of course, in the most dangerous state; and it is, moreover, just then that cows feel the greatest hunger, and eat most grass. The effect of this state of grass is to produce *hoven* (1294), and especially on aftermath in autumn. Be the cause of injury what it may, it is certain that cows let out to grass from the byre are far more liable to be affected with hoven on wet grass than those which lie out all night, and especially on new grass. The lying out at night, too, saves the trouble of providing supper for the cows, which they must have when housed in the byre. But *whenever* the weather becomes cold and wet, cows should be brought into the byre at night, and supplied with supper, such as cut aftermath or tares.

(1992.) The *weaning of calves* should not exceed one month after the cows have been on grass, that is, by the end of June, for a calf later weaned than that period has been too late brought into the world to be worthy of belonging to the standing stock of a farm. As cows increase in gift of milk after the grass has fairly passed through them, the late calves should have as large an allowance of new milk, three times a day, as the quantity obtained will allow, reserving a little for the use of the house. The elder calves are off sweet milk by the time the cows go to grass, and

have received lythax (1685) with a little skimmed milk among it, cut Swedish turnips and hay, until the grass is ready. These calves having been in the court *k*, fig. 3, Plate III. of the steading, for some time, may be put on grass when the cows are let out. The most convenient first grass field for calves is a contiguous paddock, from which they should be brought into the court for a few nights and receive turnips and hay, until the grass has safely passed through them, and the weather prove mild and dry for them to lie out all night in the paddock. The youngest calves should now leave their cribs R, and pass a few days in the court *k* until they become accustomed to the air and sun, when they also may be put into the paddock during the day, and there supplied with their diets of milk, and brought into the same court at night until they are able to lie out all night. In weaning the youngest calves, the milk should be gradually taken from them until they take with the grass, upon which they must then entirely depend. A little after all this has happened, say by the middle of July, the pasture in the paddock will become rather bare, and the whole lot of calves should then be taken to good pasture, where they will have a full bite, for nothing can be more injurious for calves than to place them on bare pasture to fall away in condition immediately after weaning, and which they will assuredly rapidly do, and from which it will be very difficult to recover them all summer. Calves may be grazed among cows, or in a field by themselves. In their peregrinations through the field, it will be found that those which have been brought up and weaned together will keep together for the greater part of the season. The older calves may be 4 months old before they are weaned; but as the season of grass approaches, the younger ones may be weaned at an earlier age, being seldom indulged with milk for more than 13 weeks, but it should never be forgotten that the first month's nourishment to a calf is of much greater importance to its future growth and health, than any period beyond 13 weeks, supported on a stinted allowance of inferior milk. There are parts of Ireland where calves are brought up on buttermilk and gruel, after the first 8 days they have received sweet milk, and it is boasted that they thrive well on that beverage. This is possible, but they will thrive far better on sweet milk.

(1993.) *Bull*-calves should have good milk every day until the grass is able to support them, in order to strengthen their bone, and maintain their condition. When a number are brought up together, they should be grazed by themselves on the best grass the farm affords, or they may go along with the cows, or they may go along with the ox-calves while the quey-calves are with the cows. Under any arrangement, they should not be allowed to accompany the quey-calves. I knew an instance of a quey-calf being stinted at so early an age as to bear a calf at 15 months old; and I knew another quey-calf, one of my own, that was so injured by a young bull-calf, that she was thereafter rendered incapable of impregnation, though her season recurred periodically. To avoid every such vexatious casualty, it is far better to keep apart young animals of different sexes that are capable of breeding. When there is only a single bull-calf he may go with the cows, or with the young oxen.

(1994.) The young 1-year-old bulls should now be furnished with a *ring* in their nose.* This instrument is useful not only in leading the animal, but being constantly in use, in keeping his temper in subjection. I have no doubt whatever that such a ring affords the most complete command over the most furious bull. In case of a bull becoming more irritative and troublesome as he advances in years, which many bulls are

* The form of this ring will hereafter be given by an engraving.

inclined to be, the ring furnishes the means of curbing him at once, when it would otherwise be impossible to get hold of his nose. It affords also an easy means of suspending a light chain from the nose to the ground, upon which the fore-feet are ready to catch the chain in walking, when the nose receives so sudden a check that whenever the bull attempts to run at any one in the field he pains himself. Even a young bull in a field may follow you at first in sport, and run at you afterward in earnest. The ring is put into a bull's nose in this way: Let a ring of iron be provided of perhaps 2½ inches in diameter over all, and ¼ inch diameter in the rod, when finished. It should have a joint in it, to let the ring open wide enough to pass one end through the nose, and the two sides of the ring, on being closed again after the operation, are kept together with two countersunk screws. An iron rod tapering to the point, and stouter than the rod of the ring, should be provided. Let a cart-rope have a noose cast firm at its middle, and put the noose over the bull's head, and slip it down his neck, with the knot undermost, till it rests upon the breast. Any mortared wall sufficiently low to allow the bull's head to reach over it will answer to put him against; or what is safer for his knees, any gateway with a stout bar of wood placed across it as high as his breast. Place the bull's breast against the wall or bar, and pass the rope from the lowest part of the neck along each side round the buttock like a breeching, and bring one end of the rope over the wall or bar on each side of the bull's head, where a stout man holds on at each end, and it is the duty of both these men to prevent the bull from retreating backward from the wall or bar. A man also stands on each side of the bull's buttock to prevent him shifting his position. The operator having the iron rod given him heated in the fire, just red enough to see the heated part in daylight, he takes the bull by the nose with his left hand and feeling inward with his fingers, past all the soft part of the nostrils, until he reaches the cartilage or septum of the nose, he keeps open the nostrils, so as on passing the hot iron through the septum it may pass clear through without touching the outer skin of the nostrils, taking care to pass the iron parallel to the front skin of the nose, otherwise the hole will be oblique. Immediately after the rod has been passed so far as to make the hole sufficiently large, and the wound has been sufficiently seared, the operator takes the ring, opened, and still keeping hold of the bull's nose with the left hand, passes it through the hole, and on bringing the two ends together, puts in the screws, and secures them firmly with a screw-driver. On being satisfied that the ring turns easily round in the hole, and hangs or projects evenly, the bull is then released. The ring, as it should appear in the nose, is represented in the portrait of the Short-Horn bull. It cannot be too highly finished or polished, and its cost in this state may be 2s. The ring should not be used until the wound of the nose is completely healed, though it is not uncommon to see the poor animal tormented, in the attempt of being led about by the ring immediately after the operation, when every part of the nose is still tender and sensitive. So alarmed do some bulls become from the operation, that they hang back from the leading rope of the ring with such force as to pull the ring through the nose; but such a use is an abuse of the rope, and rather than such a result shall occur the rope should be slackened, and the animal relieved from pain as often and until he learns to yield to the rope. The readiest and neatest way to attach a rope to a bull's ring is with a swiveled hook, retained in its place by a spring, and a rope should be kept for the purpose. On first trying to lead a bull by the ring, the drover should not endeavor to *pull* the animal along after himself, but allow him to step on while he walks by his side, or even

behind him, with the rope in his hand. While so following, to relieve the animal as much as practicable of the weight of the rope upon the nose, the drover should throw the middle of the rope upon the bull's back, and retain a hold of its end. Should he offer to step backward, a tap on the shank with a stick will prevent him; and should he attempt to run forward, a *momentary check* of the rope will slacken his pace. On no account should the drover attempt to struggle with the bull on the first occasion; on the contrary, he should soothe and pacify him, and endeavor to inspire him with confidence in himself and the rope, and to show him that he will receive no hurt if he will but walk quietly along. The animal, in the circumstances, will soon learn the nature of the tuition he is undergoing if he is properly dealt with, but if tormented merely that the drover may show his power over a powerful animal, it may be a long time, if ever, before he will learn to behave quietly when led. A useful instrument for leading a bull by occasionally, when he has not been ringed, or for leading a cow to the bull at some distance, or for taking away any single beast, and at the same time retaining a power over it, is what is named the *bullock-holder*. It consists of iron in two parts jointed, which are brought together or separated by a thumb-screw passing through them. The ends farthest from the joint terminate in a ring having an opening at its extreme side, each end of which opening is protected by a small ball. The arms of this ring embrace the septum of the nose gently between them; and the shank of the instrument being screwed close together, the balls approach no closer than just to embrace the septum, and the nose of the animal prevents them slipping out. The leading rope is attached to the jointed end of the instrument, which is formed for the purpose into a small ring.

(1995.) A bull that is serving cows is never in a better position than when attending them in the field. He knows much better than either the shepherd or the cattle-man when a cow is coming into heat, and he will attend her faithfully until the proper time of service; and I believe it is a fact, that a bull which is constantly among cows in a field never teases or abuses them so much as one that is taken to them for the occasion out of his own house. At any rate, I have seen very striking instances of what I have now stated. But a bull can only be left in the field where he is intended to serve all the cows. It may be necessary, however, in the course adopted by you for the improvement of your stock, that different bulls shall serve the cows, in which case no single bull can have access to all of them alike, and therefore cannot be grazed in the same field with them. When a bull goes among cows he is usually quite safe to approach, and is quiet within the fence; but a bull is always troublesome by himself in a paddock or field, or even among oxen. He is restless, often bellows, and few fences will retain him when he is resolved on breaking through, especially where he can snuff the cows at a distance. In such circumstances, it is much better to confine him in his hammel or byre, and support him on cut forage of some kind, such as clover, lucerne, tares, and the like. When so confined, bulls, like watch-dogs always kept on the chain, dislike the approach of any one but their keeper, and even a keeper has been known to fall a victim to resentment. Some bulls become so prone to mischief when constantly confined, that they will attempt to run on any one, when brought out of the house to serve a cow, the presence or smell of the cow in heat having so maddening an effect upon them as to render them reckless. The air and daylight together have an intoxicating effect upon them. Besides the rope or chain in the ring, a safe precaution for the keeper, in such a case, is to to have a stout stick about 6 feet long, with a swiveled hook

on its end to fasten into the ring, and with this he will not only have a better command over the ring than by the rope, but it will enable him to keep the bull off to a certain distance, the animal not being able to run at him without first giving a warning of his intention by pushing the stick. Bulls display a natural fondness for calves. Bulls that have served cows should never be allowed to herd together, as they will inevitably fight, and a serious bull-fight is a terrific thing, seldom terminating before the infliction of serious injury to both parties.

(1996.) The young cattle—the 1-year-old and 2-years-old—may be put on the inferior pasture, that is, on the second and third year's grass; inferior, not because it is insufficient to maintain the stock in full condition, but because new grass is usually considered the most nourishing on a farm for the youngest stock, and most profitable for cows when bringing up calves. Certainly it is the most succulent grass, and stock are fondest of it, and it springs the earliest of any on a farm; but then all the stock cannot have new grass at the same time, and that part of the stock which are not employed in reproduction, should receive the least valuable grazing in summer, though the entire pasture may be very good.

(1997.) Grass land requires peculiar management to render it the most available as pasture in every variety of season. The circumstances which most injure grass are *overstocking* and *continual stocking*. The most obvious plan, of course, of avoiding overstocking is to have no more stock upon the farm than its grass will in summer maintain in good condition, and to avoid continual stocking, the stock should not be allowed to remain too long on the same field. I believe the safest principle upon which each grazing field can be treated, is to stock it at once as fully as that it shall be eaten bare enough in a short time, say in a few weeks, and then it should be left unstocked altogether, *hained*, as it is technically called, for perhaps a fortnight, in order to allow the grass to grow sufficiently to afford a bite for cattle. One obvious advantage of this plan is, that the stock at periodic times during the grazing season will enjoy fresh grown grass; and another is, that the same growth of grass will not be so long depastured as either to cloy the appetite of the animals, or become foul by being constantly trodden upon. That this is a rational and natural mode of managing grass land is evinced by the fact that all stock delight in consuming fresh grown grass, and all loathe grass which has been long trampled and dunged upon, and the breath passed over it times out of number. There is another important consideration to be borne in mind in conducting the grazing of grass land, which is, the modes in which different kinds of stock crop the grass, one kind biting it close to the ground, while another bites it high. The ox gathers each mouthfull of grass with his tongue before he cuts it with his teeth, and therefore requires the grass to be some inches in length before he can obtain a full bite. Grass which is not sufficiently long for this purpose, either before it is grown, or after it has been eaten down, is in an unfit state for cattle; they may live, but cannot gain condition upon it, and as long as they are confined upon it will lose so much time. Horses and sheep, on the other hand, crop grass in quite a different way; their lips being very mobile and muscular, seize the grass firmly, while the teeth cut it over, and in doing this they bite very near the ground. This is a remarkable peculiarity in regard to the sheep, inasmuch as the arrangement of their teeth being the same as that of the ox, but wanting them in the upper jaw, one would have expected them to employ a similar mode of cropping; but the difference in the form of their lips explains the peculiarity, those of sheep being decidedly prehensile, like those of the horse, while those of the ox are thick and inac-

tive, but the ox's tongue is prehensile, and thus we see that it is the prehensile organs which are the active agents in the collection of food. And this is a wise distinction in the formation of these two classes of ruminants, in as far as it is suited to their respective natures—sheep being suited to mountainous regions, where pasture is always short, and where they are able to crop it with the assistance of their prehensile lips, notwithstanding the want of teeth in the upper jaw; whereas the ox is better suited to the plains and valleys, where grass grows long, and is therefore better suited to be cropped by the scythe-like operation of the ox's tongue and teeth. The practical conclusion to be drawn from these different distinctions in the formation of these animals is, that the horse or sheep should follow the ox in grazing, or graze in company with him, but not precede him. When they follow, the pasture will be eaten barer by the horse or sheep than when the ox left it; and, when in company, it will be eaten barer by the horse or sheep where the ox has eaten before, and it may first be topped by them before the ox has touched it. Of the two modes of treating the horse or sheep, the latter is the preferable, because choice is offered them to take the long grass as well as the short. The same reason, however, that should graze the ox *with* the horse or sheep should cause the separation of the horse *from* the sheep, and especially in the latter part of the pasture season; both kinds of animals biting close, will render the grass too bare for the maintenance of both. Horses too, work-horses especially, seem to have a greater dislike to sheep than to cattle.

(1998.) There is a difficulty attending the grazing of all kinds of stock on a farm of mixed husbandry which I must mention, that as there is every summer the same number of stock, there may not be the same quantity of grass to support them; for the same number of acres of grass, secured by following a regular rotation of crops, may produce different quantities in different seasons—one year being scanty, another superabundant. The number of stock, therefore, should correspond with the produce of an average year. In such a case, a bad year very much stints the condition, while a good year supplies perhaps even more than the same stock can consume. The stinted condition cannot be alleviated by the sale of any of the stock, as it is impolitic to disturb the equilibrium of the stock of several years' produce which exist on the farm at the same time; and if the stock suffer hunger, as it did in the severe drouth of the summer of 1826, there is no alternative but to make up the deficiency by hay, even though it should be purchased for the occasion. On the other hand, superabundance of pasture does no harm, for, independent of its maintaining the entire stock in high condition, the rough aftermath will be of essential use to sheep in winter. Of farms whose stock are purchased every year, the number can be regulated by the likelihood of the crop of grass, but even in this case the season may turn out worse than was expected. Seeing, therefore, that no one can foretell the future state of any crop, the prudent plan is, in every case, to keep the number of stock under the mark which a farm can support.

(1999.) One essential requisite in all pasture-fields is an abundant supply of *water* for stock to drink. Both cattle and horses drink largely, and sheep, grazing early on the dewy grass, do not require so much water to keep them in a healthy condition; still, when there is no dew, they do drink water. The proper construction of a watering-pool is sadly misunderstood in this country. The entrance to it generally consists of poached mud of at least half a foot in depth, and to avoid this, the animals go into the water before they drink, when, of course, it is at once rendered muddy. Not unfrequently there is scarcity of water, and if there is just sufficient sup-

ply to prevent the pool being evaporated to dryness, the water is rendered almost stagnant. So obvious are the objections to this mode of administering so necessary and wholesome a beverage to the brute creation as water, that all that seems necessary to an amendment of the system is to point out its inconveniences. True, in some cases, tanks of wood or stone are provided in fields, which are supplied from some adjoining spring, or even pump-well, and, as far as the quality of the water is concerned, this is a much better mode of supplying it than in pools; but this mode, good as it is as far as it goes, does not provide all the requisites of a good watering-pool. In hot days, a walk though a pool is very wholesome to the feet of cattle, and in dry weather, a stand for some time among water is an excellent preventive of that troublesome complaint, the foot-sore. The external application of water in this manner allays inflammation, and prevents irritation, and permits animals to take their food in peace even in scorching drouth. Besides the tank of a pump-well is not unfrequently neglected to be filled—because in cold and rainy weather it is scarcely visited by the cattle, in hot weather it is supposed to be viewed with the same indifference; and, even where tanks are duly attended to for cattle, there are none set down at a lower level for sheep. A watering-pool should be securely fenced, as cattle are very apt to push one another about while in it, and for that reason it should also be roomy. It should be of considerable length and narrow, to allow access to a number of animals at the same time, if they choose to avail themselves of it; and I have often observed cattle delight to go to the water in company. Pools are usually made too small and too confined. The access to them should be made firm with broken stones in lieu of earth, and gravel placed on its bottom keeps the water clean and sweet, while the water should flow gently through the pool.

(2000.) The want of *shade* in pasture-fields is also a sad reflection on our farmers. Observe, in summer, where the shade of a tree cast itself over the grass, how gratefully cattle resort to it, and where a spreading tree grows in a pasture-field, its stem is sure to be surrounded by cattle. The stirring breeze under such a tree is highly grateful to these creatures; and such a place affords them an excellent refuge from the attacks of flies. In cold weather, also, observe how much shelter is afforded to cattle by a single tree, and how they will crowd to the most wooded corner of a field in a rainy day, even in summer. Ought not such indications of animals teach us to afford them the treatment most congenial to their feelings? I am no advocate for hedge-row trees, even though they should cast a grateful shade into a pasture-field, and still less do I admire an umbrageous plane in the middle of a field that is occupied in course with a crop of grain or turnips; but similar effects as good as theirs may be obtained from different agencies. A shed erected at a suitable part in the line of the fence of a field, would not only afford shade in the brightest day in summer, but comfortable shelter in a rainy day, or in a cold night in autumn. Such an erection would cost little where stone and wood are plenty on an estate, and they could be erected in places to answer the purpose of a field on either side of the fence when it was in grass. But no matter what it may may cost, when the health and comfort of stock are to be maintained unimpaired by its means. The cost of a shed may, perhaps, in this way be repaid in the first year of its existence, and it would stand, with slight occasional repairs, during the currency of a long lease. When such an erection is properly constructed at first, it is surprising how many years it will continue to be useful with a little care. Let it be roomy, and its structure light, as it may be roofed at a moderate cost with zinc, or composition of

some sort, or tiles, when they are manufactured in the neighborhood. It may be troublesome to carry straw for litter from the steading to a shed situate at a distance, but there is no occasion for straw for litter in summer; the rough grass from an adjoining plantation or ditch will supply litter, and the dung at any rate should be shoveled up and carried away before it becomes uncomfortable to the animals. I should like to see a farm with such a shed erected in it for every two fields.

(2001.) The teats and udder of cows are at times subject to certain complaints in summer; and these are *chapped teats*, *sore teats*, *warty teats*, and *cow-pox*. Chapped teats consist of cracks occurring across the teats, which when drawn downward, the cracks are forcibly opened, and, of course, inflict pain on the animal: and the cows then become troublesome to milk. The easiest mode of milking them while under this complaint, is that described by nlovling in (1667), while stripping aggravates the complaint. I do not know the certain cause of this complaint, but suppose it to arise from leaving the teats in a wet state after milking; and perhaps cows lying upon wet ground may have the same effect. Sore teats are, when blotches of skin come off the teats, and their fleshy substance becomes sores by exposure to the air. This complaint may arise from the milker who strips seizing a particular part of the teat too hard, where an inflammation being set up, terminates in the sloughing of the skin, and consequent exposure of the fleshy substance to the air. Warty teats, I conceive, may originate in the skin of the teats being ruffled by too much force in stripping, or by too long a nail upon the thumbs; and the warts produced in consequence may be exuberances of the skin in covering the injured parts. I am not sure that these conjectures, for they are nothing more, will explain the causes of these complaints, but I believe when care is used not to abrade the skin or pinch the substance of the teat, but to keep it clean and dry, these complaints seldom or never occur. As to the cow-pox, it is a constitutional disease, and cannot be either induced or retarded. The pock makes its appearance both on the udder and the teats of the cow; and as milking must be performed frequently by all the teats, the operation feels very painful to the cow and she of course, becomes very troublesome to milk. Very soon the pustules are rubbed off by the operation, and their sites become skinless sores. Nothing but the utmost gentleness will prevent the cow becoming distracted under the torture. After having run its course, the disease declines, the sores become less acute, and heal up by degrees. The disease fortunately is not of frequent occurrence; I have only seen it once in the course of a fifteen years' experience, and it affected all the cows I had at one time—9 in number. I acquainted several of my medical friends of the existence of a disease, imagining that they would have been glad of so favorable an opportunity of obtaining fresh vaccinating matter, but they treated the offer with indifference. There was an ointment I found very efficacious in affording relief to the cows when afflicted with the cow-pox, sore teats, or hacked teats. It consisted of fresh butter melted and burnt in a frying-pan, and mixed with half its quantity of tar. While hot it was poured into a gallipot, and applied cold to the affected parts. The tar had the effect of keeping off the flies, while the burnt butter never became dry. The ointment was washed off with warm water before milking commenced, and the udder and teats dried with a soft linen cloth; they were again bathed with warm water after milking, again dried with the soft linen cloth, and the ointment again applied. Calves, after being weaned, are subject, toward the end of summer, to a disease commonly called the *joint-fellon*, which, when oxen take it upon the loins, is named the *chine-fellon*. It is nothing else than acute rheumatism, ending in a resolution to low fever, and so severe is it at times upon calves, that they cannot bear to be moved when lying stretched out all their length upon the ground. Had cattle sheds to retire to whenever a cold dash of rain came in the evening of a cold day, even in summer, this disease would perhaps never occur. Its treatment is removal to the courts and sheds of the steading among straw, bleeding, moderate purging, with fomentation, and embrocations of liquid blister, forcibly and long rubbed in, of the swelled joints. Another effect of the same feeble affection on calves in autumn is the *quarter ill or evil*. "Its characteristic symptoms are general disturbance of the circulation, and feeble, rapid pulse, weakness, prostration of strength, determination of blood to particular, but in different instances and epidemics, very different parts, producing pain, and manifesting a tendency to inflammation, but of a degenerate kind, so that the very texture of the tissue becomes disorganized. The progress of the disease is often rapid, and the result very fatal. In some cases the lungs or heart are attacked, and in others the liver, bowels, or even some external part of the body." Its immediate cause is plethora, or fullness of blood in the system, which shows its effects in this manner: "When the supply of food is greater than the exigencies of the system requires," as Professor Dick observes, "an animal usually becomes fat, but still may be tolerably healthy. When, however, a sudden change is made from poor to rich feeding, not fatness but plethora may be the consequence; more blood is formed than the system can easily dispose of, and it becomes oppressed. The effect is often witnessed in cattle and sheep, which, after indulging for a time in luxuriant pasture, take what is called a *shot of blood*. All at once they become very ill; some part of the body swells, becomes puffy, as if containing air, and in two or three hours the animal is dead, from the *quarter evil* already described. Upon dissection a large quantity of black and decomposed blood is found in the cellular membrane, which during life was distended."* This disease is of frequent occurrence on farms where fine stock are bred, and from the above description of its nature, there is no wonder that the best calves first fall victims to it. As its name implies, the disease attacks the hind quarter, and its effects are as sudden as described. Since its cause is known, calves should not be put at once on strong foggage from a comparatively bare pasture, nor, for the same reason, should calves in low condition be put on rank foggage; the transition, both as regards the pasture and the state of the calves, should be gradual. As a preventive, some

* Dick's Manual of Veterinary Science.

farmers introduce a seton into the dewlap of all their calves before putting them on foggage in autumn. The use of the seton is to produce counter-irritation. The seton consists of a piece of tape or soft cord passed under a portion of the skin by a seton-needle; the ends may be tied together, and the cord may be moved every other day from side to side, being previously lubricated with oil of turpentine or blister-plaster, and in this way the amount of irritation may be regulated. As to the cure, I believe every one is unavailing after the disease *has been observed to exist*; but as a remedial measure applied by anticipation, large blood-letting with purging of repeated doses will reduce the plethoric tendency of the animal system. Perhaps a cribfull of hay, with some salt, placed in a foggage field, would not be a bad alternative for calves to resort to at times, in order to modify the effects of the succulence of rank aftermath.

24. MARES FOALING, OF STALLIONS, AND OF HORSES AT GRASS.

"Yet when from plow or lumbering cart set free,
They taste awhile the sweets of liberty:
E'en sober Dobbin lifts his clumsy heel
And kicks, disdainful of the dirty wheel"
BLOOMFIELD.

(2002.) Whenever field-labor commences in spring, whether with bean or oat-seed, draught-horses are indulged with hay instead of straw, and their allowance of corn is increased. The hay is supplied to them at will, and a strong work-horse is supposed to eat about 1½ stones, or 33 lbs. a-day, and some will eat even more. The oats are increased to 3 feeds a-day, which at 40 lbs. the bushel, will weigh 7½ lbs., but if the measure is heaped, which some farmers will allow to be done with horse-corn, the feeds will weigh 8 lbs. The quantities of hay and corn here specified are supposed to be given in their ordinary state, but when given in a cooked state, I have already described their treatment in (1351) to (1353) inclusive.

(2003.) The *hay-stack* is seldom broken upon until the horses get hay in spring. Its site in the stack-yard is marked by an *n* in Plate IV., fig. 4, of the steading, and the hay-house is contiguous to it at H, the apartment which also contains the corn-chest *y*, and the whole adjoins the work-horse stable O. When the hay is to be used, as much of the stack is brought in as will fill the hay-house, and thence distributed to the horses. Every portion cut off the length of the stack should be 4 or 5 feet, and they are cut off with a *hay-knife*, fig. 360, which represents the usual form of that instrument. It will be observed in the figure, that the line of the back of the blade is not so much as at right angles to the handle, a position which gives the cutting edge of the knife an inclination to the line of section, which, when the knife is used alternately up and down in a perpendicular motion with both hands, causes it to cut a longer space than the breadth of the blade. The person who uses the knife, usually the steward, while it is the field-workers who carry the hay and fill the hay-house, sets himself on his knees upon the part he is cutting off, with his face to the body of the stack. This form of knife requires considerable strength in its use, and unless the edge is kept remarkably keen with a whet-stone, and the hay is firm, it does not make good work. The hay-knife I prefer is of the form of the dung-spade in fig. 308, which, being used when standing, can be wielded with more force and make a deeper cut; and it cuts equally well in both directions, whereas the common knife cuts only in one direction—to the right.

Fig. 360.

THE HAY-KNIFE.

(2004.) There is considerable waste of hay as it is commonly used in hay-racks *i*, fig. 7. The plowmen staff the rack not only full, but squeeze the hay firm, from a mistaken notion that they cannot give too much at a time to their horses; but when horses find it in this compressed state, and are unable to select the morsels they want, they toss out a considerable quantity among the litter, with which, after being trampled upon, and refused to be eaten, it is thrown into the dung-yard. True, the cattle there will eat it, and prefer it much to straw, because of its being hay and having a saline taste, so that it cannot be said to be entirely lost, yet the object of supplying the horses only upon hay is frustrated. If it is desired to give hay to cattle also, it should be given them in a direct manner. To avoid waste, therefore, small quantities should be put into the racks at a time, and these frequently; but the best way to prevent waste is to chop the hay and bruise the corn, and the mixture will also go a greater length in feeding the horses. Young horses should also receive hay after the stuck has been broken up, straw becoming too hard and dry after March; and hay, besides, serves to improve their condition, and prepare them for grass. They should also get a little corn every day, until grass time, as nothing tends so much to enlarge and strengthen the bone, and confirm the spirit of young horses as corn. So much am I convinced of the truth of such a result, that I entirely agree with the observation of the late celebrated Nimrod (Mr. Apperley), that the belly of the young horse should be the measure of his corn. It is to the niggardly disposition, in regard to corn, which farmers evince toward their young horses, that is to be ascribed the number of weak horses that are met with on farms; for the greatest abundance of corn administered to the adult state, will never compensate for its want when the animal was in the state of adolescence.

(2005.) May is the particular month in which *draught-mares* usually *drop their foals*. They continue to work until the immediate symptoms of foaling are observed. These are great loosening of the ligatures on each side of the root of the tail, and the appearance of a waxy-like matter projecting from the point of the teats. As it is impossible to predict a mare's foaling within a few hours, it is proper to put her into a loose-house or a box by herself, and to watch her every night. Too many farmers contemn such precautions, and allow their mares to foal in their stall in the stable, to the risk of having both them and their foals kicked by the other horses. That watching is necessary at night, even in a loose house, is evinced by a fact mentioned to me by the late Mr. Airth, Mains of Dun, Forfarshire, of a mare of his which, having been neglected to be watched at night, or even removed from the stable, was found in the morning lying on the floor with her womb protruded and the foal smothered in it. The mare shortly after died in great agony. It is a remarkable fact that few people have observed mares to foal, even though watching for the purpose, for somehow they contrive to foal when left by themselves for even a few moments. I have endeavored for successive years to witness the foaling both of blood and draught-mares, and was always disappointed. A mare will eat with heartiness until the pains of labor seize her, when she suddenly lies down, foals easily, quickly, forcibly, requiring no assistance, and starts to her feet almost immediately after parturition, takes up with, though licks but little at her foal, and soon begins to eat again. The foal is not long of gaining its feet after a few staggering attempts on its long legs, but some time elapses before it can steady itself, so as to lay hold of the teat. It should be assisted in this its first attempt, in order to get filled with milk, after which it may lie and sleep among straw until it becomes dry. The placenta soon drops from the mare, and should be imme-

diately removed. The thin pellicle which covers the foal is, when dried, very like the finest gut-skin used by gold-beaters, and it forms a very good protection from the air when applied as a plaster over the surface of a green wound. The mare should have a drink of lukewarm water and oatmeal, and a few handsfull of corn, after parturition, and, on partaking of which, she may be left with the foal. For the sake of increasing her milk she should be put to grass immediately after foaling, if she is not on grass, and should remain there without being put to work for a month; by which time she will have recovered her tone of body sufficiently to bear again the fatigue of labor. The sort of work for a mare having a foal should be of a nature to interfere but slightly with the more important operations of the farm; because having to suckle the foal every half yoking, she should be employed singly, such as at sowing and scuffling turnips, scuffling potatoes, and leading grass or other forage. When the mare is again made to work, the foal should be left by itself to rest in a well-littered apartment of the steading until it become accustomed to be alone, rather than in a court or hammel, out of which it may attempt to escape and injure itself. Should there be two mares with foals, both should be worked together; the treatment of both being alike, little inconvenience will arise to work, from being taken to their foals out of yoke together (3141). A stout mare will be able to perform her own share of summer work, and bring up a foal at the same time; but should she be in a weakly state, which she will be when becoming old, or is overworked, she should be put either to very gentle work, or to work only in half yokings, or one yoking a day, or be idle altogether and constantly with her foal. She should not be neglected of corn, however, though idle at grass with her foal. It is seldom that any illness attacks a draught-mare while bringing up a foal, and it is as seldom that anything is the matter with a foal. I had one work-foal, however, which, though safely and easily foaled, and seemed lively enough, could never stand upon its feet, or lay hold of a teat, and it died in the course of a day after it was foaled, though fed on cow's milk. A mare when thus deprived of her foal, should be occasionally milked, and kept on dry food for a few days, until the tendency of the milk to secrete subsides. The mare will be ready to receive the horse in 3 weeks, or a month at farthest, after parturition, and the first symptom of heat is frequent twitching of the vulva, and emission of a clear fluid. When a mare is touched in this state, she immediately presses toward the object that touches her.

(2006.) In presenting a mare to the stallion, caution should be used to prevent her striking him with her heels when she refuses his attentions; and this consists simply in holding her by the head with a bridle across the outside of the stable door, while the stallion is kept within, and allowed to snuff and pinch her flank. If she takes the teasing kindly, presses closer toward him, twitches the vulva, and emits, she is in proper heat, but if she squeal and kick whenever he touches her, she is in an unfit state for him; but the tickling of the horse for a time not unfrequently confirms the season of the mare when it at first evinces a doubtful issue. If in season, she should be taken to an open piece of level ground, and held by the head as long as the horse covers her, and the time occupied by a stallion in covering is much longer than by the bull or tup, which is instantaneous. A horse which is safe to use requires no encouragement from his leader, but many need some assistance from him. Making a mare stand to the horse by a twitch on her nose is an unnecessary act of cruelty; for if she will not voluntarily receive him she will not become impregnated by any *force* that can be used against her. One cover is quite

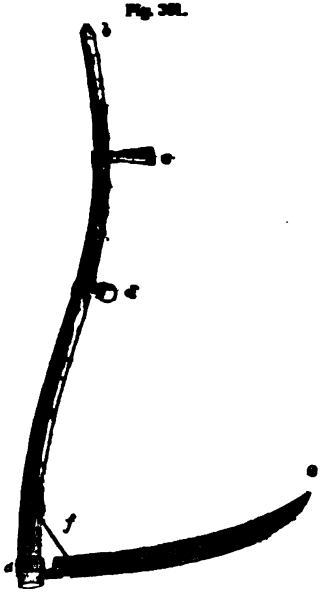
sufficient at a time. In about 3 weeks it will be seen whether the mare has held to the horse; and should she again exhibit symptoms of season, simple and safe expedients may be used to secure her holding, such as throwing a bucket of cold water upon her rump the moment the horse leaves her, or drawing blood from her neck vein while the horse is covering, or, what is better than all, unless the season is going rapidly off her, retaining the horse all night and offering her a fresh cover in the morning, or, to adopt a different plan altogether, covering her with another horse, or another kind of horse—one or other of which expedients generally secures the holding, unless the mare is past bearing, which casualty befalls mares at very different ages. I was told by a man who led stallions for many years, that the expression of a sigh, from both horse and mare, immediately after an embrace, is an infallible sign of the mare proving in foal. The circumstances which militate against a mare's holding in foal is too high and too low condition. Whenever a mare is seen to eject semen as soon as the horse has left her, she will certainly not hold. Sometimes the fault is as much that of the horse as the mare, for when subjected to much traveling, and is, moreover, not a good traveler, and has undertaken more service than he can easily overtake, he is often so much fatigued when brought to a mare, especially toward evening, as to be quite unfit for effective service. When a horse is observed to be in a state of lassitude, the very best policy for the farmer is to give the horse and his leader a night's quarters, and let him cover the mare in the morning when he is comparatively fresh. Many farmers grudge maintaining a horse and man all night, but much better incur that small expense than run the risk of a mare proving barren. When a mare has been covered 3 separate periods without success, it is needless to persevere with her, as the foal will come too late next season, and a late foal is as objectionable stock to bring up as a late calf.

(2007.) The usual treatment of *draught-horses* in summer is to allow them to lie out in the pasture-field all night, and give them cut grass between the yokings in the stable. Forage is supplied them, because the time between the yokings is too short to fill themselves with grass on pasture; but on the Borders, where the first yoking is over by 9 or 10 o'clock in the forenoon, the horses are put into the pasture-field until the afternoon yoking at 1 o'clock; and this plan saves all the trouble of cutting grass for the horses. The piece of grass allotted to horses is cut by the plowmen, who each take the duty for a week by turns, and he quits the yoking in time to allow him to cut the requisite quantity and cart it to the stable. It is not his duty to supply the racks in the stable, except his own horse's, but to empty the load of grass on some convenient spot near the stable door—a dirty and slovenly practice. No doubt it is better to keep the fresh cut grass in the open air than to put it into a house; but still a crib or inclosure could be made in a shady place conveniently near the stable, to keep the grass fresh, and place it off the dirty ground.

(2008.) Grass is cut with the common scythe, which is so well known an implement that a particular description of it seems unnecessary. A few words, however, on the *choice of scythes* and of the *manner of mounting them*, may be useful to you. The handle, or *snead* or *sneath*, fig. 361, *a b*, is made either curved to suit the sweep of the instrument by the hands round the body, as in the figure, or straight, and the suitableness of both for work you shall learn when we come to consider harvest-work. The curved snead is usually made of willow, which, being shaped in hot water, and restrained, on being released when the wood becomes cold, retains the shape. Of scythes there are various kinds: the *common* kind keeps

its edge but a short time, and in the long run is, I believe, more expensive than the *patent* kind, which consists of a steel plate riveted between 2 small rods of iron, and which plate will continue to cut keenly until it is worn to the back-bone. The length of the blade of scythes varies from 28 inches to 46 inches, and the price of the common kind varies between these lengths from 2s. 4d to 3s. 3d. each, and the patent from 3s. 2d. to 4s. 8d. each. There are besides these, other kinds termed *crown*, *labeled*, and *extra-warranted* scythes. Bent sneads cost from 1s. 3d. to 1s. 6d. each, straight ones 1s. each. The straight are made of any sort of wood; I have seen good ones of larch. Scythes are sharpened with *strickles* and *stones*. The strickles are made of fine sand imbedded in an adhesive medium laid over the surface of a piece of wood of square or flat shape, and cost 6d. each. They are used to smooth the edge after the stone, and serve of themselves, for a time, to keep the edge keen; and they are always attached to and carried along the upper end of the snead at *d*, by a T headed nail and spike. Scythe-stones are either square or round, are formed of the same sandstone as grind-stones, and cost 4d. each. They are only occasionally used to set a new edge on the blade. Ragstones cost 4d. per lb. The blade of a scythe is mounted in this manner: the snead is furnished with an iron ring at the end, to which the blade is attached; the projecting hook at the butt-end of the blade is imbedded flush into the snead by taking away a portion of the wood, and the ring is then slipped over the imbedded hook, and is held tight in its position by an iron wedge as at *a*. The peculiar position which the blade bears to the snead is determined by measuring the length of the blade *a c* straight along the snead from *a* to *d*, where is fastened the handle for the right hand, and the same length from *d* to *c* fixes the point of the scythe, so that *a d c* forms an equilateral triangle; and of course the blade stands at an angle of 60° with the snead. Theory would advise the placing of the *plane of the blade* parallel with the ground, when the scythe is held as intended for cutting; but practice requires the cutting edge to be a little elevated above the ground, and above the back of the scythe which sweeps along the surface of the ground; and the reason for keeping the edge elevated is, that it would not only be apt to run into the ground if swung parallel with it, but the scythe would be worked with greater labor, as the stems of the plants to be cut would present an obstacle directly at right angles against the blade, whereas the edge set upward cuts the stems in an oblique direction. The blade is still farther secured in its position by the grass-nail *f*, which is hooked by one end into a hole in the blade, and is nailed through an eye by the other to the snead; and a great use of the grass-nail is to prevent any plants cut from being entangled between the blade and snead. The left-hand handle *e* is placed to suit the convenience of the workman. I shall reserve remarks on the mode of using and sharpening the scythe until we treat of harvest-work.

Fig. 381.



THE PATENT SCYTHE WITH BENT SNEAD.

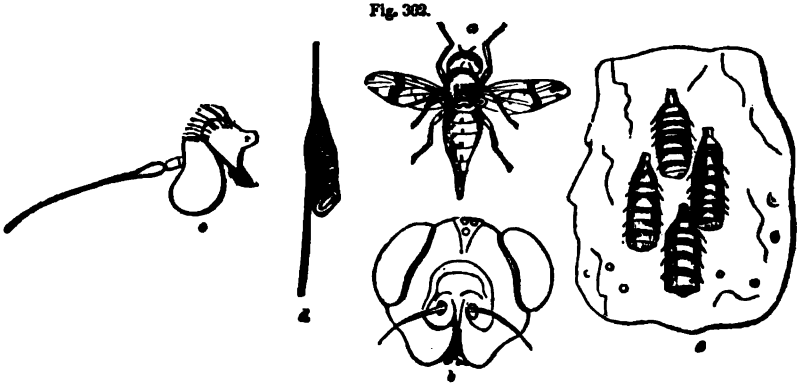
(2009.) Objections have been made to pasturing grass at all by any species of stock, inasmuch as the same extent of land will maintain a greater number of animals when cut and given them in houses or yards. To express this proposition shortly, *soiling* is a more profitable and less wasteful mode of using grass than pasturing. Although there is much truth in the observation, it is too generally expressed to be true in all cases. In the case of mountain-grass it is evidently an impracticable proposition to use it by soiling. Much cattle and sheep must, therefore, be allowed to pasture; and with regard to much of the old grass of the low country a great part of the summer would elapse before it would be fit for the operation of the scythe. What is to become of stock in the mean time? The only other grasses left are the cultivated kinds, such as clover and rye-grass, and that from irrigated meadows. Of these two kinds it is quite possible to procure a supply of cut grass from water-meadows by the time the Swedish turnips are exhausted in the beginning of June; but the cultivated grasses are not fit for cutting by that time except in the neighborhood of large towns. What, again, is to become of stock in the mean time? Some other plants than clover and rye-grass must be cultivated to support the stock till that period; perhaps lucerne and Italian rye-grass might be cultivated for the purpose, but both cannot be cultivated everywhere, for lucerne will not thrive in Scotland, and before either could be cultivated anywhere for an extensive system of soiling, a different system of husbandry will have to be contrived, and a system to produce early forage in a late climate will not be easily discovered. In regard to the comparative extent of a ground required for soiling and pasturage, it has been alleged to be 3 to 1 in favor of soiling; that is, 33 head of cattle were soiled from 20th May to the 1st of October, 1815, on 17½ English acres, and which number of cattle, it was said, would have required 50 acres to pasture them.* On the face of this statement I would say, that any 33 head of cattle that could be maintained on 17½ acres of cutting grass, would as easily be maintained on the same land on 33 acres of pasture—1 acre of pasture to an ordinary sized ox being quite sufficient to maintain it from May to October. So that the proportion is reduced from 2 to 1, which I believe is near the truth in regard to the maintenance of oxen. In regard to work-horses, it is different, for they will certainly require a much greater extent of ground in cutting grass than in pasture. To cut grass, however, for all the cattle on a large farm, to lead it to the steading, and to supply them with sufficient litter in summer, is what I consider an impracticable thing, were it for no other reason than that the crop of grain on any farm that admits of its grass being pastured cannot afford sufficient straw to litter stock the whole year; and if sheep are to be included in the soiling system, where is the steading that could afford them accommodation? Nor is the objection against grazing of the manure of animals being entirely lost, altogether valid, because land that is constantly grazed will support stock to an indefinite time; whereas where grass is cut and carried off every year, the time will soon arrive when the grass can no longer be cut until manure be applied to the ground. Does not this circumstance of itself show that the dung dropped on pasture is not entirely lost, and that the land derives considerable advantage from being pastured? I have often thought that all the work-horses on a farm might be supported in the steading night and day upon cut grass. I have tried the experiment twice myself, but failed in both cases, at one time for want of cutting grass, the second cutting having entirely failed that year, and the other for want of straw for litter until the arrival of the new crop.

* See Sinclair's Code of Agriculture, and Notes.

The straw might have been economized in the stable, but the stable in summer, even with open doors, ventilators, and no hay-loft, is insufferable; and the horses required far more straw to keep them dry in the hammel on cut grass than they did on straw and corn in the stable in winter. Taking all these untoward circumstances into consideration, they led to the conviction that soiling on a large scale is impracticable; and until early growth of grass, as well as a late growth of aftermath, and plenty of straw, are assured to the farmer every year, I cannot see how soiling can be established as a regular practice in husbandry on a farm of even moderate extent. On a small scale where only a few animals of every kind are kept, I conceive that soiling might be practiced with advantage, and it behooves all small farmers to make their grass land go as far as possible.

(2010.) Work-horses, when on grass, are subject to few distempers, the principal being annoyance from a host of insects, and among these the common horse-fly or cleg, and the bot-fly, are the most troublesome. The cleg delights in warm and sultry weather; is most active on the wing during the day, and therefore most troublesome to horses and cattle when they stand most in need of repose. They are particularly excited and eager for blood when the atmosphere is in a warm and humid state, such as it usually is after a thunder shower; and it is this circumstance which has obtained the specific name of *pluvialis* for the cleg. Another pest to the horse is the great spotted horse-bot, *Gasterophilus equi*, seen at *a*, fig. 362. It is about 7 lines in length;

Fig. 362.



THE HORSE-BOT—GASTEROPHILUS EQUI.

general color clear yellowish-brown; thorax inclining to gray; abdomen rust-brown, with a tinge of yellow; wings whitish; and legs yellowish. The antennæ are inserted in the cavity of the face, as seen at *b*, the second joint large and kidney-shaped, the remaining three forming a naked bristle as at *c*. The eyes are equally distant in both sexes; mouth either entirely wanting, or consisting merely of an indistinct line or opening. This insect takes no nourishment of any kind; in fact, the alimentary canal has no opening at its anterior extremity. It flies in company, producing a humming sound. "The female having selected the individual to which her treasure is to be intrusted," says Mr. Duncan, "she continues to hover about for a short time till the egg be propelled through the oviduct, and placed in the pincers at the extremity of the anal tube. Thus prepared, she makes a sudden descent upon the horse—her body carried nearly in a perpendicular direction, and the ovipositor curved forward—and deposits the egg upon a hair, to which it instantly adheres by means of a glutinous matter secreted along with it. This process, which is performed with so much expedition that the fly can scarcely be said to alight on the horse, is repeated at intervals till the whole of the mature eggs are discharged." These eggs, which are very numerous, 400 or 500 being sometimes placed on a single hair, are somewhat pouch shaped, and shagreened with transverse and longitudinal striæ, as seen at *d*. Under the guidance of an instinct which cannot be sufficiently admired, the fly almost invariably attaches her eggs to some part of the fore quarter of the horse, the inside of the knee and the shoulder being the spots most commonly selected, so as to be within the reach of his mouth, for he is himself to be made the unconscious instrument of conveying them into his stomach, where alone they can be brought to maturity, the temperature of a horse's stomach being as high as 102° Fahrenheit. Even when beyond the reach of the mouth, the eggs are not necessarily lost, for the horses are in the habit of licking each other, and a horse free from bots may thus receive them from another. "When the eggs are mature," continues Mr. Duncan, "it would seem that the larvæ make their appearance very soon after they are touched by the tongue, the warmth and the moisture both contributing to their immediate development. Indeed, if the larvæ were not disclosed before reaching the stomach, or very shortly after, the eggs would very soon pass into the alimentary canal. The larvæ fix themselves by hooks to the inner tissue of the stomach, where they remain in security, uninjured by the powerful action of the gastric juice, and enjoying the warmth of a

tropical climate." A small group of these larvæ adhering to the coat of the stomach are represented by *e*. Their color is pale reddish yellow. Their only food seems to be the humor secreted by the internal membrane of the stomach, or it may be the chyme, the latter undergoing a further elaboration to adapt it to their system. Bots take up their quarters in the stomach in the end of summer or autumn, and pass the whole winter and spring months there, without undergoing any change, save gradually enlarging and advancing to maturity. When that is complete, they cease to retain their hold, pass into the intestinal canal, and are ejected by the anus. On account of the many ordeals which this insect has to pass in its transformation, perhaps not 1 in 100 of the eggs ever arrive at the perfect state of fly. The red-tailed horse-bot, *Gasterophilus hæmorrhoidalis*, though only half the size of the preceding, is nevertheless a greater torment to the horse. The female parent fly deposits her eggs on the lips of the horse, and this operation is attended with so much pain, that no sooner does it make him aware of the presence of the fly, than he tosses his head and gallops off to a different part of the field, or, if he has the opportunity, betakes himself to the water, where his tormentor generally leaves him, having a peculiar dislike to that element. Indeed all the tribe of gad-flies have, and, to avoid them, it is not uncommon to see numbers of cattle lying on the sea-shore until the approach of tide alone compels them to retire. When this fly succeeds in fixing an egg, the horse rubs his mouth against the ground or upon his fore-legs in great agitation, frequently striking out with his fore-foot, which occasionally comes in contact with the jaw, and serves but to increase his irritation. The larvæ are taken into the stomach, and fix themselves there, exactly in the same manner as the greater bot. When they reach the intestines, they remain a long time, casting anchor again in the rectum, where they cause great uneasiness to the horse, causing him to kick frequently, and even rendering his movements awkward. These bots should occasionally be looked for in horses that have been out at grass the *preceding* year, at the extremity of the anus. The only speedy remedy for getting quit of them is in back-raking by the anus. The more rare species are the *Gasterophilus nasalis*, *salutiferus*, and *Clarkii*. Mr. Bracey Clark was of opinion that the presence of bots in no way injured the horse, but on the contrary, by stimulating the stomach, they tend to prevent colic, gripes, and other indigestions which affect the head of the horse and produce staggers. "The appearance of exanthemous eruptions on the skin," he says, "and the formation of local abscesses, from the same cause of partial irritation, often relieve a general disorder of the system. The mucous membranes of the skin possess this power, when irritated, in the most eminent degree, and to these the larvæ of the *Œstri* are applied. Irritating the membranes of the stomach in other animals would excite nausea and vomiting; but the horse not possessing this power, his stomach is peculiarly fitted for the stimulus of such animals."* An annoying insect of less importance is the *Chrysops cæcutiens*, which is of a bright color, and though frequent in some parts of England, is not so great a pest there as to horses on the Continent. Another fly, the *Stomoxydæ calcitirans*, is in size and markings not unlike the common house-fly, *Musca domestica*. This insect attacks various animals, as well as man himself, and becomes very troublesome in certain localities. It attacks the legs, and its punctures are attended with great pain, especially in damp, moist weather. Another annoyance to horses is the forest-fly, *Hippobosca equina*. "The attacks of this insect," says Mr. Duncan, "are principally confined to horses. It occasions no other harm than an extreme degree of irritation, and if the flies are numerous, the animal is apt to become unmanageable. It insinuates itself by a sideling, crab-like motion beneath the hair, and anchors itself to the skin by means of its largely-toothed claws. It also runs about among the roots of the hairs with great ease, creating an insufferable titillation, which is still more increased by the frequent insertion of its proboscis into the pores of the skin. The places to which it prefers attaching itself are the under side of the belly, beneath the tail, and on the under side of the jaws. The insect is so flat, tough, and unyielding, that it is by no means easy to kill it by pressure, and it is, moreover, tenacious of life. It is said that horses long accustomed to its attacks become, in some measure, indifferent to them; those which have never experienced this plague, which is enough to render some animals almost frantic, may be saved from it, according to M. Köllar, by the following application. Take of mineral earth 8 oz. and of lard 1 lb., and make them into a salve. Some of this salve is to be rubbed on here and there upon the hair, and worked in with a wisp of straw. After 24 hours the salve is to be washed off with warm water, in which brown soap has been dissolved. Care must be taken that the horse does not catch cold."

---

25. SHEEP-WASHING, SHEEP-SHEARING, AND THE WEANING OF LAMBS.

"Gay shearing time approaches. First, howe'er,
Drive to the double fold, upon the brim
Of a clear river—gently drive the flock—
And plunge them one by one into the flood."
DYER.

(2011.) I have said that as lambs become strong enough to be put to pasture, they always get new grass, in order to increase the milk of the

* Clark's Essay on Bots.

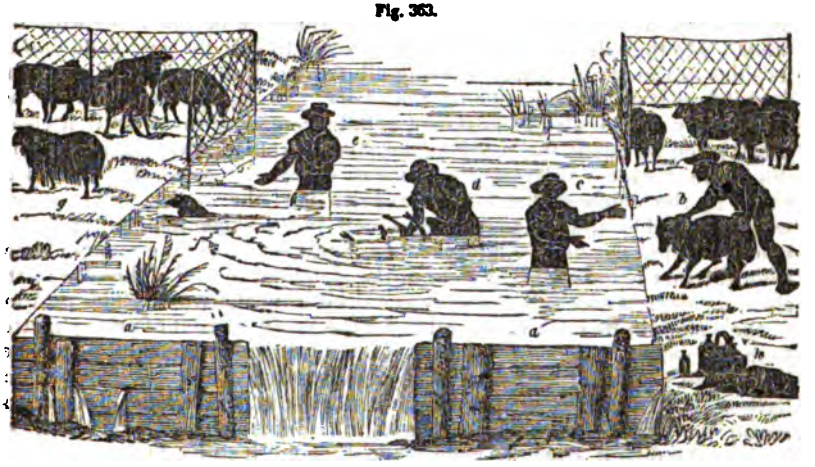
ewes (1835). The new grass, to be pastured by ewes and lambs, should be selected with judgment, and that intended for hay should first be stocked, because it is found that new grass, if moderately eaten down in spring, stools out, and affords a thicker cutting at hay-time, than if it had not been so pastured. For the same reason, the new grass intended to cut for horses' forage, should also be earlier pastured than what is to be pastured all the season, not only to give both it and the hay-grass time to attain their growth when they shall be wanted, but to give the pasture-grass time to become so strong as to support being pastured. None of the new grass should be eaten too bare, even the part which is to be pastured by the ewes; and rather than commit such a mistake, even in a late season, the ewes should have a hasty run over the best of the older grass for a fortnight or so, till the hained new grass has revived. After the castration of the lambs (1841), there is nothing to do to them until the ewes are washed preparatory to shearing the wool for them, and which is done about the beginning of June (1843).

(2012.) When the turnips are all consumed, and the time has arrived for the last of the turnip land to be plowed up for barley (1852), the *hoggs* receive a change of treatment. The *wether*-hoggs are either sold to the dealer of the turnips, or put to grass till shorn of their wool, and then disposed of; but the *ewe*-hoggs are always retained on the farm, because it is they which supply the waste of ewes, and are, of course, clipped of their wool in due time. The circumstance that determines which of these ways the *wether*-hoggs should be treated, is the state of the wool and mutton markets. If you find, on examination, that the hoggs are so forward in condition as to realize as much money off the turnips, with current prices, as they probably would after being kept for a month on grass, and washed and clipped, it is, of course, more profitable to dispose of them at once; and, independent of this circumstance, should you fear the grass to prove insufficient to support them well till they are clipped, there is a necessity for parting with them immediately off the turnips; but should you find that you have grass to maintain their condition, and that the wool market is likely to be brisk, it would, of course, be advisable to clip them. It is of less importance to *increase* the condition of the *ewe*-hoggs off the turnips by putting them on the best grass, nevertheless they should not be allowed to *fall off* in condition, for fear of injuring the quality of their wool. If you determine on selling the wether-hoggs, you should first ascertain their value; and in attempting this you will at once perceive, that a sheep wearing its coat of wool cannot be subjected to the ordinary rules of measurement; nor can its true weight be found by weighing it alive, because the weight of the wool enters as a disturbing element into the calculation, and the value of that material depends on very different circumstances from that of mutton. A new clipped sheep, however, may either be measured or weighed, and its value ascertained pretty nearly.—The eye and the hand must be employed to judge of the weight of a rough sheep; and there is no more certain way of acquiring a correct judgment of its weight in that state, than by first handling the sheep in the way I have before described, and weighing the 4 quarters after it is slaughtered. An average sized sheep of a large flock thus treated will enable you to form a pretty correct idea of the average weight of the whole, and the market price of mutton per stone is quoted in all the newspapers of the day.

(2013.) The season for *washing* sheep having arrived, a fit place should be selected for the purpose. It should consist of a natural rivulet, or, where that is wanting, of a large ditch, having both its banks clad with

clean sward. The next step is to form a damming across the rivulet, if it is not naturally sufficiently deep of water to conduct the operation of washing. The bottom of the river or ditch should be hard and gravelly, and the water in it pure, or it will not answer the purpose; as a soft and muddy bottom, and dirty water, will injure the wool more than do it good. A damming may be made either entirely of turf-wall built across the stream, though that imposes considerable labor and waste of grass, or with an old door or two or other boarding placed across the bed of the stream, supported by stabs against the weight of water, and the chinks at the bottom and sides filled up with turf; and over which, when the water accumulates, the water falls. In constructing this dam, the overflowing should be as great as to cause such a current in the pool as to carry away quickly all impurities, such as earthy matter, greasy matter, small locks of wool, and scum. One side of the pool is occupied by the unwashed, and the opposite by the washed sheep. They are confined in their respective places by flakes, fig. 216, or nets, fig. 217. To prevent any sheep taking the water of themselves, which they are apt to do when they see others in before them, the fence should be returned along the sides of the pool as far as the men who wash the sheep are stationed. Fig. 363 brings out all these

Fig. 363.



SHEEP-WASHING.

particulars pretty well. The damming *a a*, by means of doors and stabs, and turfing, retain the water until it overflows. The net on each side of the pool is returned so far down both its sides. The depth of the water is seen to take the men to the haunches—the proper depth.

(2014.) Everything being thus prepared at the pool, the sheep are also prepared for the washing. The lambs not being washed, and to save trouble with them at the washing pool, they are separated from their mothers, and left in a court of the steading until the washing is over. The ewes, hoggs and dinmonts are all taken to the pool in a lot. They should be driven gently, and not allowed to be at all heated. The ewes will be troublesome to drive, being always in search of their lambs; but, notwithstanding this annoyance, they should not be dogged, and rather give them plenty of time upon the road. They should be driven along the road most free of dust or mud. The men who are to wash also prepare themselves by casting their coats, rolling up the sleeves of their shirts, and putting on

old trowsers and shoes to stand in the water with. The shepherd and other 2 men are quite enough to wash a large number of sheep thoroughly, but, if the stream is very broad, another may be required to save time in handing the sheep across. These 3 men are represented in the figure, *e* being the shepherd, and the last man to handle the sheep, and *d* and *c* his assistants. At least 2 men are required to catch the sheep for the washers, of whom 1 is seen at *b*. On an occasion of this kind the men receive a gratuity of bread and cheese, and ale, and also a dram of spirits as a stimulus, as at *h*, where the dog is seen to keep watch. Indeed, some stimulant of this kind is requisite for men who stand for hours in the water, the lower half of their body being chilled by the water, and the upper half being heated by the work. If they were provided with large fishermen's boots, they would less require such a fillip.

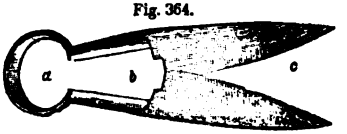
(2015.) The *washing* is performed in this way: While the 3 men are taking up their positions in the water, the other 2 are catching a sheep; and, to render this fatiguing work more easy, the fold should not be made larger than to contain the sheep easily. A sheep is caught, and is being presented by *b* to the first washer *c*, who takes the sheep into the water, and, allowing its wool to become saturated with it, turns it over upon its back, keeping up its head, and taking a hold of the arm of a fore-leg with either hand, and of the wool on the opposite side of the head with the other. He then dips the sheep up and down, to and fro, and from one of its sides to the other, slowly, causing all the wool to wave backward and forward, as if rubbing it against the water. In doing this the water becomes very turbid about the sheep, and he continues to do it till it clears itself, when he hands the sheep to the next washer *d*, standing in the middle of the stream. Whenever *c* gets quit of one sheep, another should be ready by the catchers for him to receive into the water. The second washer *d* holds and manages the sheep in the same manner, and then hands it to the shepherd *e*, and is immediately ready to take another sheep from the first man. It is the duty of the shepherd to feel if the *skin* of the sheep is clean, and every impurity removed from the wool. The position of the sheep on its back is favorable for the rapid descent of earthy matter from the wool. Wherever he feels a roughness upon the skin, he washes it off with his hand; and wherever any clots are felt in the wool which have escaped the other washers, he rubs them out. The belly, breast, and round the head, he scrubs with the hand. Being satisfied that the sheep is clean, he dips it over the head while turning it to its natural position, when it swims ashore, and gains the bank at *g*. Its first attempts at walking on coming out of the water are very feeble, its legs staggering under the weight of the dripping fleece; in a little after it frees itself from the water entirely by making its fleece whirl like a large mop. It will be observed in the figure that the 3 men do not stand abreast across the water, but in eschelon; and they stand so for this reason, namely: the sheep being in the dirtiest state when in the hands of the first man *c*, his standing farthest down the stream allows the dirtiest water to flow away at once, and not come near the stations of the other men. The sheep being in a comparatively clean state when it reaches the second man *d*, the water from it cannot render that more dirty which runs past the first man *c*. In like manner, the same sheep, when with the shepherd *e*, can but very slightly render the water impure to those below it, and, being washed highest up the stream, gets an immediate supply of the cleanest water for finishing its washing. This is the way in which sheep are washed in the Lowlands; and from 2 to 3 scores may be washed in 1 hour, according to the size of the sheep, the activity of the washers, and the supply of water.

Tups are washed 2 or 3 weeks before the rest of the flock, and clipped as long before to allow time to their wool to grow; and, as they are usually in high condition, their new wool rises soonest, and, of course, soonest allows the old fleece to be taken off. After washing, sheep should not be driven along a dirty or dusty road, nor should they be put into any grass-field having bare earthy banks, against which they might rub themselves. In fact, they should be kept perfectly clean until their fleeces are taken off. How long they should be kept depends on the state of the weather; for the wool must not only be thoroughly *dry*, but the *yolk*, as the natural oil of the wool is called, must return again into it. Perhaps 8 or 10 days may suffice to produce both these effects. But another circumstance, more important than either, should receive attention before the wool is clipped, which is, that the new wool be risen from the skin before the old be attempted to be taken off. Disregard to this state of the fleece will make good clipping very difficult to accomplish, and it will certainly deteriorate the appearance of the fleece. You need be under no apprehension of the wool falling off when the new growth commences, for wool will remain for years upon the sheep's back if not clipped off, and the sheep be in a clean and healthy state. How many years the fleece may continue to grow I do not know, but I have seen a 3-years' fleece. Lord Western showed Anglo-Merinos, at the Show of the Royal English Agricultural Society at Oxford, in 1839, the fleeces of which, when clipped, weighed, I think, 20 lbs. each.

(2016.) A place under cover should be selected for clipping the fleeces. The straw-barn L, fig. 4, Plate IV. of the steading, is a very suitable place for the purpose. The end next the chaff-house *r*, between the two doors, will answer for the clipping process, and the remainder will contain the sheep under cover until they are returned clipped to the fields again. The clipping floor is prepared in this way: Let clean wheat straw be spread equally over the floor 2 or 3 inches thick, and spread over it the large canvas barn-sheet, the edges of which should be nailed down tight to the floor. The use of the straw is to convert the floor into a sort of soft cushion for the knees of the clippers, as well as for ease to the sheep. A broom should be provided to sweep the cloth clean. A board 2½ feet above the floor should be provided to wind the fleeces upon, and it may be placed along the wall of the barn opposite to that occupied by the clippers. A space near this should be cleaned, and a sheet spread upon it, for putting the rolled fleeces upon. The remainder of the barn should be cleared of dust both from the floor and walls as high as the sheep can reach, and a little clean straw strewn upon the floor for them to lie upon.

(2017.) The instrument by which the wool is clipped off sheep is named *wool-shears*, as seen in fig. 364. They require no particular description farther than to explain that the bend or *bowl a*, which connects the two blades, acts as a spring to keep them separate, while the pressure of the hand on each side of the handle *b* overcomes and brings the blades together. There are wool-shears which have additional springs placed between the handles *b* to separate the blades more forcibly, but are not so agreeable to the hand as the simple bent spring *a*. Sometimes the spring of *a* is so strong as soon to tire the hand, to relieve which a piece of cord is wound slackly round the handles.—Strong shears are more easily worked if held near the blades; but if held upon their sharp edges they will soon hurt the hand. When not in use,

Fig. 364.



THE WOOL-SHEARS.

the blades are held together by their points being passed through a ring of leather. A rag-stone is used to sharpen wool-shears. The cost of the shears is from 2s. 6d. to 3s. 6d. each. A shepherd requires 2 or 3 pairs to do other jobs, and he makes it a rule to use clipping-shears on no other occasion than at regular shearing.

(2018.) In case of dew or rain in the morning, it is customary to bring into the barn as many dry sheep on the previous evening as the clippers will shear on the ensuing day. About 1 score of Leicester sheep to each clipper is considered a very good day's work. It is a frequent custom for neighboring shepherds to assist each other; and though the plan does not, perhaps, expedite the entire sheep-shearing of the country, yet a number of men clipping at the same time makes work seem lighter, and it gets the clipping of any individual flock the sooner through. It is seldom that a steward can clip sheep, but it is an accomplishment not unfrequently possessed by a hedger; and, if the cattle-man has been a herd, he can lend a hand as far as he is able, and in this way a party of clippers is mustered upon the farm itself. Clipping being both a dirty and heating work, the coat should be stripped, and the oldest clothes worn; and the hat and the vest are commonly thrown aside. Garters or tight knee-breeches will be found very irksome pieces of dress in clipping. There is an order followed in the classes of sheep as they are clipped—the tups are taken first, then the hoggs, and lastly the ewes; and, where there are dinmonts or wethers, they follow the tups. The reason for adopting this order is, that as tups are highest in condition, and having been earliest clipped the season before, their fleece rises earliest in this; and, if they are to be let in autumn on hire, the sooner they are washed and clipped, they will then show in better wool. Hoggs, too, being forward in condition, should be ready before ewes, as the latter lose their flesh by suckling, or require longer time to bring the yolk again into their old wool, and for the new to rise. The object of washing the sheep perfectly clean will be apparent at shearing, for if the shears grate upon anything, they will make bad work; and if any dirt is found on clipping, either upon the skin or fleece, the shepherd is alone to blame who had the sheep last through hands, and had the charge of them afterward on pasture.

(2019.) *Clipping* is done in this way: Whenever a sheep is caught in the barn, every straw or dirt on the wool or hoofs should be taken away before it is laid on the canvas carpeting. Clipping consists of 3 stages, the *first* of which is represented in fig. 365. After setting the sheep on its rump, and, on the supposition that the clipper is a right-handed man, he goes down on his right knee, and leans the back of the sheep against his left leg *a*. Taking the shears in his right hand, and holding up the sheep's face with his left, he first clips the short wool on the neck, and passes down the throat and breast between the fore-legs to the belly. Then placing the fore-legs under his left arm, as seen at *b* under *c*, the belly is left exposed to be next shorn across front side to side down to the groins. In passing down here, while the shears *d* are at work, the left hand *e* is engaged keeping the skin tight where it is naturally loose. The scrotum *f* is then bared, then the inside of the thighs *g g*, and then the under side of the tail *h*. These complete all the parts of this position. For clipping this part of the sheep, small shears, as in the figure, will suffice; and as the wool is short and of a detached character on the under side of a sheep, it is best clipped away by the *points* of the shears, as by *d*.

(2020.) The shears are used in a particular manner, to be safe alike to the fleece and the skin of the animal. The essential thing is to keep the *points always clear of the skin*, for, if held downward, they will inevitably

run into it; and, should such a prick be made when the hand is about to close, the consequence will be that a large piece of the skin will almost be clipped out before the clipper is aware of what he is about. This is a

Fig. 365.

THE FIRST STAGE OF CLIPPING A SHEEP.

common error committed by new clippers, and it is a great offence in any clipper's hands. The only way to avoid this serious injury to sheep is to rest the *broad* part of the shears only and always upon the skin. In this position, with the skin drawn tight by the left hand, the shears are made to move forward with a hold of the wool not exceeding 1 inch in breadth, in very short and frequent clips, taking care only to bring together the broad parts of the blades from where they are seen to separate in fig. 364 to as far as *c*, keeping the points always apart. The form of the carcass of a sheep being round, it is clear that the shears cannot make a long clip by bringing the points of the blades together at every stroke, without cutting the wool with the points at a considerable elevation above the skin. *Very* short clips, no doubt, make slow work, but rather work slow with short cuts than injure the wool with long. Experience will teach you to make longer clips effective when you know how to manage the shears dexterously.

(2021.) Fig. 366 represents the *second* stage of clipping. Its position is gained by first relieving the fore-legs from the first position, fig. 365, and, gently turning the sheep on its far side, the fore-legs *c* are put under the right or clipping arm *f*, while the clipper, going on both knees, supports the shoulder of the sheep upon them, thus giving the animal an easy reclining posture. You may rely upon this fact, that the more at ease the animal feels, the more readily will it lie quiet to be clipped. Supporting the head of the sheep with his left hand, the clipper first removes the wool from behind the head, then around the entire back of the neck to the shoulder-top. He then slips its head under his left arm, as *a* under *g*. Having the left hand thus at liberty, he keeps the skin tight with it, while he clips

the wool with the right, from where the clipping in the first position was left off to the back-bone. In the figure the fleece appears to have been removed about half way down the carcass; the left hand *b* is laid flat,

Fig. 366.

THE SECOND STAGE OF CLIPPING A SHEEP.

keeping the skin tight, while the right hand *e* holds the shears at the right part and in the proper position. The clipper thus proceeds along the thigh and the rump to the tail *d*, which is entirely bared at this time.

(2022.) Clearing the cloth of the loose parts of the fleece, the clipper, holding by the head, lays over the sheep on its clipped side, and still continuing on his knees, slips his left knee *a*, fig. 367, over its neck to the ground, while his left foot *b*, resting on the toe, supports the left leg *c* over the neck of the sheep, and keeps its head *d* down on the ground. This is the *third* position in clipping. The wool having been bared to the shoulder in the second position, the clipper has now nothing to do but to commence where it was left off in the first position, and clear the fleece entirely to the back-bone, meeting the clips where they were left off in the second position, the left hand *e* being still at liberty to keep the skin tight, while the right hand *f* uses the shears along the whole side of the tail. The fleece *g* is now quite freed from the sheep. In allowing the sheep to rise, care should be taken that its feet do not become entangled in the fleece, for in its eagerness to escape from the unusual treatment it has just received, its feet will tear the fleece to pieces. Immediately that the lot of sheep in the barn is clipped, it is taken to the field, and another brought in its place.

(2023.) A new clipped sheep should have the appearance of fig. 368, where the shear-marks are seen to run in parallel bands round the carcass, from the neck and counter *a*, along the ribs *b*, to the rump, and down the

Fig. 367.

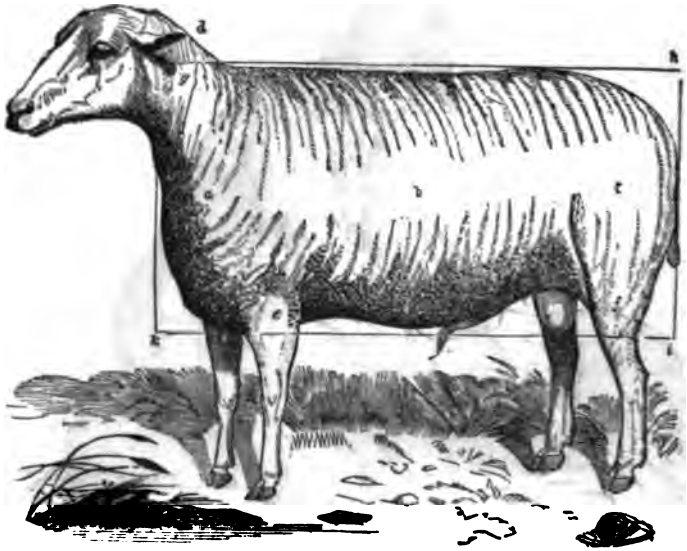
THE THIRD AND LAST STAGE OF CLIPPING A SHEEP.

hind leg *c*. When pains are taken to round the shear-marks on the back of the neck *d*; to fill up the space in the change of the rings between the counter and the body at *e*; to bring the marks down to *f* to the shape of the leg; and to make them run straight down the tail, a sheep in good condition so clipped forms a beautiful object. A sheep clipped to perfection should have no marks at all, for they are formed of small ridglets of wool left between each course of the shears; but such nicety in clipping with shears is scarcely possible, and, at any rate, the time occupied in doing it would be of more value than all the wool that would be gained. It should be borne in mind, however, that the closer a sheep is clipped, it is in a better state for the growth of the next year's fleece.

(2024.) I have introduced so many illustrations on this subject, in order to show the most easy positions that can be assumed in clipping, both to man and animal, that those positions may easily be compared with the common ones. On making this comparison, it is necessary to look again at the *first* stage of the process, fig. 365, the common practice being to place the sheep upright on its tail, and the clipper to stand on his feet, supporting its back against his legs—an insecure and painful position for the sheep, and an irksome one for the man when he bows down to clip the lower part of the animal. Again, in the *second* stage, fig. 366, it is customary for the man still to remain on his feet, and the sheep upon its rump, while he secures its head *sideways* between his legs, in order to

tighten the skin of the entire side which is now bent outward. The skin is thus certainly tightened, but at the expense of the personal ease of the animal; for the hand can tighten the skin as well, as shown in figs. 366 and 367, by *b* and *e*, while the bowing down so low, and as long, until he

Fig 368.



A NEW-CLIPPED SHEEP—THE PARALLELOGRAM SHOWING ITS SYMMETRY.

clips the entire side, cannot fail to pain the man's back. The *third* position is nearly the same in both plans, with this difference in the old one, which keeps the right leg bent, resting on its foot—a far more irksome position than kneeling on both knees. The treatment of the fleece I shall consider in a separate section; and the mode of washing and clipping Highland sheep will be found below. I may here remark that sheep-shearing is usually held as a merry season, a sort of harvest in which an allowance of good victuals—beef and broth and beer—is usually awarded to clippers engaged at their fatiguing task.

(2025.) Clipping makes such a change on the appearance of sheep that many lambs have difficulty at first in recognizing their mothers, while a few forget them altogether, and wean themselves, however desirous their mothers may be to suckle them; but as the ewe is content with one lamb, many a twin which does not follow her is weaned on this occasion. It should be the shepherd's particular care to mother the lambs frequently after clipping; but I am aware of the difficulty of bringing an old lamb and ewe together, without much disturbance to the rest of the flock; and besides, the shepherd cannot attend constantly on the clipped portion of his flock while engaged with clipping the rest, and this being the case constitutes another reason, besides those previously given (2018), for clipping the ewes last. Leicester lambs are *weaned* at the end of June or beginning of July; and the process is simple and safe, as most of them by that time chiefly depend upon grass for support. All that is required is to separate the lambs from the ewes, in fields so far lying asunder as to be beyond the hearing of the bleatings of each other. Where there is the convenience, lambs should be put on hilly pasture for some weeks at this

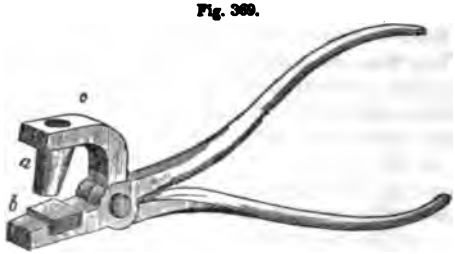
time, the astringent quality of which gives an excellent tone to their system, and renders them more hardy for winter. Some farmers even hire rough hill pasture for their lambs, but where such cannot be had, they are put on the oldest, though good pasture, for a few weeks before the aftermath is ready to receive them.

(2026.) The ewes, when separated from their lambs, should be kept in a field of rather bare pasture, near at hand, until their milk be dried up. They must be *milked* by the hand, for a few times, till the secretion ceases —once, 24 hours after the lambs are taken away—again, 36 hours thereafter—and the third time perhaps 2 days after that. Even beyond that time a few may feel distressed by milk, which the shepherd should relieve at intervals until the udders become dry. Indeed, milking after weaning of lambs, is essential to the safety of ewes, and I fear it is not so effectually performed as it should be until the udders go dry. The danger to be apprehended from its neglect is the plugging up of the teats with caseous matter, deposited therein by the milk which should have been drawn away; and which plugging, in the next lambing-season, will probably prevent the natural flow of the new milk; and the consequence will be that inflammation will be set up in the udder, and the ewe either take puerperal fever, that is, *udderclap*, or *garget* (1847), and die, or her lambs be so restricted of milk as to be half starved. Ewes are milked in a very different manner from cows. A long, narrow bught, formed of hurdles on both sides is erected along a fence close to the gate of a field near the steading or dairy, and it should be no larger than to contain all the ewes in a crowded state. The ewes being driven into the bught head inward, women proceed with the milking, which is accomplished by holding a small handy, that is, a small vessel formed like a milking-pail, in the left hand, and, squatting down *behind* the ewe, the milk is stripped clean from the teats alternately, with the right hand into the handy. The milker requires to be always on her guard, and remove the handy the instant she sees the ewe showing the least symptom of voiding either water or fæces, and a ewe is very apt to void the former whenever she is touched behind for the first time. Every ewe is turned out of the bught by the shepherd as it is milked, to prevent its coming in hand again. Time was when ewe-milking created a great stir in the farm-house for the making of ewe-milk cheese, and so much anxiety did housewives evince to make it, that the ewes were milked till they were perfectly lean to supply a sufficiency of this sort of milk. Better ideas now prevail, and farmers very properly will not allow their ewes to be milked oftener than is requisite to render them completely dry. It was misplaced economy to reduce the condition of the entire ewe flock for the poor boast of making a few strong-tasted cheeses.

(2027.) When lambs cease to bleat for their mothers, they should be *marked* and *buisted*, not only to identify them with the flock of the farm on which they are bred, but as a record of the particular blood from which they are descended. The *markings* are confined to the *ears*, and consist of small pieces being cut out, or slits made in the tips, with a knife, from the fore or back margin, or of holes made with punching-nippers, or of a combination of both sorts of marks. The female stock are always marked on the *near* ear, and the male on the *far* one. Thus, a single round hole is punched through the near ear of all the ewe-lambs, and a similar hole through the far ear of the wether-lambs; and should any of the ewe-lambs be considered fit for breeding tups, they either receive an additional hole through the near ear, or a bit cut out from a margin of the same ear, corresponding to a similar mark on their dams or sires, to distinguish their

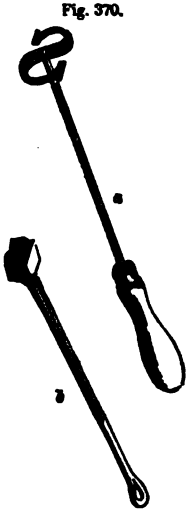
particular blood from the rest of the flock. Twin ewe-lambs receive a hole through both ears. Tup-lambs receive no *ear*-marks, their long tail serving the purpose till they are weaned, when they are at once transferred to the tups. Individual tups are so easily identified, and their descent so well known by the shepherd, that they require no marking. Fig. 369 are the *punching-nippers*, of which the inverted hollow cone *a*, having its small end sharpened, is employed to cut the hole out of the ears; and, to save the ears from being unduly pinched, a pad of horn *b* is inserted into the straight under-arm of the nippers, the pieces nipped out rising out of the orifice *c*. The figure at once shows how the instrument is used, being similar to the one used by shoemakers to punch holes into the lappets of shoes, through which the shoe-strings are passed, and it costs 2s. 9d. *Buisting* consists of stamping a letter or letters, expressive of the initials of the name of the owner or of that of the farm, or of both. The buist or mark is effected by a simple instrument *a*, fig. 370, which carries the capital letter S. This mark is made on the same principle as the ear-marks, the *near side* indicating the female, and the *far side* the male sheep. The material of which the buist is made is boiled tar, made viscid by a little pitch. The sheep to be buisted are put into a convenient apartment of the steading, and handed out one by one, and kept steady by holding the head and rump by the hands; and a knee being placed against the opposite side causes the side to be marked to project. The buist is then dipped lightly into the melted tar, to prevent its dripping; and, to make the mark vivid, it should be applied with some force, and with the entire surface at once, to compress the wool equally, and then quickly withdrawn. The wool must be quite dry, or the tar will not adhere to it. All new-clipped sheep are buisted in this manner; and though but a temporary mark, being in time obliterated, though not on short wool, it serves the present purpose well. To my taste, the buist looks best on that point which is the roundest part of the rib, but others prefer it on the shoulder, the rump, or the loins. In fig. 370 is another instrument *b*, the *branding-iron*, also bearing the capital letter S. It is sometimes used, and, on being heated in the fire, is applied to brand the letter on one side or other of the nose, or on one of the horns, of Black-faced sheep, or on the horns of Highland cattle, in lieu of the punching-nippers or knife, and it makes an indelible mark. To save twice handling of the lambs, they should be marked and buisted at the same time—one person making the marks, another applying the buisting-iron. The buist costs 3s., and the brand 4s., though a smaller instrument, as the letter has to be cut out of the brand like that of a die, and it must be made of the best iron to stand frequent heating. These are all the operations to which sheep are subjected in summer.

Fig. 369.



THE PUNCHING-NIPPERS.

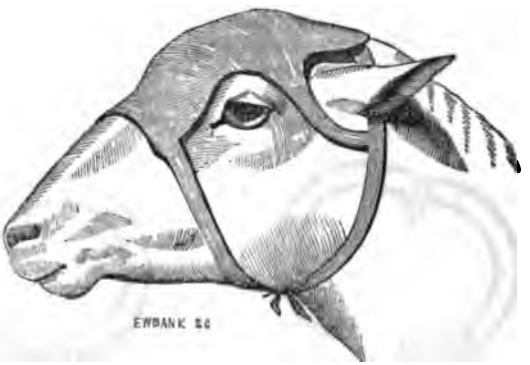
Fig. 370.



THE BUISTING-IRON AND BRANDING-IRON.

(2028.) *Scalded Heads.*—Sheep are much infested in summer with flies. As a protection to the *head* against them, the simple *cap*, or *hood*, as seen in fig. 371, is effectual. It may be made of stout linen, and fastened with 4 tapes tied crosswise under the chin, or of leather, and buckled at the same place.—Leicester tups should not be without these caps in summer, especially when grazing near woods; and, as tups are occasionally apt to box each other, any little portion of skin which may thereby be abraded on the head will receive immediate protection from the cap.

Fig. 371.



THE HEAD-CAP, OR HOOD, FITTED ON THE SHEEP.

(2029.) *Doddering.*—One great means of warding off the attack of the fly on hoggs is *doddering*, especially in localities obnoxious to flies. This operation consists of clipping away all the wool off the tail and between the hind legs.—Should hoggs scour, which they are not unapt to do when put on foggage immediately after being weaned, and when there is no rough moory or hilly pasture to put them upon previously for some weeks, the removal of the wool will prevent the discharge remaining about the animal, and, of course, deprive the fly of one object of attraction. The use of docking the tails of sheep is now made obvious (1841).

(2030.) Those who have many horse-chestnut trees, *Æsculus hippocastanum*, may be pleased to learn that their fruit, which is considered worthless, and even poisonous in this country, though both opinions are erroneous, may be usefully employed in feeding sheep. "While I was at Geneva in the autumn of 1837," says a correspondent, "I observed every one collecting carefully the fruit of the horse-chestnut, and on inquiry I learned that the butchers and holders of grazing stock bought it readily at a certain price per bushel. I inquired of my butcher, who himself kept a very extensive grazing farm, and he told me it was given to those sheep in particular that were fattening. The horse-chestnuts were well crushed—something in the way, so I understood, that apples are—previous to cider being made. In Switzerland, they are crushed or cut up in a machine kept solely for that purpose; then about 2 lbs. weight is given to each sheep, morning and evening. Sheep eat it greedily; it must be portioned out to them, as too much would disagree with them, it being of a very heating nature. The butcher told me that it gave an excellent rich flavor to the meat. The Geneva mutton is noted for being as highly flavored as any in England or Wales."*

(2031.) Sheep on hill-pasture delight in summer to spread themselves over, and to go to the highest point of their range. Ewes are restricted in their range by the lambs, which, when young, show little inclination to wander afar, but rather to lie down and sleep after being satisfied with milk. Hoggs keep much together, and on that account do not wander far from their morning lair, wherever that may be. Wethers, on the other hand, attain the hight of their pasturage at an early period of the day, and remain till dusk. You thus see, when sheep of different ages are brought up together, how usefully they distribute themselves over their entire pasture; and where only one class of sheep are reared, they extend their range according as their age increases, or their food becomes bare. On contiguous estates, where there is no march dyke to define their common boundary, it is quite possible that the flock of one property may occasionally trespass on the pasture of another. Should this happen in the early part of the day, the shepherds should not dog off the strange sheep, as that may render them restless even for days; but wait till nightfall, and then point them gently over the march to their own ground, where they will take to their usual lair. Sheep usually select a spot for resting at night, and it will mostly be that which is safest for them, especially if the sheep are aged, and well acquainted with the ground. In fine weather they should not be disturbed in thus selecting their lairs, but in case of threatening storm they had better be directed to the sheltered side of the pasture, or even near the stells, if need be. Within inclosed fields in the Lowlands, sheep can hardly go wrong in summer in selecting their lairs for the night.

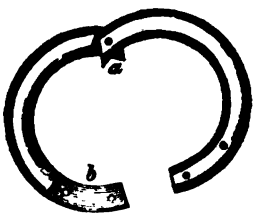
(2032.) The figures of the bull's ring and bullock-holder not having reached me when their use was described in (1994), I here give them before concluding the account of the treatment of stock in summer. Fig. 372 represents the *bull's ring* in an open state, ready to be inserted into the bull's nose, the joint *a* allowing the two sides of the ring to open as wide as the end *b* may be inserted into the hole burned into the septum of the nose. Fig. 373 shows the ring closed, after it has been fastened into the nose, *a* being the joint, and *b* the two ends of the ring lapped over and secured together by 2 countersunk screws. The ring is formed of ¼-inch rod-iron, and its diameter over all is 2½ inches, and it should be highly finished.

* The Gardener's Chronicle, 21st October, 1843.

(2033.) The *Bullock-holder* is well represented by fig. 374. where *a* is the joint which allows the two parts to open so far as each to enter a nostril of the animal. The lever nut *c* brings the two knobbed points *b* as close as to embrace and hold firm the septum of the nose. The leading rein is fastened to the under ring *e*. This form of bullock-holder would allow the points *b* to be

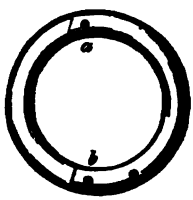
Fig. 374.

Fig. 372.



THE BULL'S RING IN A STATE TO BE INSERTED INTO THE BULL'S NOSE.

Fig. 373.



THE BULL'S RING AS FASTENED IN THE BULL'S NOSE.

THE BULLOCK-HOLDER.

screwed to any degree of tightness, until they meet each other; and it is, in my opinion, so far objectionable, as the screwing may be carried as far by a rash hand as to hurt the animal when the instrument was moved in the least degree to either side. Another form which I have seen and approve of, never allows the two knobs *b* of the instrument to be screwed closer than just to embrace the septum of the nose, allowing the holder to swing from the nose at ease while it holds the nose firmly whenever the animal attempts to move away. The cost of a bullock-holder of either of these forms is 4s. each.

26. ROLLING THE FLEECE, AND THE QUALITIES OF WOOL.

"Come, gentle swains, the bright unsullied locks
Collect: * * * *
Be faithful; and the genuine locks alone
Wrap round; nor alien flake, nor pitch enfold;
Stain not your stores with base desire to add
Fallacious weight."

DYER.

(2034.) Whenever a fleece is clipped from the sheep, a field-worker should be ready to roll it up. I have already said that a board should be provided to roll the fleeces upon, and it may be erected either in the clipping-barn, or any other adjoining apartment, such as the corn-barn; but the most convenient place for it is beside the clippers, as is also the stance for the rolled-up fleeces to lie upon till the end of the day's work, when they are removed to the wool-room. Suppose the board to be placed in the clipping-barn, the fleece, whenever separated from the sheep, is lifted unbroken from the cloth, and spread upon the board on its clipped side. The winder examines the fleece that it is quite free of extraneous substances, such as straws, bits of thorn, of whin, or burs, and removes them, and she also removes, by pulling off, all locks that have lumps of dung adhering to them, and which have escaped the notice of the washers. The farmer should be very particular in giving instructions on the purity of the fleece, as the purchaser cannot unloose every fleece he buys; and should he find as much filth in the fleeces after purchase as to warrant the belief that it had been purposely left in them, he may either relinquish his bargain, or make a large deduction from the price—in the former case imply-

ing fraud on the part of the farmer, and in the latter diminishing his profits. And besides the disgrace, any person who attempts to commit fraud in the case of wool is liable to be merced in heavy fines when informed against, which he puts in the power of the purchaser of the wool to do. The winder being satisfied that there are no impurities in the fleece, folds in both its sides, putting any loose locks of wool into the middle, and making the breadth of the folded fleece from about 24 to 30 inches, according to its size. She then begins to roll the fleece from the tail toward the neck as tightly and neatly as she can, and when arrived at the neck, draws the wool there as far out, twisting it into a sort of rope, as will go round the fleece, hold its own end firm, and make the entire fleece a tight bundle. The fleece is then easily carried about, having the clipped surface outside, which, being composed of wool saturated with yolk, exhibits a shining, silvery lustre. Fleeces are by no means all alike either in structure or color. Those of ewes, for instance, will be found thin and open in the locks, of pale color, and feel light in hand; those, again, of hoggs will be close and long in the pile, of a rich color, and the rolled fleece will feel heavy and be bulky in hand. Neither will all the fleeces be alike entire and in proper condition. An occasional fleece may want some part, having been shed off; and another may be *coated*, that is, have its wool felted together like a piece of very thick cloth; while another may be a black fleece. Whenever any such difference is observed in a fleece, it should be laid aside. The inferior stray locks, and those clotted with dirt, should be put into a basket by themselves, to be afterward washed, dried, and used at home for various purposes, such as in repairing of saddlery. Every day's clipping is carried into the wool-room, at W in the steading, fig. 4, Plate IV., which enters by a stair from the straw-barn. Previous to being occupied, the room should be completely swept of all dust from its floor and plastered walls, and washed clean and dried. The fleeces are built up on the floor at a little distance from the wall, putting the hogg and ewe fleeces in separate divisions. The whole are covered with clothes, and the shutters of the window closed. The reason for these precautions, which are too seldom attended to by farmers, is, that the cloths keep off dust, prevent too quick evaporation of the yolk of the wool, which, if allowed, will diminish its weight, and the window-shutters being closed excludes the light, which obscures the bright lustre of clipped wool. The odd fleeces and locks should not be brought into the wool-room at all, but the former sold, and the latter prepared for use immediately, as their unclean state creates an effluvium which induces the wool-moth, the *Tinea sarcitella* of Linnæus, to come into the wool-room.

(2035.) Wool is a ticklish article for a farmer to keep long. If the wool-room is too dry, the natural moisture, occasioned by the yolk, evaporates, and the fibres become curled, and feel harsh; and on the other hand, if it is too damp, which is its usual condition, the fleeces become compressed, feel clammy, and affected with green and yellow mould. The wool-moth then takes up its residence, in summer, among such fleeces, and breeds numerous larvæ, which subsist on the very fibres of the wool, and of course entirely destroy their character. There are farmers who have no wool-room, but keep their wool in the granary or an outhouse, where, of course, either of these effects are aggravated. The best means that I know of preserving wool for a length of time in the fleece, is to keep it in a wool-room with a wooden floor, packed in the pack-sheet, in which it will be out of reach of dust, light, and moths, and where no more air and light need be admitted than is desirable. If it is meant to keep wool only for a few weeks, the means spoken of in the last paragraph are all that

are requisite. The safest plan for the wool-grower is so sell it every year at the current prices, which are determined at the great wool fairs that take place in summer in many parts of the country, where wool-dealers attend, and whose proceedings are duly reported in the newspapers.

(2036.) When a wool-dealer purchases wool from a farmer, he sends his own people to pack it in his own pack-sheets. Wool is weighed and packed in this way: wool is sold in Scotland by the wool-stone of 24 lbs. avoirdupois, and it is weighed out in double stones of 48 lbs., each being called a *weigh*. Usually 7 Leicester hogg and 11 ewe fleeces make 1 weigh. In England, wool is sold by the lb. and weighed out by the *tod* of 2 stones of 14 lbs. each, or 28 lbs. In weighing out, the above number of fleeces may not exactly weigh the double stone; and, as fleeces are never broken to equalize the scales, a few small weights are used to balance the scale either on the side of the wool or of the weights, at each weighing. In this way the weight of the number of scalefulls required to fill each pack are correctly ascertained, a memorandum being taken of the number of weighings. While a simple and large beam and scales for weighing the wool is erecting, the pack for containing the fleeces is also making ready, so that they may be packed immediately from the scales, and save much handling. Pack-sheets are made of thin canvas, of the shape of an oblong rectangle, about 8 feet long when empty, and open along one side. A small stone being placed in each end of the opening of the sheet, a rope for each end being suspended from the ceiling, the stones form knobs which prevent the corners of the sheet slipping through the ropes, as at *a a*, fig. 375. The sheet *d* is suspended just

Fig. 375.

THE WEIGHING AND PACKING OF WOOL.

to swim above the floor. Two men, *b* and *c*, then get into the sheet, and placing the fleeces, as handed to them by the woman *e*, in regular order lengthways *across* its bottom, trample them down with considerable force especially at the corners, where they are pushed down with both feet set together, while both hands are holding firm by the outside of the corner of the sheet immediately under the tying, as shown in action by the man *b* The second layer of fleeces is laid contrary to the first, that is, in length along the sheet, placing 2 or 3 fleeces parallel in the breadth of the sheet; but the fleeces at the ends are always placed across the length of the sheet, in the same position as before, and pressed down in the same manner. The sheet is thus filled with alternate layers of fleeces to the top, when

the packers leave it, and then loosening the ropes, and reserving the small stones for the next sheet, immediately close the mouth of the pack; for if left open, the elasticity of the wool will cause the fleeces to rise so far as to render the closing afterward impracticable, and a pack is difficult to close at any time. With the aid of hand-cramps, inserted into the opposite sides of its mouth, the edges are brought together, and are so held by iron skewers being passed through both edges. When a farmer is packing wool on his own account, it is as well to know that common table-forks answer as well as hand-cramps for pulling the edges of the pack-sheet together, and for keeping them as close as skewers. The edges being thus brought together, they are permanently secured by sowing with packing-needle and stout twine, and the skewers are removed as the sewing proceeds. Thus, one pack is filled after another. A pack of wool *f* contains 10 stones, that is, 240 lbs. Any wool I have seen packed in the Highlands, was not put so regularly into the sheet as I have described; the fleeces were crammed in and trampled down in the most irregular and promiscuous manner. I once had an opportunity of seeing merino wool packed on a large scale at Leipsic. The sheets were made of horse-hair, and, during the packing, were occasionally subjected to the pressure of a long pole of wood acting upon them as a lever. The pole was fastened at one end by a ring to the ground, and heavy weights were suspended, and a rope passed from the other through a ring in the ground, to keep good what the lever had gained. The wool was packing for Great Britain, and was to be conveyed in large wagons, each drawn by 8 stallions, to be shipped at Rotterdam. In the rest of the cut the wool is seen piled up at *g*, and the man *i* is in the act of weighing a scalefull with the large beam and scales *h*.

(2037.) Even on the slightest inspection of a fleece on the sheep's back, one can perceive that it contains wool of different qualities; the coarser is evidently below and the finer above; but none but wool-staplers would discover 10 different qualities of wool in the same fleece. As a general description of a fleece, I may mention that the finest wool is upon the shoulder and along the top of the back to the rump; the next best is below the shoulders, along the ribs to the rump—the coarsest being on the haunches—and that below the belly is short and detached, and cannot be classed with the rest. Each of these parts have their respective qualities, which wool-staplers classify, in order to satisfy the wants of their customers, the manufacturers. The subdivision of the fleece by wool-staplers, after they have purchased the wool from the farmers, is technically in these terms: Prime—choice—super—head—downrights—seconds—fine abb—coarse abb—livery—short coarse or breech-wool. It would be well for wool-growers to receive lessons from wool-staplers on the essential properties which constitute good wool, that they may be able to judge whether the wool which they grow be intrinsically good or bad, comparatively improving or deteriorating, or to what species of manufacture it is best suited. According to present practice, wool-growers, I believe, demand prices for their wool on the faith of markets, without knowing whether their wool is really worth a high or low price.

(2038.) Good wool should have these properties: The *fibre* of the staple—a staple being any lock that naturally sheds itself from the rest—should be of uniform thickness from root to point; it should be *true*, as the phrase has it: the finer the wool, the smaller is the diameter of the fibre; the fibre should be elastic, and not easily broken; its surface should have a shining silvery lustre; and it should be of great density or specific gravity. Of a *staple*, all the fibres should be of the same length, otherwise the

staple will have a pointed character; the end of the staple should be as bright as its bottom, and not seem as if composed of dead wool; the entire staple should be strong, and its strength is tested in this manner: Take the bottom of the staple between the finger and thumb of the left hand, and its top between those of the right; and, on holding the wool tight between the hands, make the third finger of the right hand play firmly upon the fibres, as if in staccato on the strings of a violin, and if the sound produced be firm and sharp, and somewhat musical, the wool is sound; if the fibres do not break, on repeatedly jerking the hands asunder with considerable force, the staple is sound; if they break, the wool is unsound, and, what is remarkable, it will break at those places which issued from the felt of the sheep when the sheep was stinted of meat or had an ailment; though it will not break at every place simultaneously, because the weaker part, occasioned by the greater illness, will first give way. A *good fleece* should have the points of all its staples of equal length, otherwise it will be a pointy one; the staples should be set close together; and it should be *clean*. One essential good property of wool is *softness* to the feel like silk, which does not depend on *fineness* of fibre, but on a peculiar property of yielding to the touch at once, and readily returning to the hand. There should be no *hairs* in wool—neither long ones, which are easily distinguishable from wool, and give the name of *bearded* to the fleece; nor short ones, soft and fine, like *cat's* hair, which are not easily distinguishable from wool, and are denominated *kemps*. The long hairs are frequently of a different color from the wool, but the kemp hairs are of the same color; and, of the two, the latter are much the more objectionable, as being less easily detected.*

(2039.) Keeping all these properties in view, it is clear that a farmer who breeds sheep having fleeces with pointy staples, thinly set on, and of unequal lengths—who stints his sheep of food at one time, and overfeeds them at another, thereby producing wool of unequal size, and therefore *untrue*—who, moreover, does not wash his sheep clean, or, having so washed them, allows their wool to be again dirtied before being clipped, thereby creating much waste to the manufacturer to bring the wool again to a clean state—the farmer who manages his sheep and wool so as to produce these effects, injures himself to an incalculable extent.

(2040.) It is remarked by Mr. Culley that "the Herefordshire sheep that have the finest wool are kept *lean*, and produce 1¼ lbs. each; if better kept, they grow larger, and produce more wool, but inferior in quality."† This is true of every breed of sheep, and particularly of the Merino, whose *propensity to leanness* caused their culture to be abandoned in Great Britain, as being unprofitable. Their wool did not so much deteriorate in this cold climate, as there was no possibility of getting mutton upon their carcass. But, though leanness produces wool of finer quality than high condition, yet the remark is only strictly true when applied to breeds which yield fine wool in every state of condition; for no degree of leanness will cause a coarse-wooled breed of sheep, such as the Black-faced, to produce *fine* wool. To obtain any given quality of wool, therefore, it is necessary to possess the breed that produces it, and then the wool will be finer or coarser in comparison as the sheep are kept in low or high condition. There is no doubt that the general quality of wool in this country has become coarser than it was years ago; not because the breeds of sheep have deteriorated—for, on the contrary, they have all improved—but because the animals are now kept throughout the year in much higher condition; and this result might have been anticipated, for, if there is any analogy between the vegetable and animal economy, we know that well manured soil will produce flax of thicker and longer fibre than the same soil in poor condition; so, in like manner, sheep when in high condition produce wool of thicker and longer fibre than when lean. During the improvement that has taken place in the breeds of sheep, a counteracting influence, as I conceive, has been at work to retain the wool of finer quality than the high condition would produce—I mean the influence of shelter; and though it may only be of a negative character, preventing unequal evaporation of the yolk of wool, by warding off cold and drying winds, yet, in preventing these, its effects are positively beneficial, inasmuch as Mr. Luccock observes that "the silky softness, like most other good qualities of the fleece, depends very much upon the breed of the sheep, *and the quality of yolk which they constantly afford*." It is difficult to say whether the density of the fibre of wool, that most desirable property, depends on some general law connected with the breed, or the circumstances in which the fibre

* See Luccock on Wool; Ed. 1805.

† Culley on Live-Stock—*Note*.

is produced; for the mere coarseness or fineness of the fibre does not affect its specific gravity—as, for instance, the close full-grown wool off the shoulder of a sheep does not differ materially in density from that from the thin and hairy breech; and hence, perhaps, the density does not depend on the breed. I am inclined to believe that soil and climate very much affect the general condition of fleeces, for we find wool grown in the chalky districts of England much drier and coarser than that which is produced on fine, soft hazel loam; and wool grown upon turnips appears to me coarser than when grown on grass in the same soil in similar condition. This fact is undeniable, that fleeces from the same breed, reared even in similar circumstances, differ much in density. The conclusion to be inferred from all these considerations seems to be, that whatever induces the greatest secretion of yolk, whether it be breed, condition of animal, nature of soil, or climate, will produce fibre of the greatest specific gravity; and hence on grass on a deep mellow soil in good heart, and in a sheltered situation, a breed of sheep, capable of continuing in good condition throughout the year, should produce the densest and the finest quality of fibre of wool. If these views be at all correct, you can easily perceive how much depends on the judgment of the farmer himself, to produce wool that will possess the greatest number of good qualities.

(2041.) Chemically, "wool has not yet been subjected to a rigid examination," says Dr. Thomson; "but, from the experiments made on it by Berthollet, there is reason to conclude that its chemical qualities do not differ much from those of hair. When growing upon the sheep, it is enveloped in a kind of soapy matter, which protects it from the attacks of insects, and which is afterward removed by scouring. Vauquelin has examined this matter, and found it to consist of the following ingredients: A soap of potash—carbonate of potash—a little acetate of potash—lime—a very little muriate of potash—and an animal matter."*

(2042.) Mr. Youatt has examined the external structure of wool with the microscope, and has ascertained that the surface of the fibre is covered with a sort of scale which forms a series of serrations along the entire length. The general outline of the woolly fibre consists of a central stem or stalk, probably hollow, or at least porous, and possessing a semi-transparency not found in the fibres of hair. From this central stalk there springs at different distances, in different breeds of sheep, a circlet of leaf-shaped projections. It is thus ascertained that wool possesses a property common to all independent horny fibres which issue from the felt of animals—namely, an irregularity which constitutes a certain degree of roughness upon their surface from the root to the point. Hence, both physically and chemically, wool and hair are analogous substances. Some of the results of Mr. Youatt's investigations with the microscope, in conjunction with the micrometer, were these:

	Diameter.		Serrations.	
Merino wool	$\frac{1}{750}$	an inch, and	2,400	in an inch.
——— Picklock	$\frac{1}{750}$	..	2,560	..
——— Saxony	$\frac{1}{840}$	..	2,720	..
Leicester	$\frac{1}{500}$	..	1,860	..
Deccan, black	$\frac{1}{1000}$	..	1,280	..
Odessa	$\frac{1}{750}$	..	2,080	..
Wallachian	$\frac{1}{750}$	..	2,080	..
Australian	$\frac{1}{750}$	..	1,920	..

Lincoln	$\frac{1}{480}$	..	1,280	..
Irish	$\frac{1}{560}$	..	1,920	..†

Another instrument besides the micrometer, named the eirometer—the invention of the late celebrated optician, Dolland, of London, and which reads off diameters to a very minute fraction of an inch, is used for measuring the diameters of wool, and it may be employed by an inexperienced hand with less chance of error than a micrometer. It produces a double image of the fibre which are brought in contact, and the result is then read off from a circular index.

(2043.) Wool is well known to have a felting power, but it is unknown in what that power consists. A *coated* fleece is a natural instance of the felting tendency of wool. Mr. Youatt seems to believe that the discovery of the serrations on the fibre of wool accounts for its felting property.

* Thomson's Animal Chemistry, (589)

† Youatt on Sheep.

"It is a curious and interesting point that has been established," he says, "the existence of an irregularity of form in the wool, accounting for and necessarily giving it a felting power—is there a variation in this structure corresponding with the degree of felting power?" Mr. Boyd, of Innerleithen, Peeblesshire, is much disposed to question Mr. Youatt's views. "Mr. Youatt asserts with much confidence," he remarks—and in this remark Mr. Boyd is supported by Mr. Luccock—"that the felting properties depend entirely on the structure of the wool. During an experience of many years I have found this not to be the fact, and therefore state, without fear of contradiction, that in many instances it is impossible to estimate the extent of the felting properties in a variety of wools, until they have been submitted to the actual test of experiment; and I am decidedly of opinion," he adds, "that however perfect the structure of wool may be, if produced in the absence of an oily or saponaceous substance, it cannot possess the requisite properties of a clothing material."* Mr. Boyd is again supported by Mr. Luccock, when the latter says, "If the wool grower be anxious to promote the growth of fleeces in which the felting quality greatly prevails, I should recommend, from the little knowledge at present possessed, that he attend closely to the supply of natural, rich, and nutritious yolk, which the pile receives while growing." I confess that Mr. Youatt's theory to account for the felting property of wool, in reference to the action of the serrations on the surface of the fibre upon one another, appears to me unsatisfactory. On the authority of Mr. Luccock, the application of *moisture*, *warmth* and *pressure* are necessary to bring the felting property of wool *into action*. "*Without* the aid of moisture," he affirms, "it remains perfectly *dormant*; the warmth and pressure are required to *quicken* the process." And he adds, "the degree of heat required to make the felting property act with the utmost force is considerably below the boiling point of water," and that "a higher temperature loosens the texture of the thread, and increases the elasticity of the hair, thus giving it a disposition to start from the substance of the cloth and spoil its surface."† If the action of the serrations on the fibres is the principal means of felting wool, it must be proved that they change their structure on being immersed in water of a temperature near the boiling point, which has not yet been done. It is also known that wool, after being combed with heated iron combs, will not felt; and yet the figures given by Mr. Youatt, of combed and uncombed wool of different varieties, indicate no such decided change by combing, on the structure of the serrations, as to warrant us in believing that in the one state wool shall felt, and in another it shall not.

(2044.) Having mentioned the application of the microscope to the structure of wool, it may prove instructive to show, by the same instrument, in what manner wool grows. "If the fœtus of a sheep," says M. Raspail, "taken when it is of the length of about 4½ inches, and preserved in alcohol, be examined, it will be found studded with globules of uniform size, elegantly arranged, and almost at equal distances, round certain white spots disposed in quincunxes, which seem, even at this early period, to indicate the places where the hairs are to grow. On the epidermis of the temple, instead of thin white spots, we find vesicles projecting in the form of bottles, or rather of urns, whose sides are granulated in the same manner as the epidermis. These vesicles are the rudiments of hairs."‡

(2045.) The number of sheep in the empire, estimated by Mr. Macculloch, from different sources of information, is the following:

In England	26,148,463
In Scotland	3,500,000
In Ireland	2,000,000
Total	31,648,463‖

By a statement made by the late Mr. Hubbard, an eminent wool-stapler in Leeds, the number of packs of wool grown every year in England is 463,169, of 240 lbs. each, or of 111,160,560 lbs., which gives an average weight to each fleece, including those of lambs, of 4½ lbs.§

(2046.) The term *Merino*, applied to a particular breed of sheep and variety of wool, is of obscure origin. Mr. Southey informs us that "Merino is an old Leonese title, still preserved in Portugal, though long since obsolete in the other kingdoms of Spain. Perhaps it is a mongrel diminutive of the Arabic title *mir* or *emir*, likely enough to have been formed when the two languages, Spanish and Moorish, were, as it were, running into each other. *Mirquebir*, the augmented title, was in use at Ormuz. *Merino* would be sufficiently explained by supposing it a diminutive grade. The old laws of Spain define it thus: 'He is a man who has authority to administer justice within a certain district.' The first mention of this office is in the reign of Bermudo II. The Merinos then commanded the troops of their respective provinces in war; but, before the time of Henrique II., it was become wholly a civil office, and the title was gradually giving place to that of Alguacil, mayor. Most probably the judge of the shepherds was called the Merino, and hence the appellation extended to the flocks under his care." It is the general opinion that Merino sheep came to this country from Spain, and so they did at the end of the last century; but it appears that *fine-wooled* sheep were sent from England to Spain a very long time ago. That *sherp* were sent from England to Spain at a known period is certain, for Mr. Youatt quotes from the chronicles of Stowe, that "this yere (1464) King Edward IV. gave a license to pass over certain *Cotteswolde* sheep into Spain." And he quotes Baker also, who says: "King Edward IV. enters into a league with John, King of Arragon, to whom he sent a score of *Costal* ewes and four rams—a small present in show, but great in the event, for it proved of more benefit to Spain, and more detrimental to England, than could at first have been imagined." The wool of the Cotteswolde sheep of the present day is long, and not remarkable for fineness. Perhaps the old Cotteswolde wool was finer than the present, because the latter has been much crossed with the Leicester. But if the old Cotteswolde conferred so much benefit on Spain, it may be fairly in-

[‖ Recent estimates make the number from 50 to 70,000,000. *Ed. Farm. Lib.*]

* Prize Essays of the Highland and Agricultural Society, vol. xiv. † Luccock on Wool.

‡ Raspail's Organic Chemistry, § Macculloch's Dictionary of Commerce, art. *Wool.*

ferred that the wool of Spain was not so fine as that of England at the time. But sheep were exported from England to Spain prior to the reign of Edward IV., as Mr. Southey intimates that "Fernan Gomez de Cibdareal, in one of his letters (Epist. 73), mentions a dispute between two Spaniards concerning rank in the presence of Juan II., 1437. It was objected tauntingly to one of them, that he was descended from a judge of the shepherds. The reply was, that this office had always been held by hidalgos of great honor, and that 'King D Alfonso had instituted it in the person of Inigo Lopez de Mendoza, *when the English sheep were first brought over to Spain.*'" This dispute occurring in 1437, and referring to an ancient title of honor which had been conferred as far back as the time of the introduction of English sheep into Spain, and a taunt being given in 1437 to a *descendant* of a judge of the shepherds—that is, of a Merino—thereby implying that he, the descendant, was at least of the second or third generation, it is clear that the English sheep referred to could have no reference to the Cotteswoldes exported in 1464, as mentioned by Stowe. "How long was it before the Merino fleece became finer than that of the original stock?" asks Mr. Southey; and he replies, "Brito, who wrote toward the close of the 16th century, says, in praise of the wool grown about Santarem, it is so fine that *it may vie with that of England.* (*Monarchia Lusitania*, f. 1., p. 93.) If the Spanish wool had been as fine then as it is now, he would hardly have drawn his comparison from the English."* While these facts are recorded in Spanish literature regarding the origin and ancient quality of the wool of Spain, the opinion of Mr. Youatt seems much too strongly expressed, when he says that "Europe and the world are *originally indebted to Spain* for the most valuable material in the manufacture of cloth." And, again, "The chunahs, therefore, may be descendants of the English sheep," namely, those sent to Spain in 1464. "mixed with the common breed of the country; but farther than this England cannot, with any degree of justice, urge the claim which some have done, of being instrumental in producing the invaluable Spanish wool."† And yet, as we have seen, sheep were probably sent from England to Spain long before that date, or even long before 1437; for if the King Alphonso, mentioned above as having instituted the order of judge of the shepherds, be Alfonso the Wise, King of Leon and Castile, who is stated to "have digested a code of excellent laws, and rendered his name famous in history by his patronage of the arts and sciences,"‡ he reigned at the early period of from 1252 to 1284. And another fact mentioned by Mr. Southey—when Catherine, daughter of John of Gaunt, was espoused to Henrique III., she took English sheep with her as her dowry—fixes another exportation of sheep to Spain about 1390, a considerable while prior to the Cotteswolde exportation of 1464; and, if the English sheep had been of an inferior description to those of Spain, it is not likely that the future Queen of Castile would have taken them with her as her own dowry. In concluding this subject, Mr. Southey puts this doubting query: "Can there possibly be any truth in the remark of Yepes (t. 7, § 134), who says: '*Daily experience shows us* that, if a lamb is suckled by a goat, the wool becomes hard and hairy; and, on the contrary, if a kid is suckled by a ewe, the hair becomes soft?'"

27. THE MAKING OF BUTTER AND CHEESE.‖

"And now the DAIRY claims her choicest care,
And half her household find employment there:
Slow rolls the churn—its load of clogging cream
At once foregoes its quality and name:
From knotty particles, first floating wide,
Congealing butter's dashed from side to side;
Streams of new milk through flowing coolers stray,
And snow-white curds abound, and wholesome whey."
BLOOMFIELD.

(2047.) THE dairy operations on a farm of mixed husbandry are limited, both in regard to the season in which, and the quantity of materials by which, they can be prosecuted. Until the calves are all weaned, which can scarcely be before the end of June, there is no milk to spare to make butter or cheese, but what of the former may suffice for the inmates of the farm-house; and as some of the cows, at least, will have calved 4 months before all the cows are free to yield milk for the dairy, a full yield of milk cannot be expected from them even when entirely supported on grass.—But though thus limited, both in regard to length of time and amount of milk, there is ample opportunity for performing every dairy operation, according to the taste and skill of the dairy-maid. For example: Butter

‖ The dairy products of the United States in 1840 were put down at $33,787,008. *Ed. Farm. Lib.*]

* Southey's Omniana, vol. ii. † Youatt on Sheep. ‡ Bigland's View of the World, vol. ii.

may be made from cream, or from the entire sweet milk. It may be made up fresh for market, or salted in kits for families or dealers. Cheese may also be made from sweet or skimmed milk, for the market; and any variety of fancy cheese may be made at a time—such as cream-cheese, imitation Stilton, Gloucester, or Wiltshire. With all these means at command, to a moderate, indeed, but available extent, it is quite possible for the dairy-maid to display as much skill and taste in her art on a mixed as on a dairy farm—not only in these respects, but in the endless forms in which milk may be served on the table of the farmer. In short, the only advantage a dairy-farm possesses over one of mixed husbandry is, that all its dairy operations are conducted on a larger scale.

(2048.) The *milk-house*, large enough and otherwise convenient and suitable for a farm of mixed husbandry, may be seen represented in plan at *m*, fig. 32; and the cheese-room adapted to the same is seen in plan at *h*, fig. 33. The mode in which a milk-house should be fitted up, is described in (231), as well as a cheese-room in (237).

(2049.) The *utensils* with which a dairy should be supplied, comprise a large number of articles, though all of simple construction. The *milk-dishes* are composed of stone-ware, wood, metal, or stone.* The stone-ware consists of Wedgewood and common ware; the wooden of copper-work, of oak-staves bound with hoops of iron; the metal of block-tin, or of zinc; and the stone are hewn out of the block, and polished. Besides these, utensils formed of a combination of materials are used, such as wooden vessels lined with block-tin or zinc, and German cast-iron dishes lined with porcelain. Of the whole variety, the stone and wooden ones lined with metal, are stationary, and the rest movable. All milk-dishes should be of a broad and shallow form, for the purpose of exposing a large surface with a shallow depth of milk, in order to facilitate the disengagement of the several parts of the milk. There seems to be a difference of opinion, which of those substances have the greatest influence in disengaging the greatest quantity of cream from the milk. I have heard it maintained at one place that stone is much the best; at another, that wood is the best; at another, that stone-ware is preferable to all others, and of the two kinds of stone-ware that of the common ware is better than Wedgewood's; and at another, that zinc is by far the best; from all which difference of opinion I would infer that the subject has not been satisfactorily ascertained by comparative experiment, and which I believe to be the case; but I am sure that different management, even in the same circumstances, will produce very different results in this product of milk. Independently of the consideration of cream, however, other circumstances should be regarded in making choice of milk-dishes. Wooden ones require much labor to keep them thoroughly clean, though they are the least liable to injury in the use. Metal ones also require much cleaning, and are liable to be bruised; and it is not questionable that they are unwholesome for milk, if not kept thoroughly clean. Tin produces no injurious salt with the acid of milk; but the salt produced by the action of lactic acid upon zinc, is believed to be in a slight degree poisonous to the human stomach. At all events, the thought of *keeping* milk in metallic dishes is unpleasant to the mind. Stone-ware is easily frangible, but is, nevertheless, so cheap, so easily cleaned, and so safe in use, that it forms the most convenient material for milk-dishes to every class of country people. The advantage of Wedgewood ware consists in its hardness, and the durability of its glazing. The price of dishes of common ware, of 15 inches in di-

[* Better if made of glass, with their capacity stamped in the making. *Ed. Farm. Lib.*]

ameter, is 9d. each; of Wedgewood's ware, from 12 inches to 24 inches, from 2s. to 8s. each; of wood, 16 inches diameter and 4 inches deep, 2s. each, and of zinc, 18 inches in diameter, 3s. 9d. each, and others are 3d. per inch more or less, as the diameter increases or diminishes from this size.

(2050.) The other utensils are: Creaming scallop, for taking the cream off milk; a jar for containing the cream until it is churned; a Wedgewood one, with top and opening in it to be covered with muslin, to keep out dust and let in air, costs from 6s. to 7s. 6d.; a churn, of which there are many forms, all of which will be found described below by Mr. Slight; a flat wooden kit, to wash butter in; scales and weights for weighing butter, whether in pounds, fractional parts of a pound, or in the lump; jars or firkins for packing salted butter; moulds for forming prints of butter for the table; covered dishes for holding fresh butter in pounds; a tub for earning the milk in when about to make cheese; a curd-cutter, and a curd-breaker; a drainer to lay across the cheese-tub while the whey is straining from the curd; cheese-vats for giving the form to cheese; a cheese-press, a figure of the most convenient and powerful form of which is given below; a furnace and pot for heating water and milk; and a supply of spring-water is an essential concomitant to a dairy.

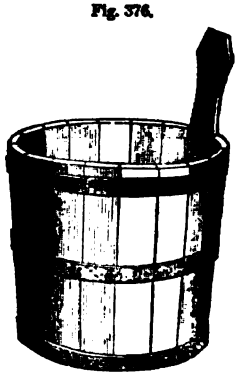
(2051.) A word or two on *churns*. The old-fashioned upright hand-plunge-churn is now confined chiefly to the use of small farmers and cotters; but, when inanimate power is applied to the making of butter, the upright churn is yet used by many dairy farmers who conduct their operations on a large scale. About 20 years ago the barrel-churn was much in vogue, and it was very well suited for making butter, as it kept all the cream in constant agitation; but the trouble required to keep it clean, from its inconvenient form to get within it, has tended to bring it into disrepute. It is now superseded by the box-churn, whose construction admits of its being easily taken to pieces and cleaned. Of the two forms of box-churn, I prefer the one in which the agitators move horizontally, because it can be filled to any degree of fullness, without danger of the cream or milk working out of the journal-holes of the axle. Long ago, small churns were in repute; though they fell into desuetude, but lately have again come into use, and for making small quantities of butter they are admirably adapted. Various constructions of small churns, intended to regulate the temperature of the cream, have of late been proposed, some of which are noticed below.

(2052.) A word or two also on *cleanliness*. Unless the milk-house is kept *thoroughly* clean, in its walls, floors, and shelves, the milk will become tainted; and in order to keep them clean, the floor and shelves should be of materials that will bear cleansing easily and quickly. In most farm-houses the shelving is of wood, and the floor of pavement or brick. Wooden shelves can be kept clean, but are too warm in summer. Stone shelving is better, but must be *polished*, otherwise cannot be sufficiently cleaned; and to be kept clean, requires at times to be rubbed with sandstone. Marble shelving is the best of all for coolness and cleanliness, and they are not so expensive as many imagine. Polished pavement makes a more durable, easier cleaned, and cooler floor than brick. There should be ample means of ventilation in the dairy when required; the principal object, however, not being so much a constant change or a larger quantity of air, as an equality of temperature through summer and winter. To obtain this desideratum, the windows, which should face the N. or E., should not be opened when the temperature of the air is above or below the proper one, which, on an average, may be stated at 50° Fahren-

heit. The milk-house should be thoroughly *dry;* the least natural damp in the walls and floor will emanate a heavy fungus-like odor, very detrimental to the flavor of milk and its products. The utensils should all be kept thoroughly clean, and exposed to and dried in the air. Some dairy-maids are so careless in this respect, that I have seen seams of green and yellow rancid butter left in the corners and angles of churns, and a heavy smell of dirty woolen rags pervading wooden utensils. However effectual woolen scrubbers may be in removing greasiness left by milk and butter on wooden articles, they should never be employed in a dairy, but only coarse linens, which should always be washed clean in hot water without soap, and dried in the air. All the vessels should be quickly dried with linen cloths, that no feeling of clamminess be left on them, and then exposed to the air. In washing stone-ware dishes, they should not be dried at that time, but set past singly to drip and dry; and they should be rubbed bright with a linen cloth when about to be used. If dried and set into one another after being washed, they will become quite clammy. The great objection to using stone milk-coolers is the difficulty of drying them thoroughly before being again used. No milk-house should be so situate as to admit the steam rising from the boiler which supplies hot water for washing the various utensils; nor should the ground before its windows contain receptacles for filth and dust, but be laid out in grass, or furnished with evergreens. It is said that the odor from the blossom of the common elder, *Sambucus nigra*, in summer is a complete muscafuge, if I may be allowed to coin a word.

(2053.) The articles which engage the dairy-maid's attention within the dairy are milk, butter, and cheese; and, first, as to *milk*. I have already said that the milk is drawn from the cow into a pail (1670), the most convenient form of which is given in fig. 376, and the size of which may vary to suit the pleasure of the dairy-maid. It is made light, of thin oak staves bound with iron hoops, and costs from 2s. 6d. to 5s., according to the size. The milk, in being drawn from the cows, is put into a tub, and left to cool; but not to become so cold or stand so long as to separate the cream. The tub should be placed in the air, and out of reach of animals, such as cats and dogs. After it has cooled, the milk is passed through the milk-sieve into the milk-dishes, and as much only is put into each dish as not to exceed 2 inches in depth. To know at once the age of milk in the dishes, *one* mark or score should be made with chalk on the dishes just filled, to show that they contain the last drawn milk, or freshest meal; a *second* mark is made, at the same time, on the dishes containing the meal before this; and a *third* is put on the dishes containing the milk drawn before the second meal, and which constitutes the third meal, or oldest milk. If the cows are milked three times a day, when the first mark is put on the dishes of the evening meal, those of the morning meal of the same day will have 3 marks, to indicate its being the third meal previous, and the dishes of the mid-day or second meal will have 2 marks. At every meal all the utensils that have been used should be thoroughly cleaned, and set past dry, ready for use when required.

Fig. 376.



THE MILKING-PAIL.

(2054.) The next care of the dairy-maid is taking the *cream* off the milk. In ordinary weather in summer the cream should not be allowed to remain

longer on the milk than 3 meals—that is, when a fresh meal is brought in, the cream should be taken off the dishes which have 3 marks, when the milk will be 20 or 22 hours old; but, should the weather be unusually warm, the milk should not be allowed to be more than 18 hours old, or that having 2 marks, before the cream is taken off it. For example: in ordinary routine, the cream of the previous mid-day's milk should be taken off in the morning, and at mid-day the milk of the previous evening would be creamed, and so on; but, when the weather is very warm, it would be well to anticipate the creaming of one meal, and take the cream of the two oldest meals at one time, and in this way take off all the cream that can be got every 18 hours. The reason for using this precaution in taking off cream is, that the milk should on no account be allowed to become sour before the cream is taken off, because the cream of sour milk makes bad butter. Let sweet cream become ever so sour after being taken off the milk, and no harm will accrue to the butter. Not that sour cream off sour milk is useless, or really deleterious, for it may be eaten with relish by itself, as a dessert, or with porridge. The cream is skimmed off milk with a thin, shallow dish, called a *skimmer* or *creamer*. It may be made of wood or of stone-ware; and, of the two substances, the ware is preferable for cleanliness; and, of ware, Wedgwood's or porcelain is the best, being light, thin, hard, highly glazed, and smooth. There is no other way of taking cream off dishes but with a skimmer; but in stationary coolers, of metal or of stone, a spigot is drawn cautiously from a hole in the bottom, through which the milk runs slowly down into a vessel, and the cream is left on the bottom of the vessel; and this manner of separating the cream from the milk is said to be the most effectual; but, of course, the skimmer can be used for creaming the milk in coolers, as well as other dishes. The cream, when taken off the milk, is put into a *cream-jar*, in which it accumulates until churned into butter. Every time a new portion of cream is put into the jar, the cream should be stirred, in order to mix the different portions of cream into a uniform mass. The stirring is usually done with a stick kept for the purpose, but spoons of Wedgwood ware are made for doing it. The cream soon becomes sour in the jar, and it should not be kept too long, as it is apt to contract a bitter taste. Twice a week it should be made into butter, however little the quantity may be at a time. The skimmed milk is put into a tub and made into cheese; but, if a cheese is only made every other day, the milk kept for the following day should be scalded before it is put into the tub.

(2054.) On converting cream into *butter*, the first act is to put the churn into a proper state. It is assumed that the churn when last used was put aside in a thoroughly clean and dry state. This being the case, a little hot water, about 2 quarts, should be poured into it to scald and rinse it. In summer it should be rinsed with cold water after the hot, but not in winter. Some people sprinkle a little salt into the churn before the cream is put into it, but whether it does any good or not I cannot say. The churn being thus prepared, the cream is strained into it through a bag of coarse, open sort of linen cloth, well known under the name of cheese-cloth. This cloth is always kept in a sweet state, no soap ever being employed to wash it. It is dipped in water, and then held over the churn; and, on the cream being slowly poured into it from the jar, the greater proportion will run through into the churn; but the clotted part, which will contain in it dust, drowned flies, moths, and spiders, and other impurities, which it is impossible to keep out of an open cream-jar, the cloth will keep back, on being gently pressed. In the small hand plunge-churn, and in a barrel-churn, a churn-cloth is required to be put round the mouth of the former, and un-

der the bung of the latter, to prevent the cream being thrown out in churning. The temperature at which *cream* is put into the churn has a considerable influence on the time which the butter will take to make, and also on the weight of butter obtained from a given quantity of cream. It has been found that 55° Fahrenheit is the temperature which best attains these ends, and it is one easily attained in a cool apartment early of a summer's morning. The churning should be done slowly at first, until the cream has been completely broken—that is, rendered a uniform mass—when it becomes thinner, and the churning is felt to be easier. During the breaking of the cream a good deal of gas is evolved, which is usually let off by a small spigot-hole, if the churn be tight, such as a barrel-churn; but in other churns, which have a cover, the air escapes of itself. When the motion of churning is rotatory, it should be continued in the same direction, and not changed backward and forward. I am not sure that a satisfactory reason can be given for continuing uniform motion, but the opinion is that the butter is formed more simultaneously, and that the backward and forward motions are apt to make the butter soft. It is certain, at all events, when the motion is uniform and rather slow, the butter, whenever it is formed, is felt to stop the motion of the agitators at once. After the cream has been broken, the motion may be a little increased, and continued so until a change is heard in the sound within the churn, from a smooth to a harsh tone, and until an unequal resistance is felt to be given to the agitators. The butter may soon be expected to form after this, and, by increasing the motion a little more, it will form the sooner, and, the moment it is formed, the motion should cease. The rate of motion in churning butter is of some importance, for, when performed too slowly, a longer time will be spent in churning than is necessary, and the butter will be strong-tasted; and, on the other hand, when the motion is too rapid, the butter will be soft and frothy, when the churning is said to have *burst*. In very warm weather, and when the cream is put in too warm, the churning is liable to burst with any degree of fast motion, and hence the judgment is required to be exercised in the circumstances. I suppose that the most proper motion in churning has never been ascertained by experiment, and to determine which would probably be tedious, but it would be worth while being tried. When butter forms from cream in ¾ of an hour to 1 hour churning, it is satisfactory work; when it comes much sooner it will be soft, and when much later it will be strong-tasted. The temperature, by agitation during churning, rises 3° or 4°.

(2055.) Immediately on being formed, butter should be taken out of the churn and put into the butter tub, one of a broad and shallow form, to be worked up. A little cold water being first put into the tub, and the tub set in an inclined position, the butter is spread out, rolled up round the edges, and pressed out by the palm of the hand, in order to deprive it of all the buttermilk—for the least portion of that ingredient retained in it would soon render it rancid. The milky water is poured off, and fresh poured in, and the butter is again washed and rubbed as often as the water becomes milky. If intended to be kept or disposed of in a fresh state, the large lump is divided and weighed in scales in 1 lb. or ½ lb. lumps each, and placed separately in the tub among water. Each lump is then clapped firmly by the hand and formed into the usual form in which pounds and half-pounds of butter are disposed of in the part of the country in which your farm is situate. For the table any requisite number of the pounds should be moulded from the lump into prints according to taste, or rolled into forms with small wooden spades, figured or plain. The

(2056)

made-up butter is then floated in jars with covers, in a clear, strong brine of salt and water, fit to float an egg, made ready for the purpose.

(2057.) Objections have been urged against the use of the hand in making up butter, and small wooden spades recommended to be employed for the purpose; and the use of water has also been objected to making up of butter, as it is said to deprive the butter of its pleasing aroma. A woman who has hot, clammy hands, should never become a dairy-maid, for, butter being very susceptible of taint, its flavor will, no doubt, be injured by the heavy smell of sweaty hands; but clean, cool hands—rendered so by washing in warm water and oatmeal, *not soap*, and then rinsed and steeped in cold water—hands so prepared will make up butter far cleaner and more solid than any instrument, whether of wood or of any other material; and as to cold water injuring butter, there can be no such strong affinity between a fatty matter like butter and cold water, as that the latter shall dissolve any essential ingredient out of the former; at all events, water will more effectually take away any milky substance from butter than any dry instrument that can be used, or even all the art the hand alone can accomplish. Let the trial be made both ways, and their comparative efficacy be tested by keeping the butter fresh, and seeing which will keep the longest *sweet*.

(2058.) If the butter is intended to be salted, it is somewhat differently treated. After being washed clean, as above described, it is weighed in the scales, and salt is immediately applied. Practice varies much in the quantity of salt given to butter, so much as from 1 oz. of salt to 1 lb. of butter, to ½ oz. of salt to 1½ lbs. of butter: 1 oz. to 1 lb. is too much—it is like curing butter with as little art as a salt herring—½ oz. of fine pure salt being quite sufficient; and this quantity is intended for keeping-butter, for as to powdered butter for immediate use, ½ oz. to 2 lbs. is quite sufficient. In the process of salting, the butter is spread out in the tub, and the salt, ground fine, is sprinkled over it by little and little, and the butter rolled up and rubbed down with the side of the hand until the whole mass appears uniform, and is considered to be incorporated with the salt. To insure uniform salting, only half the salt should be applied at once, and the butter lumped and set aside until next day, when the other half of the salt should be rubbed in. Whatever of brine or milk may have subsided from the lump, in the mean time, should be poured off. The salted lump is then put into the jar or firkin on the second day. One great advantage of deferring the making up of butter until the second day is that, without it, the butter will not assume that firm, smooth, waxy texture, which is so characteristic a property of good butter. Butter when kitted is pressed firmly down in all points, and great care taken that it be particularly pressed with the side of the finger round the circumference of the jar, and its substance made solid, and its surface flat and smooth. If a former churning of butter had been put into the jar, its surface should be raised up into regular furrows, that the new lump of butter may be commingled with what was put into the kit before. The compressing of butter, then, into the kit, is of great importance, inasmuch as, if the least cell of air be left in its mass, or get access by the side of the kit, it will *wind* the butter—that is, impart to it a rancid taste. After the kit has been filled within an inch of the top, the butter is made smooth, and covered with a new piece of wetted white linen or cotton cloth. To secure its goodness, butter should be salted immediately on being made.

(2059.) The state of the kit should be particularly examined before it is used for packing butter. If composed of stone-ware, it is easily cleansed and rendered sweet. A wooden kit that has been used before should be

filled with water for some time, to render it water-tight by the swelling of the edges of the staves. It should then be repeatedly scalded with hot water, and exposed to the air, and, just before being used, should be rinsed with cold water, and a slight sprinkling of salt scattered over its bottom. A new wooden kit requires somewhat different treatment, because the odor from the new wood will impart a disagreeable flavor to the butter. It should be filled with water mixed with garden mould, or with lime-shells and water, for some days, and the mixture occasionally stirred; after which it should be thoroughly scrubbed and cleansed with hot water, and rinsed with cold water, and salted before being used.

(2060.) The quality of the *salt* has a material effect on the taste of the butter that has been salted with it. Ordinary sea-salt contains a considerable proportion of other salts which are bitter, and, of course, they will have effect upon the butter as well as the true salt. "It is easy, however, to purify the common salt of the shops from these impurities," says Professor Johnston, "by pouring 2 quarts of boiling water upon 1 stone or 2 of salt—stirring the whole well about, now and then, for a couple of hours, and afterward straining it through a clean cloth. The water which runs through is a saturated solution of salt, and contains all the impurities, but may be used for common culinary purposes, or may be mixed with the food of the cattle. The salt which remains in the cloth is free from soluble salts of lime and magnesia, and may be hung up in the cloth till it is dry enough to be used for mixing with the butter or with cheese."*

(2061.) Butter assumes a *texture* according as it has been treated. When burst in the churning, it is not only soft but frothy, and, on being cut with the knife, seems as if it could be compressed into much less bulk. When churned too rapidly, especially in warm weather, the churning may not advance to the degree of bursting, but the butter will always continue soft, and never assume a firmness, though worked up with ever so much care, and in the coolest manner; and, when one piece is separated from another, they are drawn asunder with a jagged surface, and stick to the knife that cuts them. Soft butter will not keep long, whether salted or fresh. When over-churned—that is, when the churning has been continued after the butter had been formed, it becomes soft, not unlike the state when it is too rapidly churned. When properly churned, both in regard to time and temperature, butter becomes firm with very little working, and is tenacious; but its most desirable state is that of waxy, when it is easily moulded into any shape, and may be drawn out a considerable length before breaking. It is only in this state that butter has the rich nutty flavor and smell, which impart so high a degree of pleasure in partaking it. To judge of butter, it is not necessary to taste it—the smooth, unctuous feel, on rubbing a small piece between the finger and thumb, expresses at once its richness of quality; the nutty smell indicates a similar taste; and the bright, glistening, cream-colored surface shows it to be in a clean state.

(2062.) What I have stated in reference to the making of butter, applies especially to that obtained from cream alone, and from cream in the usual state for butter—namely, after it has become sour by keeping; but butter can be obtained from sweet cream as well, though churning renders its buttermilk sour, as well as that always is from sour cream. To have butter in perfection from sweet cream, it should be churned every day; and, as the supply of cream daily is usually very limited, a smaller churn than usual is most convenient to be used; and for this purpose there is, perhaps, none better than the table-churn figured hereafter—by the peculiar

* Johnston's Lectures on Agricultural Chemistry.

construction of which, being placed in a vessel, the temperature of the cream can be regulated in all seasons. I see it alleged in advertisements of churns of similar construction to this, that butter may be made from cream in 10 or 12 minutes. I have made several experiments with such a table-churn, in churning cream at different temperatures, and with different velocities, but never obtained good butter in less than 30 minutes; and, when formed so quickly as in 15 minutes, the butter was as soft as froth. I have heard it alleged that butter of the finest quality cannot be obtained from sweet cream; but the allegation, I suspect, is made by persons who have little experience of butter from sweet cream. So far am I from coinciding in this oplnion, that I know butter of the richest quality, and of the finest flavor and appearance, can be made from sweet cream. Were this butter not necessarily good, would the nobles of the land have it upon their tables every morning? It is true that sweet cream requires longer churning than sour—still, butter is obtained from it in from 30 to 40 minutes; and, if it is an unprofitable mode of using cream, that is a different question. For my own taste, I would never desire better butter, all the year round, than that churned every morning in a small churn from sweet cream. Such butter, on new baked oat-cake, cooled, with a little virgin flower-honey, and a cup of hot, strong coffee, mollified with crystalized sugar and cream, such as the butter had been made from, is a breakfast worth partaking of, but can seldom be obtained.

(2063.) Besides cream, butter is made from *sweet milk;* but, to obtain which, a large churn is required, and the churning continued for a long time, seldom less than 3 hours. When the quantity of milk is large, power other than human, whether of steam, water, or horse, is employed to move the churn. The butter obtained from this method is very good. The obvious objection to this method is, the labor imposed in agitating a great quantity of milk, and in consequently having a large quantity of buttermilk; which, however, may easily be disposed of in towns, and may even be converted into very good cheese. The method has its advantages in the uniform character of the butter which it affords in all seasons, from the certainty of obtaining a churning at the proper temperature, which is required to be higher than that of cream, being 65° Fahrenheit, and easily obtained, in winter and summer, by the addition of hotter or colder water among the milk. Churning from sweet milk is thus a comparatively simple process. The milk is poured into coolers at first, and from them "it is drawn off by siphons into vats sufficiently large to contain both the evening and morning meals; and the vats are then put by, to stand totally undisturbed, till the whole acquires a sufficient degree of acidity. The time required for this purpose varies a little according to the heat of the weather and the temperature of the milk-house. The point is ascertained by the formation of a strong, thick *brat* or scum on the surface, when this becomes uneven." All the milk is not of the same age, but this does not affect the quality of the whole. The times of churning are these: "The milk of Sunday and Monday is churned on the Thursday morning; that of Tuesday, Wednesday, and Thursday mornings, on the Saturday evening; and that of Thursday evening, Friday and Saturday, on the Monday morning."*

(2064.) In churning either ingredient the residuum is *buttermilk*, which, when obtained in large quantity from milk, may be disposed of in towns, or converted into cheese; and, when derived in small quantity from cream, a part may be used for domestic purposes, and the remainder mixed with the food given to the brood-sow.

* Transactions of the Highland and Agricultural Society, for July, 1843.

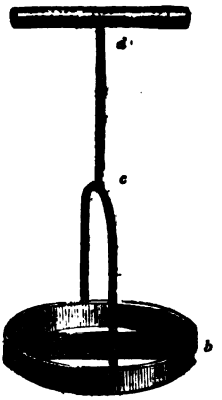
(2065.) It is now time to say something on the making of *cheese*. On a farm of mixed husbandry, as much skimmed milk cannot be procured every day as to make a cheese of ordinary size, but there may be one made every other day. To save skimmed milk from souring in warm weather till the next day, it is necessary to scald it—that is, to put it into a furnace pot, and heat it sufficiently, and then let it cool. The fire should be a gentle one, and the milk should be so carefully attended to as neither to burn nor boil, nor be made warmer than the finger can bear. After being thus heated in the morning, the milk should be poured into a cheese-tub, to await the cheese-making of the following day. The skimmed milk of next morning is poured into the same tub, except about ⅓ of it, which is put into the furnace or another pot, and made warm for the purpose of rendering the entire milk of the tub sufficiently warm. The heat is applied slowly to the pot; the milk occasionally stirred with a stick, and made as warm as the finger can hardly bear. This warm portion is then poured into the tub, the contents of which are thereby made as warm as new milk —that is, about 110° or 112°. The various degrees of heat here referred to are in rather vague terms, but I believe no specific degree of heat is required in scalding, provided the milk is not allowed to burn at the bottom of the pot, and is prevented from boiling; for, if it boil, the milk will coagulate instantly, and be useless for cheese-making, because the cheese will then be hard or flinty; and, so far as these two points are concerned, the ready and practical test of the finger is sufficiently accurate. On the contents of the tub being mixed by stirring, the rennet or earning is added to the milk, which is allowed to stand some time to coagulate, with a cloth thrown over it, to keep the proper heat.

(2066.) In the meanwhile, I shall describe the method of preparing the *rennet*, or *reed*, or *earning*. A calf's stomach is usually recommended for this purpose; but as calves' stomachs are not easily obtained in districts where calves are reared, a pig's stomach, which can be easily obtained on every farm, will answer the purpose equally well—and, indeed, many believe that it makes the stronger earning of the two. When the pigs are killed for hams in winter, their stomachs should be preserved for rennet, and they are preserved in this manner: Let the inside skin of the stomachs be taken out; the operation is somewhat troublesome, but may easily be done by an experienced dairy-maid. Any curdling in it is thrown away, as being unnecessary, and tending to filthiness; and the skin is then wiped clean with a cloth, not washed. It is then laid flat on a table, and rubbed thickly over with salt on both sides, and placed on a dish for 4 days, by which time it has imbibed sufficient salt to preserve it. It is then hung stretched over a stick near the fire to dry and won, and in the dried state is kept for use as rennet by the next season. Some people place a layer of clean wheat straw on the skin, after it is salted, and roll the skin over it to keep it open—tie a piece of paper around it, and then hang it up near the kitchen-fire to dry and won. This plan is good enough, but not better than the other. When the rennet is to be used, a strong brine of salt and boiling water, sufficient to float an egg, is made and sieved through a cloth, and allowed to cool, to the amount of 3 imperial pints to each skin. One skin is allowed to remain in that quantity of brine in a jar, with its mouth covered with bladder, for 3 or 4 days, when the coagulating strength of the brine is tested by pouring a drop or two into a teacupfull of lukewarm milk; and, when considered sufficiently strong, the brine is freed of the skin, bottled and tightly corked for use. The skin is again salted as before, and spread over a stick to dry and won, and is

again ready for use when required. Half a tea-cupfull of this rennet will coagulate as much milk as will make a 15-lb. cheese.

(2067.) When the milk is sufficiently coagulated, which it will be in half an hour, the curd is cut in the tub with the *curd-cutter*, fig. 377, which consists of an oval hoop of copper *a b*, 9 inches long and 6 inches wide, and 1½ inches deep, embracing a slip of copper, of the same depth, along its longitudinal axis *a b*. The stem *c* of round copper rod rising from each side of the oval hoop unites at *c*, and after attaining in all 18 inches in length, is surmounted by a wooden handle *d*, 9 inches in length, but 6 inches would be enough, by which it is held either by one or both hands, and on the instrument being used in a perpendicular direction, cuts the curd into pieces in the tub. Some people break the curd at first with the hand, but this instrument cuts it more effectually. On being cut, the curd lets out its whey, which is drained off by means of a flat dish being pressed against the curd-cloth, linen of open fabric, spread upon the curd. As much of the whey is removed in this way as practicable, and the curd will be left comparatively dry, when it receives another cutting with the cutter, and the whey again expressed from it. The curd is then lifted out of the tub, and wrapped into the curd-cloth, which, in the form of a bundle, is placed upon a drainer lying across the mouth of the tub, and the whey is pressed out of it by main force. This is the laborious part of the operation, and to save both time and labor in large cheese dairies, the bundle of curd is placed in a large cheese-vat, and subjected to pressure in the cheese-press to get quit of the whey. The curd becomes very firm after this pressing, and must be cut into small pieces by some instrument before it can be put into the cheese-vat. In most small dairies, I believe that the hand alone, or a table-knife, is employed to divide the curd, but a simple implement, such as represented and described below, effects the purpose with comparative ease and sufficient minuteness. The curd, being made small enough, is salted to taste with salt ground fine. In some parts of the country, such as in Cheshire, and in Holland, cheeses are salted by being floated in a strong solution of salt in water, which no doubt penetrates the new formed cheese, but it seems an uncertain mode of giving any desired degree of saltness. After being salted, the curd is put into a cheese-cloth, spread over a cheese-vat, and firmly packed into the vat higher than its edge, and on the curd being covered with the cloth, the vat is placed in the cheese-press and subjected to pressure, upon which a quantity of whey will probably exude by the holes in the bottom of the vat. In a short lapse of time, 2 hours or more, the cheese is turned out of the vat, a clean and dry cheese-cloth put in, the cheese replaced into it upside down, and again subjected to increased pressure in the press. Should whey continue to exude, the cheese must again be taken out of the vat, and a clean cloth substituted; in short, a clean cloth should be substituted, and the pressure increased, as long as any whey is seen to exude; but if the prior operations have been properly performed, the exudation should cease in about 12 hours, after which the pressure is continued until the press is wanted for a new cheese on the second day. Fig. 378 shows the common cheese-vat or *chessart*, as it is called, the form being varied according to that adopted for the cheese. This vat is built in elm staves, as being less liable to burst with pressure, and

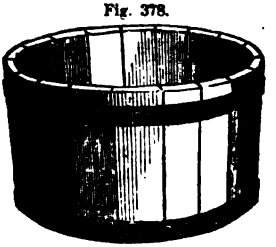
Fig 377.



THE CURD-CUTTER.

strongly hooped, and is furnished with a substantial bottom, pierced with holes, to allow the whey expressed to flow away, and a strong wooden cover cross doubled. It is of advantage that the cover fit the vat exactly, and that the vat have as little taper interiorly as possible. In some parts, as in Cheshire, cheese-vats are made of tin, with holes in the bottom. The old and inconvenient form of cheese-press, as well as the new and convenient one, are both found figured and described below by Mr. Slight. In some dairy districts large cheeses are subject to immense pressure. In Cheshire the cheese is subject to three presses, the first giving a pressure of ¼, a second of a ½, and a third of 1 ton weight. There the cheeses being unusually large, are bound round with fillets of linen until their form attains consistency.

Fig. 378.



THE CHEESE-VAT.

(2068.) After the cheeses have been sufficiently pressed, they are put into the cheese-room *h*, fig. 33, which should not be exposed to too much heat, drouth, or damp, as heat makes cheese sweat; drouth dries them too quickly, and causes them to crack; and damp prevents them hardening and wonning, and causes them to contract a bitter taste. Cheeses being exposed to a cool, dry, and calm air upon the shelves *m*, will dry by degrees, and obtain a firm skin. The skin becomes harder by being dipped in hot water, but I see no benefit to be derived from such a practice. They should be wiped with a dry cloth, to remove any moisture that may have exuded from them, and turned daily. To expedite the process of turning and rubbing, a cheese-rack, such as is figured below, has been in use in England, and found to answer the purpose. New cheeses, as they are made, are set in the rack, while as many of the oldest are removed from it and placed upon the shelves. Some cheeses burst, and throw out a serous-like fluid, which accident happens in consequence of the whey which was left in it fermenting, and which should have been pressed out. Any cheese that changes the shape which the cheese-vat gave it, should be suspected of some organic change taking place within it; but if such a cheese does not crack, so as to admit the air into it, it may soon become ripe and mould, and prove of fine flavor. The inconvenience of cracks in cheese, is the facility afforded to the cheese-fly to enter and deposit its eggs; and to prevent their egress, the cracks should be filled up every day with a mixture of butter, salt, and pepper, made to a proper consistency with oatmeal.

(2069.) But the casualties which I have mentioned are less likely to befall skimmed-milk cheese, the making of which I have been describing, than new or sweet-milk cheese. These are made exactly in the same manner with the milk as it comes from the cow. One day's milk being insufficient for a cheese, the fresh morning's meal is mixed with the meals of the previous day, the oldest part of which will have thrown up a covering of cream, which is mixed through the milk, and the entire gatherings are heated with a portion of the morning's milk. The rennet is applied in the same manner, but in rather larger quantity. Greater difficulty will be found to squeeze the whey entirely from the curd than with the skimmed milk, and it is the difficulty of expressing all the whey out of them which renders sweet-milk cheeses more liable to ferment, and burst and lose their shape.

(2070.) I have said nothing of employing *annotto* or *arnotto* for dyeing cheese, because I think it a very useless piece of trouble which cheese-

farmers impose upon themselves. It is employed in Gloucestershire to the extent of 1 oz. of arnotto to 1 cwt. of cheese; and in Cheshire, 8 dwts. to 60 lbs. of cheese, and it costs from 1s. to 1s. 6d. per lb. Arnotto is a precipitate from maceration of the pulp which covers the seeds of the *Bixa orellana* of Linnæus. It is manufactured in two forms, one in *flags* or *cakes* of 2 lbs. or 3 lbs. each, of a bright yellow color, soft to the touch, of good consistence, and comes from Cayenne wrapped in banana leaves, and is much used in giving an orange tint to silk and cotton goods, but which is not permanent; and the other kind is called *roll* arnotto, which is small, not exceeding 2 oz. or 3 oz. each, hard, dry, and compact, of a brownish-color outside and red within, is brought from Brazil, and is the kind used in the dairies. The duty on the roll kind used to be £5 12s. per cwt., and is now 4s.* When employed it is put into the milk before the earning, and it is prepared by rubbing down the requisite quantity in a bowl of warm milk. All the quantity employed is said to impart no peculiar flavor to the cheese, and this being the acknowledged case, of what utility is it? for as to the appearance of cheese, I suppose it will be allowed that Stilton and Dunlop cheese look as well on a table as that of Gloucester and Cheshire. Marigold flowers, saffron, and carrots, are also employed to give color to cheese.

(2071.) The yield of dairy-cows varies so much, even in the same circumstances, that no average result can be depended upon. I have had cows of the same breed give from 8 to 17 Scotch pints a-day, that is, from 16 to 34 quarts; and I have known a cow of a cross breed give 60 quarts a-day. So is the variation in respect of the quality of the milk. I have had cows whose milk would only yield a thin film of cream in the course of 24 hours, while that of the others would almost admit of its cream of the same age being lifted off with the fingers. But though I can say nothing satisfactory on this head, I may state a few of the circumstances which are supposed to have a controlling influence on the quantity and quality of the milk of cows.

(2072.) The circumstances which affect the *quantity* of milk are the *breed*; the smaller breeds yield the smaller quantity, and the yearly quantity of the large and small breeds may vary from 4900† to 2400‡ quarts; *the kind of food*, cows fed on succulent food, such as moist meadow-grass, brewers' and distillers' refuse, and new sown grass, will yield a larger quantity of milk than when fed on hay and roots, and old pasture: and the *time from calving*, which, according to a statement of Mr. Aiton, causes a variation from 1200 quarts in the first 50 days, to 300 quarts in the sixth 50 days after calving.‖

(2073.) The circumstances which affect the *quality* of milk are more various. The *breed* has an effect; the small ones yield richer milk than the large, in which respect the small Kerry cow is superior to the large Yorkshire. *The kind of food*, hay, corn and oil-cake, produce richer milk than turnips and straw, and yield more butter; and bean-meal and tares afford more cheese than oil cake, corn, potatoes and turnips. In the *time from calving*, it is well known that the first milk of a cow, called the *biestings* (1677), is much richer than the ordinary milk which the cow afterward gives. It has a different composition from milk, and acts as a purgative to the new-born calf, which is of essential use to it at that period of life, in removing the sticky sort of dung called the *meconium*, from its bowels. You thus see how erroneous is the practice of those breeders of calves who throw away the biestings as injurious. In *wet and cold* weather the milk is less rich than in dry and warm; and on this account more cheese should be obtained in cold, and butter in warm weather. The *season* has its effect; the milk in spring is supposed to be best for drinking, and hence it is then best suited for calves; in summer it is best for cheese, and in autumn for butter; and hence, perhaps, autumn butter keeps better than that of summer, because it contains less of the caseous principle. Cows *less frequently* milked than others will give richer milk, and consequently more butter; *morning's* milk is richer than the evening's; and the *last drawn milk* of each milking, at all times and seasons, that is, the afterings or strokings, are well known to be the richest part of the milk, and the first drawn the poorest. A cow, *before she is again in calf*, gives richer milk than when she is pregnant, a portion of the secretion which supplies the richer milk being, no doubt, withdrawn to support the fœtus. A *well-formed* cow will give more and better milk than an ill-formed one. *Old pasture* will produce richer butter than new. Cows *kept constantly in the byre* are said to give richer milk than those allowed to go at large at pasture, but the latter are supposed to yield more cheese;—the exercise, perhaps, preventing the due proportion of the richer secretion. Many other circumstances may be known in different localities to affect the quantity and quality of the milk of cows; but a sufficient number are here related to show how perplexing a thing it is to conduct a dairy in the most profitable way.

(2074.) The phenomena accompanying the changes in milk are well known to every dairy-maid, but few of them know that the constituent parts of milk are only mechanically commixed; and this must be their state even in the udder of the cow, otherwise the afterings, which had occupied the upper part of the udder, would not be the richest portion of the milk, nor the first drawn the

† Dickson on Live Stock, vol. i. ‡ Aiton's Treatise on Dairy Husbandry. ‖ Ib.

purest. All, therefore, that is required to separate the different parts of milk is rest and time. The cream or fatty part floats to the surface in the course of a few hours; in a little longer time, according to the state of the temperature, the caseous portion becomes sour, and in a still greater length of time the acidity becomes so powerful as to coagulate the milk in one mass, and in a still greater lapse of time the coagulated mass separates into two parts, one becoming firmer, or cheese, the other again fluid, or whey. The rationale of this natural process is thus well given by M. Raspail:—"Milk, when viewed by the microscope with a power of only 100 diameters, exhibits spherical globules, the largest of which are not more than .0004 of an inch in diameter, and which, from their smallness, appear of a deep black at the edges. These globules disappear on the addition of an alkali, such as ammonia, and the milk then becomes transparent. If the proportional quantity of milk be more considerable, it forms a coagulum of a beautiful white color, on the addition of concentrated sulphuric acid. This coagulum does not arise simply from the adhesion of the globules to each other, but it may be plainly seen by the microscope, that the globules are evolved in a transparent albuminous membrane, which has no appearance of a granular structure. Milk, then, is a watery fluid, holding in solution *albumen* and *oil*, by the agency of an alkaline salt or a pure alkali, and having suspended in it an immense number of globules which are in part albuminous and in part oily. The albuminous globules must tend to subside slowly to the bottom of the vessel by their specific gravity, while the oily globules must have a tendency to rise to the surface. But the oily globules being dispersed in myriads amid equally numerous albuminous globules, they cannot rise to the surface, without taking with them a greater or less number of the globules of albumen. Hence, at the end of 24 hours, we find on the surface of the milk a crust composed of 2 layers, the upper one of which contains more butter than milk, while the lower contains more milk than butter. This separation will take place equally with or without the contact of the air. The liquid part which lies under the crust contains the dissolved albumen and oil, with a portion of the sugar, the soluble salts, and a certain quantity of the albumen and oily globules."* Cream cannot rise through a great depth of milk. If milk is, therefore, desired to retain its cream for a time, it should be put in a deep narrow dish; and, on the other hand, if it is desired to free it most completely of its cream, it should be poured into a broad flat dish, not much exceeding 1 inch in depth. The quantity of cream which any given milk contains can be easily measured by the *Galactometer*, which consists of a narrow tube of glass not more than 5 inches in length, 3 of which are divided into 100 parts, and on being filled with milk to the top of the graduated scale, whatever number of degrees the thickness of the cream embraces, will be the per centage of cream yielded by the milk. For example, if the cream covers 4 lines of the scale, it is 4 per cent., if 8 lines, 8 per cent. The evolution of cream is facilitated by a rise, and retarded by a depression, of temperature. At the usual temperature of the dairy at 50° Fahrenheit, all the cream will probably rise in 36 hours, and at 70° it will, perhaps, all rise in half that time; and if the milk is kept near the freezing point, the cream will rise very slowly, because it becomes partially solidified. Milk boils and freezes about the same temperature as water. Milk may be prevented becoming sour by being kept in a low temperature; in a high temperature, on the other hand, it rapidly becomes sour, and, at the boiling point, it curdles immediately. The acid of milk is called the *lactic acid*, and, in its nature, resembles acetic acid, the acid of vinegar.

(2075.) *Milk* contains many very different substances in its composition, to each of which may easily be traced the origin of its various properties. I shall give the composition of biesting, along with that of milk, from the analyses of MM. Henri and Chevalier, in order to shew the great difference between them. It appears that biesting contains nearly 3 times more casein than milk, and only a trace of sugar of milk, no salts, and a large proportion of mucus; and more than 9 times more casein than mare's milk:

	According to Henri and Chevalier.						According to Lassaigne and Boudet.

Butter gives its richness to milk, sugar its sweetness, casein its thickness, water its refreshing property as a drink, and salts its peculiar flavor. Of the different kinds of milk enumerated above, the superior sweetness and thinness of mare's milk are accounted for by the large proportion of sugar and the small quantity of casein it contains. "The change which takes place when milk becomes sour, is, therefore, easily understood," as well observed by Professor Johnston. "Under the influence of the casein the elements of a portion of the milk-sugar are made to assume a new arrangement, and the sour lactic acid is the result. There is no loss of matter, no new elements are called into play, nothing is absorbed from the air, or given off into it, but a simple transposition of the elements of the sugar takes place, and the new acid compound is produced. These changes appear very simple, and yet how difficult it is to conceive by what mysterious influence the mere contact of this decaying membrane, or of the casein of the milk, can cause the elements of the sugar to break up their old connection, and to arrange themselves anew in another *prescrib-*

* Raspail's Organic Chemistry.

ed order, so as to form a compound endowed with properties so very different as those of lactic acid."

(2076.) "*Cream* does not consist wholly of fatty matter (butter)," observes Professor Johnston, "but the globules of fat, as they rise, bring up with them a variable proportion of the casein or curd of the milk, and also some of the milk sugar. It is owing to the presence of sugar that cream is capable of becoming sour, while the casein gives it the property of curdling when mixed with acid liquids, or with acid fruits. The proportion of cheesy matter in cream depends upon the richness of the milk, and upon the temperature at which the milk is kept during the rising of the cream. In cool weather the fatty matter will bring up with it a large quantity of the curd, and form a thicker cream, containing a greater proportion of cheesy matter. The composition of cream, therefore, is very variable—much more so than that of milk—and depends very much upon the mode in which it is collected." In warm weather, therefore, the cream should be rich though thin. Cream, at a specific gravity of 1.0244, according to the analysis of Berzelius, consists of

Whey	92.0
	100.

(2077.) "*Butter*," says Professor Johnston, "prepared by any of the usual methods, contains more or less of all the ingredients which exist in milk. It consists, however, essentially of the fat of milk, intimately mixed with a more or less considerable proportion of casein and water, and with a small quantity of sugar of milk. Fresh butter is said to contain about 1-6 of its weight (16 per cent.) of these latter substances, and 5-6 of pure fat, according to Chevreul. How much of the 16 per cent. usually consists of cheesy matter," may be seen by this statement:—"two samples of fresh butter from *cream*, examined in my laboratory, have yielded only 0.5 and 0.7 per cent. respectively. This is certainly a much smaller quantity than I had expected. Does butter from the *whole milk* contain more?"* The proportions of butter yielded by milk varies considerably, from 1 lb. of butter to 15 quarts of milk, as in Holstein, to 8 quarts of milk of the Kerry cow †

(2078.) *Curd* in a state of purity is named *casein*. "Casein has many properties in common with the albumen of blood," says Dr Thomson, "and, like albumen, may be obtained in two states, namely, uncoagulated, when it is soluble in water, and coagulated, when it is insoluble in that liquid. It is precipitated from its aqueous solution by acetic acid, which is not the case with albumen. It is coagulated by a boiling heat, but slowly; separately in films, which collect upon the surface of the liquid. Coagulated casein subjected to pressure to free it from the whey constitutes cheese. If cheese consists of nothing but casein, it has a bluish-white color, is very hard, almost like horn, and is quite insipid. Good cheese is always made from milk still retaining its cream. It is impossible to state the proportion of casein which exists in milk, because it varies so much, not only in the milk of different animals, but also in that of the same animal at different times. According to Berzelius, 100 parts of skimmed milk, which he analyzed, contained 2.8 of casein." The average proportion of curd to milk is thus given by Dr. Dickson.—"Exact and repeated trials have shown that about 15 gallons of milk are necessary for making about 11 lbs. of 2-meal cheese, and that 1 lb. of curd is produced from 1 gallon of new milk. And as the food afforded by the extent of from 2¼ to 3¼ acres of land is commonly supposed sufficient for the support of 1 cow the year round, by taking the medium of 355 lbs. of cheese for each cow, the quantity of cheese produced by 1 acre will be 118 lbs., which is supported by the authority of many statements. But during the summer season, cows will afford from 14 lbs. to 20 lbs. of cheese, or more, in the week, when no butter is made."‡

(2079.) *Whey* has a yellowish-green color, and an agreeable and sweetish taste, in which the flavor of milk may be distinguished. Almost the whole curd may be separated by keeping the whey for some time at a boiling temperature. "It still retains its sweet taste," says Dr. Thomson, "but much of the milky flavor is dissipated. If it be now evaporated over the steam-bath, it deposits a number of crystals of sugar of milk. Toward the end of the evaporation, some crystals of chloride of potassium, and some of common salt, make their appearance. According to Scheele, it contains also a little phosphate of lime, which may be precipitated by ammonia." "The sugar of milk constitutes, at an average, about 3.5 per cent., while the saline ingredients do not exceed 0.22, or 2.9 of a per cent. of whey. The water, of course, constitutes about 93.3 in the 100 parts."

(2080.) Schwartz found that 1000 parts of cows' milk left 3.697 of ashes, and of woman's milk 4.407, composed of

	Cow's.	Woman's.
Phosphate of lime	1.805	2.5
Phosphate of magnesia	0.170	0.5

Chloride of potassium	1.350	0.7
Soda, combined with lactic acid	0.115	0 3
	3.697	4.407

(2081.) There are a number of other facts given by Dr. Thomson connected with milk in various states, worth mentioning. The constituents of *skimmed* milk, for example, according to the analysis of Berzelius in 1808, are—

Brisson states the specific gravity of various milks: but it is important to remark, that it varies so much even in the milk from the same animal, that it is impossible to give a correct mean. The specific gravity of cows' milk is the lowest, being 1.0324; its whey is, of course, still lower, 1.0193; and that of ewes' milk is the highest, being 1.0409. Lassaigne examined the specific gravity of cows' milk at various distances of time before and after parturition, at a temperature of 46° Fahrenheit, and the results were generally, that at 21 days before parturition it was highest, being 1.064; and lowest at 6 days after parturition, being 1.033. The cow, from 42 days before to 30 days after parturition, was fed on the same kind of food, namely, beet-root, hay, and straw. Lassaigne also ascertained the quantity of cream yielded by the same animals at different times. There was no difference in the ratio between the bulks of cream and whey from the same cow, fed on beet root, hay, and straw, from 42 days before to 4 days after parturition, when the quantities were 200 volumes of of cream to 800 of whey; but by 30 days after parturition, the volume of cream had *decreased* to 64, and that of whey had *increased* to 936, and by that time the water in 100 parts of milk had also increased to 90.0. Lassaigne made a curious remark respecting the milk of a cow, which he examined at 10 different periods, 4 of these before and 6 after parturition. The milk examined during the first three of the former periods, namely, 42 days, 32 days, and 21 days *before* parturition, contained no casein at all, but in place of it albumen; no sugar of milk and no lactic acid, but a sensible quantity of uncombined soda. The milks examined 11 days before and just after parturition, contained both albumen and casein, while milk 11 days before parturition, and always after it, contained free lactic acid and sugar of milk, but no free soda. The milks examined 4 days, 6 days, 20 days, 21 days, and 30 days *after* parturition, contained casein and no albumen. It would appear from these observations that the milk of the cow is at first very similar to the serum of blood, and that the casein, sugar of milk, and lactic acid, to which it owes much of its distinguishing characters, begin first to make their appearance in it about 11 days before parturition.

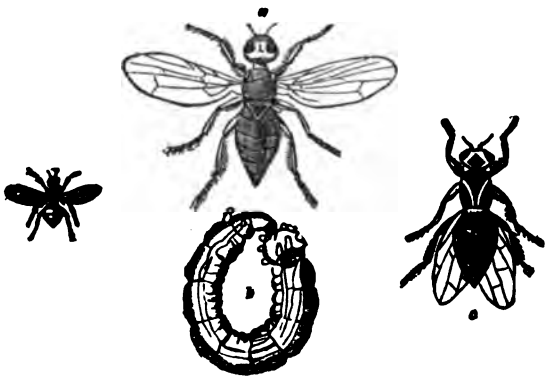
(2082.) A great deal more might be given in detail of experiments made in different parts of the country on churning butter at different temperatures, and of the various recipes for making the innumerable variety of cheeses to be found in this country; but as those experiments are merely so many isolated attempts to illustrate particular points, without reference to general principles, their results are unsatisfactory. In like manner the numerous experiments in the laboratory on milk and its constituents have as yet led to no improvement in practice. The field, therefore, to the practical and chemical experimenter is still open, and it might be usefully explored by their combined labors, with a view to the establishment of general principles on the best mode of keeping dairy stock, and of evolving their products, in a superior degree than hitherto attained. As one instance of a want of common understanding on this subject, I may adduce the numerous forms in which the cheeses of Scotland are made, whether in the homely *kebbuck*, or in the finished new-milk cheese intended for city epicures. Everywhere else but in Scotland the place of origin of a cheese may be told by its form. A Parmasan, a Gruyére, a Gouda, a Kanter, an Edam, a Cheshire, a Gloucester, whether double or single, a Wiltshire, a Cheddar, or a Stilton, can be named at sight, but who can tell where a Scotch cheese, whether of skimmed milk or new, whether poor or rich, comes from, until examined by a connaisseur? for its Stilton or Wiltshire form would not necessarily imply an imitation of those celebrated substances. There should be some settled conventional forms adopted for the identification of the respective classes of cheese of this country, that they may pass current in commerce without suspicion and challenge. I shall finish this interesting subject with recipes for making a number of pleasant dishes from milk, all of which are in the power of every farmer to have in summer as a cool diet. *Curds* are obtained by simply earning a dishfull of new milk. When served up with grated loaf-sugar, sprinkled over the curd deprived of whey, it has the appearance of a prepared dish, and is eaten with sugar and cream. A *sour cog* is a dish of milk allowed to stand with its cream until the milk becomes thoroughly coagulated by sourness, and the sour cream and milk are eaten together. *Plain cream*, whether sweet or sour, is an excellent accompaniment to oatmeal or barley-meal porridge, or to sowens. The *clouted cream* of Devonshire is prepared by straining the new milk into a shallow dish, into which a little warm water has previously been put; and after allowing it to stand from 6 to 12 hours, it is carefully heated over a slow fire or hot plate till the milk approaches to the boiling point, but it must not actually boil, or the skin of cream be broken. The dish is then removed to the dairy, and the cream allowed to cool, when it may be used as cream or made into butter. *Milk oatmeal porridge* is more agreeable to the palate than water porridge, and when eaten with cream forms a rich diet. *Half churned cream* is better with oatmeal porridge than plain cream, having a slight taste of acidity. *New unwashed butter* is a great treat to breakfast. *Hatted kit* is one of the pleasantest preparations of milk. Make 2 quarts of new milk scalding hot, and pour upon it quickly 4 quarts of fresh buttermilk, and let it stand, without stirring, till it becomes cold and firm. Then take off the hat or upper part, drain it in a hair-seive, and put it into a shape for half an hour, and serve with cream. The slight acidity of this dish, with the rich sweetness of the cream, and the addition of a little sugar, combine to make this a very delicious dessert. *Float-whey* is another preparation equally good as hatted kit, and more delicate. Pour in all the whey drained from the new-milk cheese that has just been made, into a small furnace pot; apply a slow fire, and raise the whey near the boiling point, but not to let it boil, else the curd will fall to the bottom. During the heating, a scum of curd forms upon the

surface of the whey. Take, then, 1 quart of fresh buttermilk, and pour it gently over the scum, and pour as much more buttermilk till the scum has attained some thickness and consistency. After pouring in some cold water to lower the temperature of the whey, thereby rendering the scum more consistent, skim off the scum upon a hair-sieve, put it into a mould, and on turning it out a short time after, serve with sugar and cream. A *treacle posset* is made by boiling a little milk in a pan and putting a table-spoonfull of treacle or molasses into it. On removing the curd the whey is ready for use for a sore throat or cold. *White-wine whey* is made exactly in a similar manner, but is sweetened in addition. To make *Irish two-milk whey*, put ½ of sweet milk into a saucepan, and make it boiling hot, then pour in ½ of buttermilk, gently stirring it round the edges of the pan. Let the whole come to a boil; take it off the fire, let it settle, and strain off the whey, which is an excellent drink in fever. *Cream* may be used as an emulsion with all sorts of preserved fruits, and it enhances the flavor of every kind of fruit used with it; and there is, perhaps, no form of cream more agreeable or more generally admired, than *blanc mange* flavored with almonds. *Iced-cream* flavored with pine-apple is a delightful cooler in warm weather. I conclude with a recipe for making *cream-cheese*. "One pint of cream being mixed with 12 pints of noonday milk, warm from the cow, a little rennet is added, and when the curd is come the whey is poured out gently, so as to break the curd as little as possible. It is then laid in a cloth, and put into a small sieve; the cloth is changed every hour during the day, and in 24 hours it will be fit for use. It may be served on a breakfast-plate with vine-leaves under it, and it will keep perfectly good only one day."*

(2083.) Notwithstanding the immense quantity of cheese made in this country, a large importation of foreign takes place every year, not less than 132,000 cwt. chiefly from Holland. The old duty of 20s. per cwt. is retained by the New Tariff.†

(2084.) Cheese is liable to many casualties besides those already alluded to as arising from fermentation, chiefly from the attacks of animals. When yet quite fresh, the cheese-fly *(Piophila casei)*, *a*, fig. 379, is ready to deposit its eggs in the deepest crack it can find by means of

Fig. 379.



CHEESE-FLY AND MAGGOT—PIOPHILA CASEI; AND WHEAT-STEM-FLY—CHLOROPS PUMILIONIS.

an extensile abdominal tube. The specific distinguishing characters of this insect are, in the words of Mr. Duncan, "about 2 lines in length, the whole body of a greenish-black color, smooth and shining; front of the head reddish-yellow, paler yellow on the under side; thighs ochre yellow at the base and apex; tibiæ deep ochre, the first and last pair black at the apex; anterior tarsi black, the others ochrey, with 2 last joints and the claws black; wings clear and iridescent, slightly tinged with rust-color at the base; halteres ochrey."‡ The cheese-maggots produced from this fly are commonly called *jumpers*, and it prepares itself for jumping as seen at *b*. "When it prepares to leap, our larva first erects itself upon its anus, and then bending itself into a circle, by bringing its head to its tail, it pushes forth its unguiform mandibles, and fixes them in 2 cavities in its anal tubercles. All being thus prepared, it next contracts its body into an oblong, so that the two halves are parallel to each other. This done, it lets go its hold with so violent a jerk that the sound produced by its mandibles can be easily heard, and the leap takes place. Swammerdam saw one, whose length did not exceed the fourth part of an inch, jump in this manner out of a box 6 inches deep, which is as if a man 6 feet high should raise himself in the air by jumping 144 feet! He had seen others leap a great deal higher."‖ When cheese passes its stage of ripeness, it is liable to become mouldy, if kept in a damp situation, which all ripe cheeses should be to retain their moisture and flavor, and where the latter is much enhanced by the production of blue mould. It is possible to inoculate new cheese with the blue mould of old, and thereby at once impart the flavor of ripeness. This process is easiest done by inserting rolls of moulded cheese, extracted by the scoop or *spyler*, into holes previously made in the new cheese by the same scoop, an instrument usually employed by cheesemongers to taste cheese.§ Toward

* Dalgairn's Practice of Cookery. † McCulloch's Dictionary of Commerce, art. *Cheese*.
‡ Quarterly Journal of Agriculture, vol. ii. ‖ Kirby and Spence's Introduction to Entomology, vol. ii.
§ Prize Essays of the Highland and Agricultural Society, vol. ix.

a still farther period of decay, cheese is attacked by the well known, and, by some, the highly-prized cheese-mite (*Acarus siro* of Linnæus). "We often wonder how the cheese-mite is at hand to attack a cheese wherever deposited; but when we learn from Leewenhoek that one lived 11 weeks gummed on its back to the point of a needle without food, our wonder is diminished," say Kirby and Spence. Both cheese-maggots and mites, when numerous, destroy cheese rapidly, by crumbling it into small pieces, and by emitting a liquid substance, which causes the decayed parts to spread speedily. They may easily be killed, however, by exposure to strong heat, or by plunging the cheese in some liquid capable of destroying the larvæ, without communicating any disagreeable flavor, such as whisky. Rats and mice are remarkably fond of, and commit sad havoc among, old cheese. Nothing but a cat can deter them from a cheese cellar, where poison cannot be employed with impunity.

(2085.) The process of churning, or agitating milk and cream for the production of butter, is performed in such a variety of machines, and in vessels so variously formed, each of which has its advocates, and, probably, with but little difference in the principal results, that it becomes a question of no small difficulty to answer, which of these numerous forms is the best. That there will be slight differences is at the same time sufficiently apparent, but these will arise more from the capacity of the vessel, as affecting temperature, than from peculiarity of structure, and probably, also, from other conditions affecting the chemical changes that take place during the process. It will also be obvious, on a full consideration of the subject, that causes of difference will arise, to some extent from the circumstances attending the more or less perfect nature of the agitation produced, as arising from the peculiar formation, and the motions, whether of the containing vessel or of the agitators.

(2086.) The peculiarities of form may be viewed under four distinct classes. 1. Those in which both the fluid and the containing vessel, with its agitators, are in rotative motion; 2. In which the containing vessel is at rest, and the agitators in rotative motion horizontally; 3. In which the containing vessel is at rest, and the agitators in rotative motion vertically; and 4. Wherein the containing vessel is still at rest, and the agitator having a rectilineal vertical motion.

(2087.) In the first class are to be noticed those machines acting by their gyration on a center, such as the old barrel-churn, wherein the contained fluid will have a tendency to acquire a motion of rotation approaching to that of the vessel; and if this rotation were continued always in the same direction, the process would be very much retarded from a deficiency of agitation; hence, in such machines, very frequent changes in the direction of the rotative motion is absolutely necessary to the completion of the process.

(2088.) The second class embraces those in which the vessel is permanent, and an agitator of two or four arms revolves horizontally within it. If the vessel is cylindrical the agitation will be imperfect, for the fluid will very soon acquire a motion *en masse*, and will be carried forward by the arms of the agitator, undergoing such agitation only as will arise from the central portion, acting by the centrifugal force, having always a tendency to fly toward the circumference of the revolving mass. This will no doubt ultimately, though slowly, produce the requisite effect, but it will be more speedily accomplished if the vessel is of a square form; for in that case the rotation of the mass will be interrupted at every angle, and eddies formed therein of such force as will not only cause disturbance of the fluid in these angles, but in doing so will produce corresponding counter-motions in the entire mass. From such causes, churns of this class and of the square form are found, especially on the large scale, to be very efficient, though, from the inconvenience of adapting manual power to a horizontal motion, it is seldom resorted to in the small scale.

(2089.) In the third class of machines, where the vessel is also permanent, but having the agitators revolving in a vertical direction, the agitation is regular, and pervades at all times the entire mass of fluid; and in this respect there is little if any difference in effect, whether the bottom of the vessel be flat or cylindrical, nor is there any necessity for changing the direction of motion. We accordingly find that whether on the large or small scale, churns of this class find favor in almost all localities.

(2090.) The fourth class of this useful machine is the upright or plunge churn. The vessel in this is also permanent, and its hight, unlike all the others, is considerable, as compared with its breadth. As a matter of convenience, it is always made cylindrical, or rather slightly conical, which last property is given to it for the convenience of looping, for in every other respect its tapering form is a defect. The plunger must necessarily always move vertically, without any rotative motion, and, when extended throughout the entire column of fluid, the agitation must be as complete as it is possible to attain. Plunge or vertical churns, therefore, are by many held as the most perfect for the production of butter, as well as for saving time in the operation: but there are objections to it as regards fitness for the adaptation of manual power. It is obvious to even a careless observer that the human arm, if applied directly to the upright staff of this churn, the body being also upright, will be employing that power under the greatest possible disadvantages. The muscles of the arm acting, as they do, in all cases under great natural disadvantages in respect of their leverage, will, in their peculiar position, be deprived of nearly all aid which the muscles of the trunk in many positions are calculated to give out to assist those of the arm; hence it is that the labor of working these churns by hand, is found so oppressive that the operator is unable to keep up a constant action: and the principle on which the churn is based is blamed for that delay in the operation, that ought rather to be attributed to the defect in the medium through which the power is applied. In proof of this, we find that when animal, or any of the inanimate powers, are applied to the vertical churn, it attains a character superior to all others, both as to time and production, and this character is sustained throughout some of the best dairy districts in Scotland. The advantages of applying hand-power through a proper medium are also observable in the case of this churn, when such power is applied through a winch-handle with a fly wheel. Examples of this arrangement have been attended with the best effects, and with much ease, as compared with the direct application of the power to the plunger rod.

(2091.) In proceeding to the details of the churning machinery, the first class embraces th se

machines that act by their gyration round a center, the fluid and the containing vessel revolving together, or partially so; of which the common barrel-churn may be taken as the type. The barrel, which is of capacity suited to the dairy, is sometimes provided only with a large square bung-hole, secured by a clasped cover, by which it is charged and emptied; while in other cases one of its ends is movable, and made tight by screwing it down on a packing of canvas cloth. In all cases it is necessary that the interior of the barrel should be armed with three or more longitudinal ribs of wood standing as radii toward the center, and perforated in various forms; these constitute the agitators of the churn. Each end of the barrel is furnished with an iron gudgeon or journal strongly fixed to it, and to one of them is applied the winch-handle by which the machine is turned; while it is supported on a wooden stand, having bearings for the two journals. More than one imperfection attends this construction of churn; from the circumstance of its rotatory motion, it will always have less or more of a tendency to carry the fluid round with the barrel and the agitators, more especially if a rapid velocity of rotation is given to it; and to counteract this tendency, it becomes necessary to reverse the motion at every few turns, which is of itself an inconvenience. There is, besides, the great inconvenience of getting access, either to remove the butter that may adhere to the agitators, or to cleanse the interior of the barrel. This is especially the case where there is no movable end; and even with this convenience for cleaning, the trouble of opening and closing the end is considerable. To those imperfections it is, no doubt, chiefly owing that this churn, once in high repute in East-Lothian and Berwickshire, has gradually fallen into comparative disrepute; and from these circumstances, it has been deemed necessary to give figures of this class of churn.

(2092.) The machines to be here noticed under the second class, are of a less varied character than any of the others, are seldom, if ever, used with hand-labor, but are generally worked by horse-power, and chiefly in town-dairies, or in those around Edinburgh. From the comparatively small importance of this churn, it has been deemed necessary to give a figure of it; but its structure is so simple, that the following description will convey a tolerably correct knowledge of its construction to the mechanical reader. The horse-path, especially in towns, where space is valuable, seldom exceeds 16 feet: the horse-beam, with yoke, is fixed to an upright central shaft, which carries a spur-wheel placed at a hight of about 3½ feet from the floor, the wheel being about 4 feet diameter. One, or sometimes two, churning vessels are attached to the machine; their dimensions vary with the extent of the dairy, but for one of 25 or 30 cows, where much of the produce is sold as sweet milk, the vessel may be 2 feet 8 inches square and 2 feet 8 inches deep; they are placed securely on the floor at a proper distance from the central shaft, to suit the spur-wheel. A foot-step of metal is placed in the center of the bottom, and a cross-head is attached to two uprights fixed on opposite sides of the vessel. The foot-step and cross-head serve as the two bearings for an upright spindle, which carries the four-armed agitator, and a pinion of 3½ inches diameter adapted to the spur-wheel. These parts, and a close cover for the vessel, complete the machine, which is, therefore, extremely simple, and in a dairy which is too extensive for manual power being applied effectually to churning, while want of space may preclude the adoption of more bulky machines, the one here described may be resorted to with advantage.

(2093.) In the same class stands the *table churn*, remarkable for its elegance and cleanliness, and which, though adapted only for the lighter purposes of the butter-dairy, I have considered as deserving a place here. This utensil is represented in fig. 380 in perspective, exhibiting it in the most recently improved form, with outer case to contain hot or cold water. This churn has for the last few years been brought prominently before the public as a recent invention; but on close inquiry, I find that the merit of its original introduction is due to the late celebrated Mr. Wedgewood, and that it has been in use for a period of 30 or 40 years. The containing vessel is still formed of the Wedgewood stoneware; and, as I am informed by Mr. Child of Edinburgh, the indefatigable purveyor of elegance, utility, and comfort, in the china, stoneware, and glass trade, it was in great request about 30 years ago, its lately extended appearance being merely a revival. The chief part of the utensil is the Wedgewood receptacle *a*, formed of the finest and strongest white glazed ware of that manufacture; they are of various sizes, from 1 to 4 gallons capacity; it is furnished with a varnished wooden cover *b*.—The outer case *c* is made of zinc or of tin plate; it is 2 inches wider than the churn, furnished with handles *d*, and two ears to which the iron cross-bar *e* is attached by two thumb-screws *e* and *d*, serving to secure the cover to the top of the vessel. A brass socket *f* is fixed in the cover, and an iron spindle armed with three vanes is fitted to turn in the socket, a wooden pulley is usually placed in the position of the wheel *g* on the top of the spindle, and when secured there it holds the spindle and cover in constant connection. The common drill-bow is the usual medium of power, the string of which being held in tension by the elasticity of the steel-back or bow, any movement backward or forward of the instrument will cause the pulley and spindle to revolve, and the movements are effected by applying the hand to the handle of the drill-bow. When the cover and spindle have been secured by the screws *e* *d*, and the bow-string applied as above, which is effected by bending the bow until the string is sufficiently relaxed to allow of its being laid once round the pulley, the bow is then allowed to ex-

Fig. 380.

THE WEDGEWOOD TABLE CHURN.

pand, and the operation proceeds. It has been stated (2087) that vessels in this class, if cylindrical, do not produce the effects of churning so speedily as if the form were square, to obviate which the motion of the agitator must be frequently reversed in the cylindrical vessel. The drill-bow motion is admirably adapted to the reversing process; for in pushing the bow forward by the hand, the agitator will be made to revolve 2 or 3 times, the number being in the proportion of the length of the string to the proportion of the pulley; and in drawing them back the same number of revolutions will be performed in the opposite direction, and so on till the process is completed. Fig. 381 is a view of the agitator, *a a a* are the vanes of strong tin-plate with perforations, *b* is that part of the spindle that falls within the socket, and *c* that on which the pulley or the wheel is fastened.

Fig. 381.

THE AGITATOR.

(2094.) The drill-bow being rather an awkward medium of power, especially in non-mechanical hands, an attempt has lately been made to substitute for it, in this case, the common winch handle turning horizontally. This arrangement is exhibited also in fig. 380, where *k* is a toothed beveled wheel of 4 inches diameter, on the axle of which the handle *i* is fixed, and it works into the wheel *g* fixed on the top of the agitator spindle in the place formerly occupied by the pulley, the two standards *l l* being fixed on the cover *b*, to carry the axle of the wheel *k*. By this arrangement two turns of the handle *i* produce the same result in the agitator as was done by one stroke of the bow, and the motion of the handle being reversed at every second revolution, the ultimate effect is the same as before, and the manual operation is more easily effected in the one case than in the other. With a view to determine whether the alternate motion may not be dispensed with even in a cylindrical vessel, I have instituted experiments in which the interior of the vessel is armed with combs, and the agitator being converted to a like form, but having its prongs or teeth adjusted to the intervals of those of the vessel; with this apparatus I have found that like quantities of milk and cream, and with the same temperature, yield their butter in the following times:

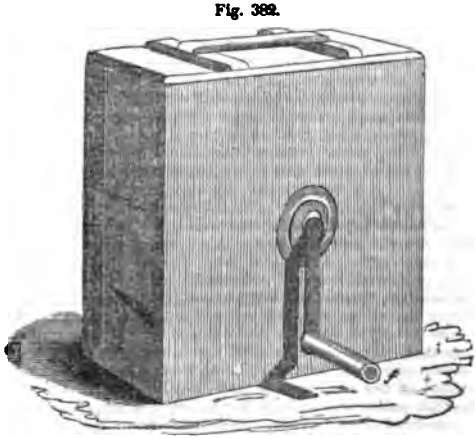
In the plane cylindrical vessel, with the agitator always moving in one direction, butter was not obtained in 55 minutes. In the same vessel, with the agitator moving alternately right and left, at every two revolutions, butter was obtained in 25 minutes. In this same vessel, fitted as above described, with counter-agitators, but with the agitator moving in one direction only, butter was obtained in 20 minutes. From these results it appears, that, even with a cylindrical vessel, if properly armed, the process is performed in a shorter time than with the inconvenient reversed motions.

(2095.) It is well known that a certain elevation of temperature is acquired by the fluid in the process of butter-making, and that the process is accelerated by producing this temperature artificially, from the application of heated water. For this purpose also, a practice is becoming prevalent to apply the water externally to the vessels containing the milk and cream, and not in mixture with them. Fig. 380 exhibits the application of this process to the utensil now under consideration, where *c* is the water case formed of tin plate, zinc, or of wood, at the bottom of which is fixed a circular stand to place the receptacle *a* upon, that the water may be under as well as around the receptacle. Wood, from its non-conducting quality, is perhaps better adapted than any metal for a water-case. Water brought to the proper temperature is poured into the space between the case and the retaining vessel, and if found necessary to increase or diminish the temperature, part of the contained water is drawn off below by a spigot, and hot or cold added to restore the requisite degree of heat. Experience seems to point out, that, in operating on the large scale *in wooden vessels*, no extraneous heat is required, the naturally acquired heat appears to be sufficient, especially if aided in winter by the admixture of a small quantity of moderately heated water, and the non-conducting quality of the wooden vessel retains it; whereas the stone-ware vessel will be continually abstracting heat, and giving it off by radiation, if not surrounded by a medium of equal temperature.

(2096.) *Churns* of the third class are much more numerous than the two former, and though in themselves not differing much in the essential points, they yet exhibit a variety of structure in their details. They are usually distinguished by the name of *box-churns*, though the class embraces not only the cubical and oblong box, but also the cylinder or barrel, the distinctive character being an agitator revolving in the vertical direction within a stationary case of any form.

(2097.) To illustrate this class, I have selected, first, the *box hand-churn*, in very general use. The present example, fig. 382, is 18 inches in length, 11 inches in width, and 20 inches in depth, inside measure. Birch or plane-tree are the best material for the purpose, and it requires to be very carefully joined so as to be water-tight. As before noticed (2088) it is of very small moment whether the bottom is formed to the circle of the agitator, or remains flat, in as far as the

Fig. 382.



THE BOX HAND-CHURN.

production of the butter is to be considered; but for the process of cleansing, the curved bottom will present some little advantages; a cover of the same material is fitted close in the top of the box, with convenient handles. The agitator, fig. 383, is of the usual form; the dimensions of its parts are unimportant, except that they have sufficient strength, and present sufficient surface to produce the requisite degree of agitation in the fluid. The two pairs of arms are half lapped at the center, and the cross-bars mortised into them; the dimensions in length and breadth being such as to allow it to move with freedom within the box. At the center a perforation is made through the sides to admit the iron spindle, which, at this part, is a square bar, fitting neatly into socket-plates of iron let into the agitator on each side, as seen in the figure at *a*. The farther end of the spindle projects about an inch beyond the agitator, and is rounded to form a journal, which has its bearing in a close brass plate-bush or socket, which is sunk into the side of the box, and fixed with screws. The outward end of the spindle is furnished with a conical journal, the smallest diameter of which is equal to the diagonal of the square part of the spindle, and is furnished with a raised collar or ruff; the conical journal lying in a thorough brass plate-bush, leaving the collar outside, but embraced by a cup of the bush, upon which a coupling-ring is screwed, covering the collar, and, pressing home the conical journal, preventing thus the spindle from being withdrawn until the coupling-ring is removed. The spindle extends beyond the collar about 2¼ inches, and is here formed into a square stud, upon which the eye of the winch-handle *f* is shipped when in work. In rigging this apparatus, the agitator is placed within the box, and the spindle is pushed through the outer bush and the agitator, until its two journals rest in the bushes; the coupling-ring is then screwed on to the outer bush, until the spindle with the agitator just turns round with freedom in the conical bush. To prevent the ring from turning round by the motion of the spindle, a smooth ring or washer of steel may be interposed between the collar and the brass ring. Various other modes of securing the spindle are employed, but in all, the object is to prevent leakage at the bush. To prevent taint from galvanic influence also, it is not uncommon to apply bone or other animal substance for the bushes.

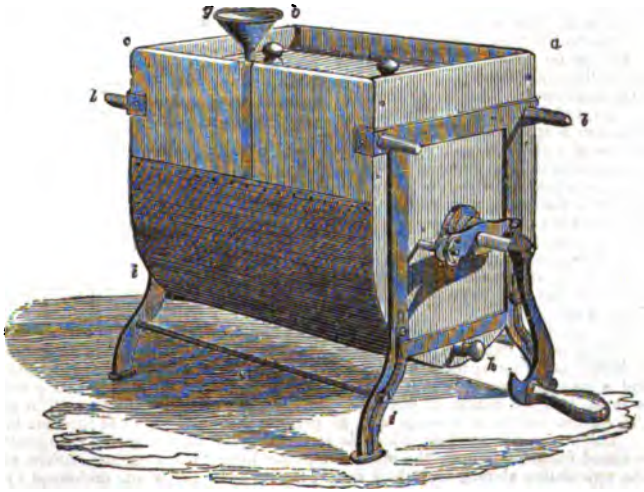
Fig. 383.

THE AGITATOR OF THE BOX-CHURN.

(2098.) Churns of this kind are made of all sizes, without any change in the principle of their construction. They are applied to all kinds of power, and the capacity is proportioned to the extent of the dairy; but the *entire* capacity of the churn must be in general about double the quantity in gallons, of the fluid intended to be acted upon. In operating with the box-churn, it may be filled to the hight of the spindle, or, if that member is well fitted, the milk may rise considerably above it, though in general practice it rises but little above. To adapt the churn to power, it is only necessary to put a pulley for a strap, or a chain, upon the end of the spindle, in place of the handle; or the spindle may be attached to another shaft, having the proper velocity, by means of a slip-coupling. The velocity of the agitator must depend upon the size of the churn; one of 24 inches diameter may make 60 revolutions per minute on the average, but may be higher or lower in different stages of the process.

(2099.) A *new churn* of this third class has been lately introduced, and meets with much favor in the north of Ireland. It is believed that its introduction from France is due to Mr. Blacker of

Fig. 384.



THE IRISH BOX-CHURN.

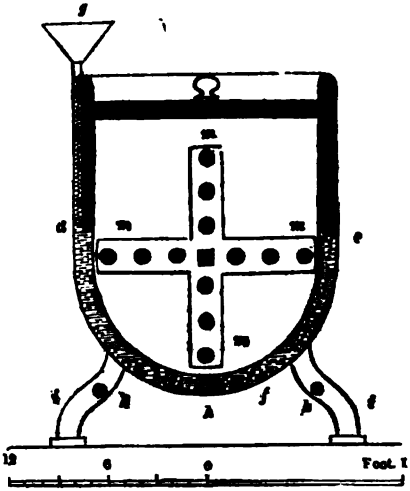
Armagh, who is ever zealous in the advancement of objects tending to the improvement of his country; but the manufacturing of it is conducted by Mr. R. Robinson, Lisburn. This churn is

represented in figs. 384 and 385; the first a perspective of the machine as it appears when in work, the second a cross section, showing the chief peculiarity of its construction. In the principle of its operation, this churn is the same as the one last described, but, like that alluded to under our second class, it is furnished with a case for containing water to regulate the temperature. It differs also from the common box-churn, in having the spindle or axis of the agitator passing through the length, instead of the breadth, of the containing vessel.

(2100.) In construction, fig. 384 represents a *hand-churn* of ordinary size; the containing vessel is of an oblong form, with a semi-cylindrical bottom, its length *a b* is 22½ inches, the breadth *b c* 14 inches, and the depth to the axis of the semi-cylinder 11½ inches, the entire depth being 21 inches, all inside measure. The sides and ends are formed of birch or plane-tree, 1½ inches in thickness, securely joined at the angles; the ends of the vessel thus constructed descend to the full depth of the semi-cylinder, while the sides are only 12 inches in depth. The bottom is formed in two plates of zinc, the edges of which are secured to the outer and inner faces of the sides, by means of close nailing, and also to the ends, making water-tight joinings all round, in the manner seen in section at *d* and *e*, fig. 385, where the space *d f e*, between the outer and inner plates, form the receptacle for the water. In the edge of one side there is inserted a funnel *g*, by which the water is introduced into the receptacle by passing down through a small bore in the side of the vessel, and the spigot *h* serves to draw off the water when required. A wooden cover is fitted into the opening in the top, with knobs for the convenience of lifting it out. The chamber thus constructed is set in the iron frames *i i i*, which are attached to each end of the box, with screw nails, and are farther secured by the stretcher-bolts *k*, and furnished with stud-handles *l l*, for the convenience of lifting the churn.

(2101.) In fig. 385 the agitator is also seen in section, whereof *m m*, &c., are the four arms, the three transverse bars in each arm being in this case round rods, which are here shown cut across by the section, as is likewise the square spindle passing through the center. The spindle is formed and inserted in the same manner as described for the box-churn (2097), and differs only from it in the mode of securing it in place. In this machine the spindle is pressed home by a perforated oblong plate, as seen in fig. 384, which passing upon the outward end of the spindle till it rest against the collar, it is then passed upon two stud-bolts fixed in the end of the vessel, having a screw-nut on their point, which presses the plate and the spindle, by means of the collar, home to the conical bush with any degree of tightness; and the winch-handle is then applied to the extreme end. It will be observed that both this and the last described churn require being placed upon a stand or table about 2½ feet high when worked by the hand, in order that the handle may be brought to a proper hight for the full effect of the hand. When either of them are worked by power, they are then most conveniently set on the floor of the dairy.

Fig. 385.



TRANSVERSE SECTION OF THE IRISH CHURN-BOX.

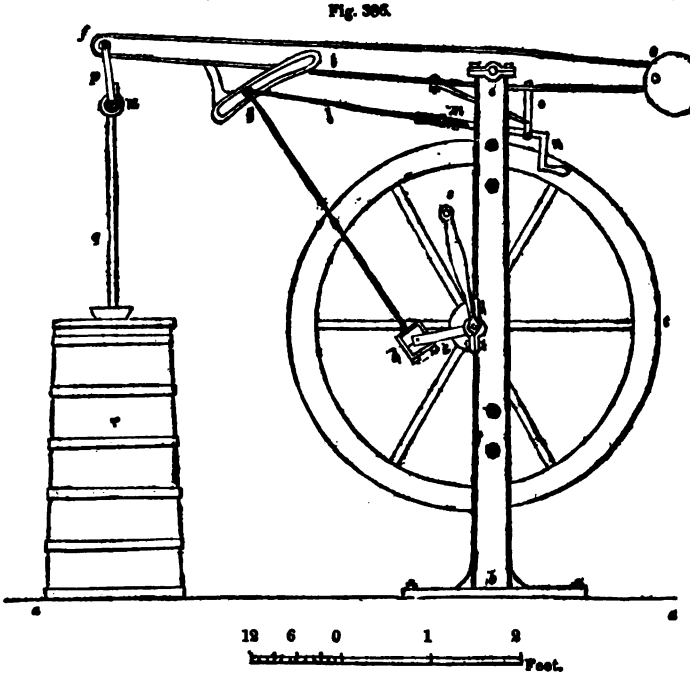
(2102.) In the fourth class of our subdivision, there is only to be considered the *plunger churn*; for in this class there is no variety, except as to the dimensions. The means of working the plunger, and the different media through which the power is applied, whether of man or of animals, are of a character much more varied than in all the others put together; and all these varieties seem to have been suggested with a view to overcome the very unfavorable position in which a man applies his force directly to the plunger-rod of this churn. Among these varieties of construction in the mechanical media through which power, of whatever kind, may be applied, we find all possible varieties of the lever and its combinations, the loaded pendulum, with combinations of the lever and of rack-gearing, crank and lever, and crank with connecting-rods; but it would be profitless to enumerate all the forms that have been devised for the improvement of this particular kind, and much more so to attempt to describe them. I will, therefore, rest satisfied with *one* that has long been in extensive use, and is equally well adapted to the hand or to power of any kind.

(2103.) The upright or *plunge churning-vessel*, is always a piece of cooper-work varying in capacity, according to the extent of the dairy in which it is to be employed, from 10 to 130 gallons. It is built slightly tapering upward for the convenience of being tightly hooped, having a strong bottom and a movable cover, which may be fastened down with an iron clasp-hoop; a perforation is formed in the center of the cover for the passage of the churn-staff or plunger-rod, and this is surrounded by a wooden cup, to prevent the lashing over of the fluid in the act of churning. The plunger or agitator, which is attached to the bottom of the plunger-rod, is a circular reticulated frame of wood; the meshes may be from 1½ to 2 inches square, and the bars forming the reticulation about ¾ inch thick and 1½ inches deep, the whole embraced by a wooden hoop, whose diameter will just enter the top of the churn. The structure of the plunger is by no means important, the only essential point being, that it shall not present too much resistance to the passage of the fluid through its interstices, nor too little to give it a too easy passage, which might render the agitation so slight as to be ineffectual; a good medium is to make the horizon-

tal area of all the interstices 1·5 times the area of the solid parts, and this rule will apply to the agitators of all churns. Such is the simple construction of this churning vessel, which is capable of adaptation to any kind of power, and to any extent of dairy.

(2104.) As an example of the application of power to the plunge-churn, the accompanying illustrations are taken from those extensively used in Lanarkshire and the neighboring counties, where they are usually worked by one horse. It will suffice at present to show the internal mechanism, leaving the horse-wheel and intermediate gearing for another occasion. Fig. 386 is a

Fig. 386.



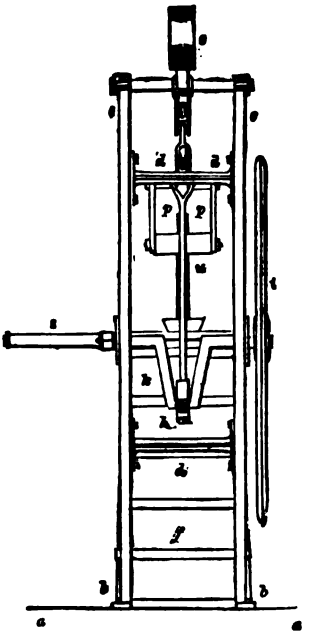
THE PLUNGE-CHURN WITH POWER-MACHINE.

side elevation of the churn, and the mechanism required within the churn-room of the dairy. It is here represented as being for hand-power, but the arrangements of the machine, so far as here exhibited, are the same whether for man or horse. Fig. 387 is a back view of the same, and the same letters apply to the corresponding parts in each figure. The floor-line of the churning-room is represented by the line *a a*, and *b c* is an upright frame of cast-iron, which is bolted to the floor. The frame consists of two cheeks, which are bolted together on the flanged bars *d*, *d*: it is 5 feet 9 inches high, and 16 inches wide. The reciprocating cast-iron lever *e f* is supported by its fulcra on the top of the frame, by means of a center-shaft passing through the lever. The length from the fulcrum to the head *f* is 4 feet 2 inches, and from the same point backward to the extremity is 2 feet 3 inches; a counterpoise is here placed upon the lever to bring it nearly to an equilibrium. The connecting-rod *g k* is jointed upon a bolt that is fitted to move along the oblique groove *g i* formed in the lever, and the crank *k* is formed on a shaft that turns in bearings in the upright frame; its throw is 8 inches, less or more, proportioned to the hight of the churning-vessel, and the foot *k* of the connecting-rod is fitted to the crank-pin. *l* is a light sheers of malleable iron, whose forked ends embrace the head of the connecting-rod, which is also forked at the head; and the pin of the groove passes through all the three. The adjusting-screw *m*, with its winch handle *n*, is supported in a swivel socket in the bracket *o*; while its screwed end *m* works in the bend of the sheers *l*, which is screwed as a nut to receive it, for the purpose of shortening or lengthening the distance *m g*, and so changing the position of the head of the connecting-rod. The head *f* of the lever is mounted with a pair of side-links *p p*, jointed on a cross-head in *f*; the links are again jointed on a wooden cross-head *u*, into which the head of the plunger-rod *q* is inserted, and fixed by a pin or key; these side-links, jointed as they are at top and bottom, produce a very imperfect parallel motion, but sufficient to answer the rise and fall of the plunger-rod. The handle *s* is fixed on one end of the crank-shaft, and on the other is placed the fly-wheel *t*, to equalize the motion of the lever, and compensate the inequality of the resistance to the plunger in its ascent and descent. The churning-vessel *r* is 3 feet high, with an average diameter of 15 inches, and its capacity about 23 gallons. In extensive dairies, it is common to have two churning-vessels attached to the machine, in which case the wooden cross-head *u* is elongated so as to receive the head of the plunger-rods of both vessels, the vessels standing side by side during the operation.

(2105.) When this machine is in operation, the revolutions of the crank produce a reciprocating

action in the connecting-rod, which is communicated to the lever, and thence to the plungers and it will be seen that, by moving the head *g* of the connecting-rod in the oblique groove of the lever, the strokes or reciprocations of the plunger will be long or short as the joint at *g* is moved upward or downward in the groove *g i*. It is found from experience that there are advantages to the process derivable from this; hence, at the commencement of the operation, the head of the rod *g h* is kept at the lower extremity of the slit, producing the shortest stroke; as the fluid becomes heated, and from the consequent effervescence, its bulk is increased, the stroke is gradually lengthened by turning the handle *n* of the screw; and by thus shortening the distance *g m*, the pin at *g* is brought to the head of the slit, producing a stroke of the greatest length; and when the effervescence ceases, and the butter has begun to form, this state is reversed, the stroke is gradually shortened, till the process is finished with the shortest stroke.

Fig. 387.



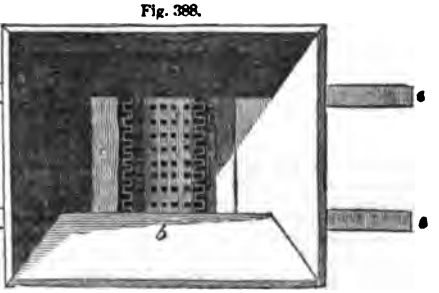
BACK VIEW OF THE PLUNGE-CHURN WITH POWER-MACHINE.

(2106.) The application of power to this machine is easy and commodious. It may be effected by a pulley placed on the crank-shaft instead of the handle *s*, and so driving with a strap or a chain; or it may be driven by a spur-wheel placed on the same point, calculated to the speed that may be afforded by the power, whether horse, water, or steam. The usual rate of the plunger in these churns is about 50 to 55 double strokes per minute, subject to the usual variation that is required in the different stages of the process. The price of the hand-machine, as in the figure, is from £6 to £8; and, when completed with horse-wheel and gearing, it is from £15 to £18.

(2107.) Besides the four established classes of churns now described, there are a few other anomalous cases which have of late years been brought forward by inventors, and though they ultimately may be found to possess merit, they cannot yet be received as of established character. The machines to which I here allude may be named "oscillating churns." They possess no distinct agitator, but produce their effects by a species of oscillation produced in the fluid. Among these may be mentioned a vessel of an oblong form, placed upon skids, curved in a manner that when the vessel is touched with even a gentle force, it will assume a motion resembling the well-known swing of a child's cradle, which will thereby produce a constant succession of irregular oscillatory motions in the contained fluid, which will produce the effect of churning.

(2108.) Another of these forms is an upright cylindrical vessel containing the fluid, and which is attached by its bottom to a crank revolving horizontally. The vessel is restrained from revolving on its own axis, but is made to describe a small circle, and every point in its base will virtually describe that circle which will be equal to that described by the crank that gives it motion. The effect of this oscillating motion in the vessel is to produce oscillation in the fluid, which will ultimately make gyrations within the vessel, combined with an undulatory motion, that will again produce the effect of the churn. In the first of these proposed machines, the motion would be so easy and equable that there appears no mechanical difficulty in the scheme; but in the second, when we consider the mass of fluid that may be contained in the vessel, and then the whole put in that kind of motion that may be described as reciprocating-circular, which, when combined with the unequal effects of the undulatory motion on the fluid within, would, it is feared, require either a much stronger fabric than is usually allotted to such operations, or otherwise the machine would be very liable to derangement and to fracture. A churning-machine, on this principle, was exhibited at the Show of the Royal Agricultural Improvement Society of Ireland, held at Belfast in August, 1843, and excited considerable interest from its apparent novelty.

Fig. 388.

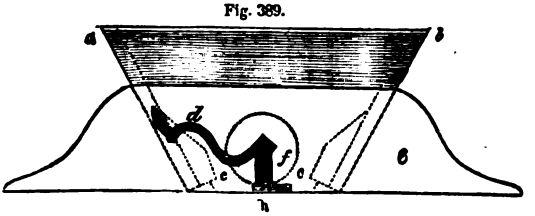


THE CURD-BREAKER.

(2109.) The utensils and machines yet remaining to be described in the cheese-making department of the dairy, consist principally of the curd-breaker, cheese-press and cheese-turner.

(2110.) The *curd-breaker*,* of which fig. 388 is a plan, and fig. 389 a transverse section, consists of a hopper-shaped vessel *a b*, 17 by 14 inches at top, and 10 inches deep. It is fixed upon two bearers *e e*, which are set upon a stand or tub when in operation. A wooden cylinder *f*, having an iron axle, which passes through the bearers *e*, and is turned by a winch-handle *d*. The axle is kept in its bearings in *c* by means of slots *k* on each side, which slide in grooves in the bearers, and are held in their place by a slider at *k*. The cylinder is 7 inches long and 3½ inches in diameter, studded all over with pegs of hard wood ¼ inch square, and projecting ¾ inch. These pegs or teeth are set in eight regular zones round the cylinder, each zone containing 18 teeth. Two wedge-shaped pieces *c c* are attached to the sides of the hopper below, serving at the same time to reduce the opening between the cylinder and the hopper, and to carry a row of pegs similar to those of the cylinder, but falling into the spaces between the zones of pegs, as seen in fig. 389. In using this machine, it is placed over the tub or other recipient for the broken curd; the hopper is filled with the curd that requires to be broken; and while one hand is turning the winch-handle, which may be turned either way, the other hand may occasionally be required to press the curd down upon the cylinder. To prevent the curd being passed beyond the ends of the cylinder, it is covered at each end, to the extent of ¼ inch, with an overlap of the sides of the hopper.

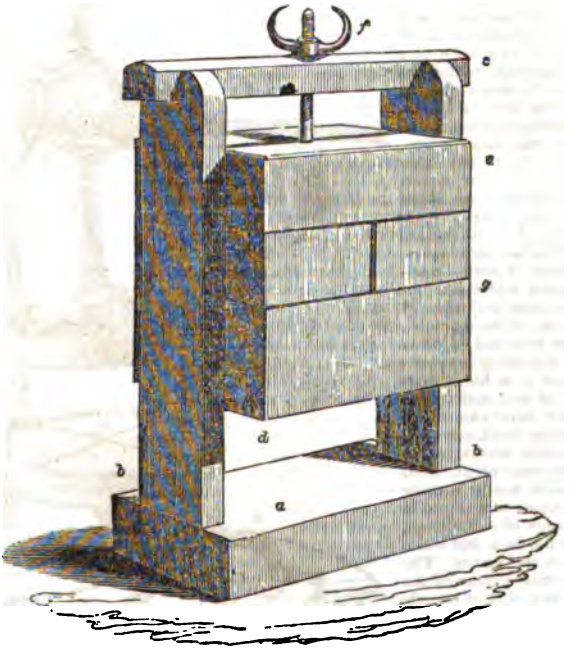
Fig. 389.



THE SECTION OF THE CURD-BREAKER.

(2111.) The *cheese-press* comes next in the order of business, and of that machine the varieties are very numerous, though they may be all resolved into three kinds, namely, the common old stone-press; the combined lever-press, of which the varieties are the most numerous, embracing from the single lever, through the various combinations of simple levers, to the more elaborate

Fig. 390.



THE STONE CHEESE-PRESS.

one of the rack and levers; and the atmospheric or pneumatic press. An essential characteristic of these presses must always be, that the load, in whatever way produced, shall, when left to itself have the power to descend after the object being pressed, as that may sink by the expression of the whey from the curd.

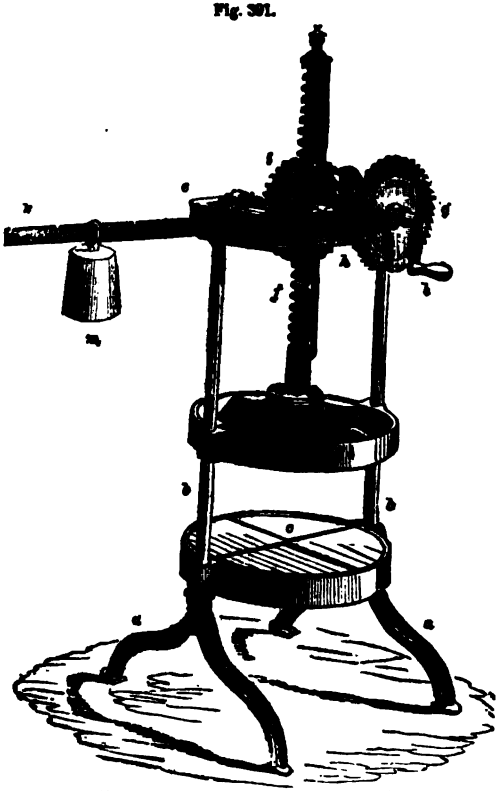
* Quarterly Journal of Agriculture, vol. iv.

(2112.) An example of the first of these is shown in fig. 390; it consists of a strong frame of wood, of which *a* is the sill, 2 feet long, 18 inches broad, and 4 inches thick; two uprights *b b* are mortised or dovetailed into it; these are each 6 inches broad by 2½ inches thick, and 3 feet high, and are connected at top by the cross-head *c* mortised upon the posts. A cubical block of stone *d e* is squared to pass freely between the posts; an iron stem of 1 inch diameter is fixed into the upper surface of the block, and the upper end of it being screwed, is passed through the centre of the top bar, and the lever-nut *f* is applied to it for raising or lowering the block. In each end of the block a vertical groove is cut corresponding to the middle of the posts; and a baton of wood is nailed upon the latter, in such form and position as will admit the block to rise and fall freely, while it is prevented falling to either side. When put in operation, the block is raised by means of the screw until the cheese-mould, with its contents, can be placed upon the sill *a* under the block. This being done, the nut is screwed backward till the block rests lightly on the cover of the mould; it is let down by small additions, as the curd consolidates, until it is thought safe to let the entire weight press upon the mould, which is done by withdrawing the nut *f*. Instead of the solid block of stone *d e*, which, when left to itself, will always produce the same pressure, it is better to have one block *d g* into which the suspending bolt is fixed, and the remainder of the mass made up of smaller pieces, as shown in the figure, by which means the amount of free pressure can be regulated to the particular size and state of the cheese; or blocks of cast-iron are sometimes used in the form last described, which are more commodious, and less liable to be broken.

(2113.) The next class of this machine, *the lever-press*, to speak in general terms, possesses the sill of the former in some shape or other, but generally of wood, with two uprights as before; but instead of a heavy block of stone, a simple movable sill of plank is employed, having an iron or a wooden stem attached to it, upon which simple or compound levers are made to act in producing the pressure. An improved form of this lever-press was brought out by the Stotts Iron Company,* made entirely of iron, of a more commodious and compact construction than had hitherto been attempted, and, with slight alterations, is here presented as the type of the class.

(2114.) The *combined lever cheese-press* of iron is represented in the perspective view, fig. 391, and is constructed in the following manner: *a a* are a pair of cast-iron feet, on which the machine is supported; they have a socket formed at the crown to receive the malleable iron pillars *b b*. The sill-plate *c* is 18 inches in diameter, cast with two perforated ears, through which the feet of the pillars *b b* also pass, and secure the sill to the feet.—the cross lines in the sill indicate channels for the escape of the expressed whey. The movable sill *d* is of the same size as the one below, with corresponding ears perforated and fitted to slide on the pillars, and having the rack-bar *f* fixed in its centre. A top frame *e*, 18 inches by 9 inches, and 3 inches deep, is seated upon the top of the pillars, where it is fixed by two screw-nuts, and adapted to carry the gearing of the machine. The action of the rack and its sill is effected in the following manner: The ratchet-wheel *g* is fixed upon an axle that has its bearings in the top frame; on the same axle is fixed a pinion of eight teeth, not seen in the figure, which works in the wheel *i* of twenty-four teeth, fixed upon an axle which has its bearing also in the top frame; and this axle carries also a pinion of eight teeth, which acts upon the rack, but is also hid from view in the figure. The ratchet-wheel *g* stands clear of the top frame about an inch, and its axle is prolonged beyond the wheel double that extent. The lever *k* is forked at the extremity *g*, and the terminations of the furcation are received upon the axle of the wheel *g*,—the wheel being embraced by the fork of the lever, but the lever moving freely upon the axle. The furcation is also lengthened toward *k* to an extent that receives a pall at *k*; between and in the throat of the fork, the pall is jointed upon a pin that passes through both,—the edge of the pall pointing downward to catch

Fig. 391.



THE COMBINED LEVER CHEESE-PRESS.

* Prize Essays of the Highland and Agricultural Society, vol. x.

the ratchet, while it has a knob-handle standing upward, by which it can be conveniently disengaged from its wheel. A small winch-handle *l* is also fitted upon the axle of the ratchet-wheel, and a pin seen near *k* is adapted to a perforation in the top frame, by the insertion of which the descent of the lever is checked, when such is required, and this completes the mechanism of the press.

(2115.) In *pressing* with this machine, the cheese-mould is placed upon the lower sill, and the lever being supported on the pin at *k*, the winch-handle is turned to the left, depressing the rack and its sill till the sill presses upon the cover of the mould. The lever is now lifted by the hand, and the pall allowed to take into the ratchet; while the lever, being loaded by the weight, will cause the ratchet to turn, and produce the descent of the rack. If necessary, this is repeated again and again, till a considerable pressure is produced; and if it is wished that a continued pressure is to go on, the lever is again raised considerably above the horizontal line, and left to descend gradually, following the consolidation of the cheese. If it is wished that the load shall not follow the shrinking of the cheese, the pin *k* is inserted, which, when the lever comes to rest upon it, checks farther descent. The amount of pressure is also regulated by the disposal of the weight *m* in the different notches of the lever. The usual selling price of this machine is £4, when constructed of iron, as in the figure; but with wooden framework, and the rack and other gearing of cast-iron, the price is £3 5s.

(2116.) In the third division of the cheese-presses there is not such a variety as in the others, and what does exist is of recent introduction. I have to notice only one—the *pneumatic cheese-press* of the late Sir John Robison of Edinburgh—as an elegant application of Science to a homely though important domestic purpose. The principle here applied is the pressure of the atmosphere, brought to bear, with any degree of force compatible with that natural pressure, upon the curd when placed in the mould, by exhausting a vessel placed below and in communication with the mould, by means of a pipe descending from the bottom of the mould to a receiving-vessel. To this pipe of communication a small air-pump is attached, and the mould having, besides its true bottom, a movable one of wire or of wicker-work, the curd, wrapped in a cloth, is laid upon the pervious bottom, and gently pressed with the hand till it fill the vessel all round. The pump is worked a few strokes to produce a partial vacuum in the receiver and below the curd, when the atmosphere, by its pressure on the surface of the curd, causes the whey to separate and descend into the receiver. The pressure may be continued or increased at pleasure by a few more strokes of the pump, until the cheese has acquired sufficient consistency to allow of its being handled, when, as recommended by Sir John, it is to be removed from the mould and placed within another of close wire-work, with a weight placed over it to complete the consolidation.* The whey that is discharged from the curd while under the atmospheric pressure, being collected in the receiver, is drawn off by means of a stop-cock.

(2117.) There falls yet to be taken notice of an important article in the cheese department of the dairy machinery—the *tumbling cheese-rack*, or *cheese-turner*. This machine is the invention of Mr. William Blurton, of Fieldhall, Uttoxeter, and its merits are believed to be sufficient to warrant its adoption on dairy-farms. The object of the machine is to save much of the labor required in the daily turning of a large number of cheeses in the drying-room, and this it does very effectually, for with a rack containing 50 cheeses, they are turned over in very little more time than would be required to turn a single one.

(2118.) Fig. 392 is a view of the cheese-turner, as constructed to stand alone, and on its own feet; though this is not the best mode of constructing the machine. It consists, first, of an external frame *a b c d*, of which the two parts *a b* and *c d* are 6½ feet high, and 7 inches by 2½ inches; they are here represented each with a cross foot *a* and *c*, and connected at top by a top-rail *b d*. If constructed in a cheese-room, the posts should be at once fixed to the floor at bottom, and to the joisting or tie-beams overhead, becoming thus a fixture in so far as regards the external frame. The second part of the machine is a movable frame or rack, formed by the two interior posts *e* and *f*, which are framed upon the 12 shelves *g h i*, &c.; the posts are 6 feet high, and are again 7 by 2½ inches, the shelves being 7 feet long and 14 inches broad, or more, according to the size of the cheeses manufactured, by 1 inch thick. The shelves extend to 5½ feet in hight over all, and are tenoned into and lipped over the posts, and each shelf is finished on both sides with a knife-edged lath, nailed along the back edge: these laths are 2 inches broad, and ¼ inch thick at the back, thus increasing the thickness of that edge of the shelves to 1½ inches. As the figure represents a rack that will contain 5 cheeses on each shelf, a corresponding number of pairs of vertical laths, *k*, *k*, &c., are nailed upon the back edge of the shelves. These laths are 1½ inches broad and 1 inch thick, chamfered off to one side to the thickness of ¾ inch or thereby at the edges, against which the cheeses are laid, and are checked upon the shelves, and securely nailed. The shelf-frame thus formed is provided with two strong iron gudgeons or pivots fixed in the side-posts at mid-hight, and these are received into corresponding holes in the outer or bearing-posts, so that the shelf-frame swings poised upon the two pivots; and it is farther provided with an iron latch at top and bottom on one end, by which it may be tilted and secured with either the shelf *g* or *e f* uppermost. The catches of the two latches are both placed at top on the external post at one side, suited to the motion of the shelf-frame, and to prevent its being turned with the back edge of the shelves upward.

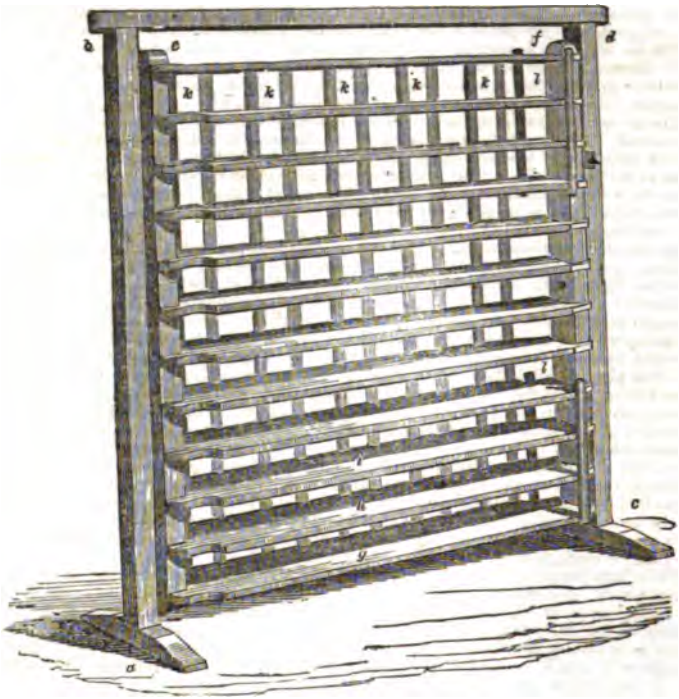
(2119.) When cheeses are placed upon the shelves, it will be found that the knife-edge laths keep them free of the body of the shelf, and thus permit air to pass under them, while the pair of vertical laths keep the cheese in its proper position on the shelf. The hight between the shelves is such as to leave a free space of 1 inch between the cheese and the shelf above it; and whatever number of cheeses may be lying upon the shelves, the simple act of tilting the frame will place every cheese which *was* resting on a shelf, on its opposite side, *upon* that shelf which immediately before was *above* the cheese, but by the tilting is now *below* it. It will be observed that the vertical laths serve to prevent the cheeses from falling out while the frame is tilting, and

* Prize Essays of the Highland and Agricultural Society vol. x.

each cheese has only to fall one inch in that operation, or from the one shelf to the other, in a reversed position.

(2120.) It will be also observed that the fixed external frame is best adapted for an extensive

Fig. 392.



THE CHEESE-TURNER.

cheese-room, where the racks may be placed in rows extending the length of the room, leaving free passage between the rows. The width of the passages requires to be equal to half the hight of the shelf-frame, or 3 feet; a room, therefore, 20 feet wide would contain 4 rows of such *racks*; and if the length were equal to 10 diameters of the cheeses, or containing that number in the length, the room would contain in all 440 cheeses in the best possible condition for their being prepared for market, having free ventilation, and access for the dairy-maids to handle and wipe any cheese at any time. We have no experience of this cheese-rack in Scotland; but, judging from its apparent capabilities, there is much reason to think that it might be employed with excellent effect in the extensive cheese-dairies of Ayrshire and Galloway. The price of a portable rack, as here figured, capable of holding 55 cheeses, is £4.—J. S.]

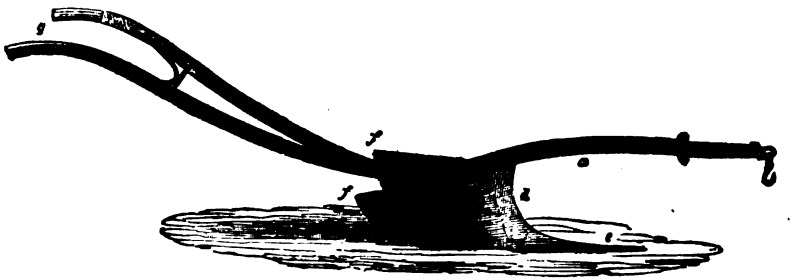
28. THE DOUBLE MOULD-BOARD PLOW.

(2121.) [The *double mould-board plow*, is an implement essentially requisite in the cultivation of the turnip and potato crop. When duly constructed, it is highly efficient in the formation of the drills or ridgelets for either of these crops, setting up at each turn the half of a ridgelet on each side, while the common plow, or one-horse plow so much employed for this purpose, sets up only a half ridgelet at each turn, doing, therefore, but half the work. In a variety of forms also, it is much employed in the earthing-up of the potato crop; for this purpose it is frequently made of wood, but in all cases the iron plow is to be recommended.

(2122.) Fig. 393 is a representation of a common double mould-board iron plow equipped for the purpose of earthing-up. The framework of it is pretty much in form of the common plow, except that the beam *a* lies right in the central line of the whole plow. The bridle *b* is variously formed according to the taste of the maker, but always possessing the properties of varying the

point of draught upward and downward, as well as right and left. The breast *d* is a shield forming part of the cast-iron body-frame afterward described. The share *e* is plain on both sides, spear-pointed, and set upon the head of the cast-iron body-frame. The right and left mould-boards

Fig. 393.

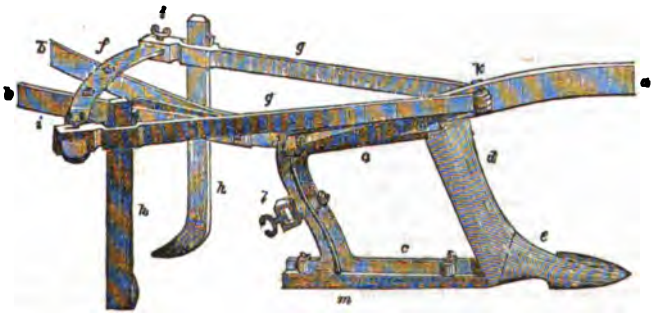


THE DOUBLE MOULD-BOARD PLOW.

f f are hinged to the edge of the shield *d* with drawing hinge-pins, and they are supported behind by a jointed iron-strap affixed to the back of each mould-board, and which slide through a socket in the body-frame, where the tails of both straps are secured by means of a pinching-screw, setting the mould-boards at any required width behind. The handles *g* are bolted on each side of the beam, as seen at *f f*, and are supported near the helves by the usual stretcher and bow. The dimensions of the plow are: from the breast *d* to the point of the beam 3 feet, 6 inches, from *d* to extremity of mould-board *f*, 2 feet 6 inches, and from *d* to end of helve 6 feet 6 inches. The hight of the mould-board, where it joins the shield, is 12 inches, and at the point *f* 10 inches; length of share 16 inches. The mould-boards of such plows are liable to great variation in their form; some of them have little or no twist, and others variously contorted. Those of the present figure have been selected as possessing all the requisite qualifications for an earthing-up plow. At the fore-edge, where they join the shield, the surface is nearly in a straight line, and along the upper edge they are slightly convex; from these two lines they twist gradually, rounding away below toward the tail, so as to leave the furrow of a round-bottomed trough shape. Where the double mould-board is employed for forming the ridgelets, the mould-board is made to fit the shield *d*, as in the figure; it then stretches away to a length of 2 feet 6 inches along the upper edge, the point *f* being at a hight varying from 11 to 14 inches above the sole-line. At this point the depth of the mould-board is only 6 inches, so that the lower edge runs off at a considerable elevation, and the surface having not more than 3 inches of twist, it is the lower edge only of the board that effects the purpose of laying up the earth to form the ridgelet. In working the plow, for the purpose of forming drills, there is frequently a marking-bar jointed to the beam immediately before the breast *d*; the bar folds to either side, and having an adjustable double-edged scraper fitted to it, a rut is drawn on the surface at the proper distance for the centre of the next furrow.

(2123.) The plow just described and represented, is convertible into a scuffling or cleaning plow, or horse-hoe. To effect this, the hinge-pins of the mould-boards are withdrawn, and the mould-boards removed, when we have an implement represented by fig. 394, which exhibits the body-

Fig. 394.



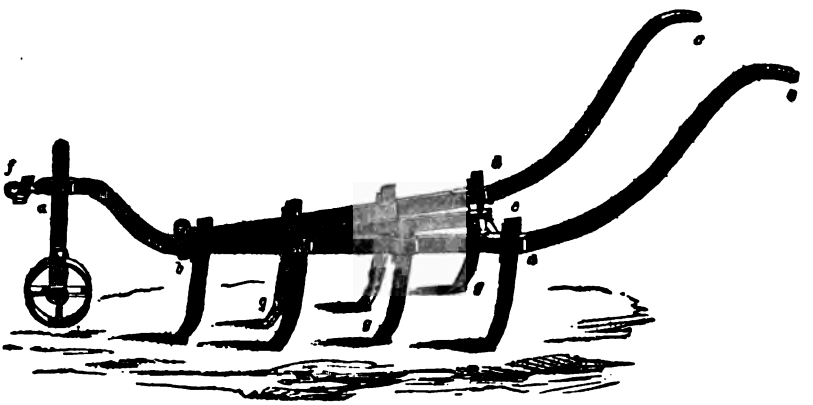
THE BODY OF THE DOUBLE MOULD-BOARD ALTERED TO A SCUFFLING PLOW.

parts of the same plow upon an enlarged scale, and from which portions of the beam and handles are cut off. Here *a* is the remaining portion of the beam, and *b b* those of the handles, exhibiting also their junction with the tail of the beam. The body-frame *c c*, is of an irregular rhomboidal form, whereof the front bar forms the shield; its breadth from right to left behind is 3 inches, running off forward to a sharp edge, and is hollowed out behind. The top bar *c*, by which it is bolted to the beam, is 2½ inches broad, and ½ inch thick; the sole-bar *c* is formed flat below,

to receive the plain sole-shoe *m*, and the hind bar is formed to receive the malleable iron socket *l*, through which the tails of the mould-board straps are passed, and secured by the pinching-screw *l*, when these are in use. To complete the implement for the purpose of scuffling, the two wing bars *g g* are jointed to a stud that projects from the beam on each side at *k*. A quadrant bar *f*, 2 feet long, and 1¼ by ¼ inch is attached by bolts to the two stilts at *f*, and the ends of the wing-bars having a mortise formed to receive the quadrant, are moved upon this to any required width, and secured by the screws *i i*. A second mortise is punched in each wing-bar to receive the scuffling coulters *h h*; these are 2 inches broad by ¼ inch thick, thinned off to a knife-edge in front, and bent inward below till the points stand 6 inches to the right and left of the shanks. A double-feathered share *e* is now fitted to the head of the body-frame, which completes this simple horse-hoe, and the change from the one state to the other is effected in a few minutes, for, in returning it to the double mould-board state, it is only necessary to remove the scufflers and the feathered share. The dimensions of the body are, hight at the breast from the sole to the top of the beam 14 inches, length of sole 2 feet 6 inches, including the feathered share. The effect of this horse-hoe in the soil is to loosen the earth between the rows of drills, or if foul, to under-cut all the weeds that exist in that space, or to such breadth as the two scufflers may be set; the upright part of these coulters performing a species of paring along the sides of the two contiguous rows. If the land is in good order, and tolerably clean, stirring it with this scuffler will be sufficient; but if overrun with weeds, one or other of the drill-harrows or grubber will be found necessary to prevent a re-vegetation of the weeds, and the following will be found to answer this purpose well.

(2124.) The common *drill-grubber*, fig. 395, is a light and convenient implement drawn by one horse. It consists of a central beam *a b c*, the neck part of which *a b* is 18 inches long, the body

Fig. 395.



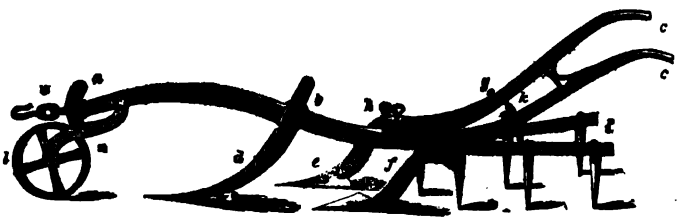
THE COMMON DRILL-GRUBBER.

part 3 feet 6 inches; and of the two wings *b d*, which are extended to *c c*, forming the handles, the length from *d* to *c* is 3 feet 4 inches. The neck part of the beam is 1¼ inches square, and pecned, or rounded, and this strength is carried past the first tine; the remainder of this bar, as well as of the wings, is 1¼ inches deep by ¼ inch thick, the handles becoming lighter backward. The beam is punched at the front for the passage of the stem of the wheel, and at *b* for the fixing of the two joint-plates for the wings, as well as for the front tine; and it is also perforated horizontally at the end *c*, for the quadrants of the wings. The wing-bars require to be very neatly forged in forming the swells, in which the tine holes are to be punched, and also for the joint at *b*, where they are hinged to the beam, between the two joint-plates, which, being riveted dead upon the beam, leave a chamber on each side for the reception of the ends of the wing-bars, and through these their joint-bolts are passed. The wing-bars are each furnished with a quadrant-bar riveted into the wings at *d d*; the tail of the quadrants passing through the mortise at *c* are secured by a pinching-screw fixing the wings at any required width. To the point of the beam is affixed a simple bridle *f* with a cross-web and shackle, giving a small range of yoke right and left; the rise of this point is 10 inches above the line of the body of the beam. The front wheel, whose office is to regulate the depth of the grubbing, is usually 8 or 9 inches diameter, set in the sheers of the stem, which may be 20 inches long, and is 1¼ inches broad by ¼ inch thick. The tines *g* are 15 inches long, the body being 1¼ inches broad by ¼ inch thick, forged with duck-feet not exceeding 2¼ inches broad and pointing slightly forward. In many localities this implement is used for all the purposes of horse-hoeing, except the process of paring or of earthing-up, and having cheapness as well as utility as a recommendation, it is very generally approved of. It is, however, subject to variety in the different districts where it is employed; in some it is shortened to five tines, in others lengthened out to nine, and in many cases the tines are plain-pointed, or not exceeding 1 inch broad. It is frequently also made with the tines standing in *zigzag* position; but except in the second pair of tines, this is of little importance, as those behind the second are sufficiently far apart to prevent them getting choked with weeds. The price of this grubber is about £2 10s.

(2125.) In this class of implements, we find a very handsomely constructed one, known as

Wilkie's drill-grubber and harrow, which is here represented in fig. 396. The implement is, however, of older date, and seems to have been invented by a Banffshire farmer,* the original having been constructed with wooden framing until Mr. Wilkie adopted the iron instead of wood.

Fig. 396.



WILKIE DRILL-GRUBBER AND HARROW

This implement is constructed with a beam *a b*, and a pair of handles *c c* attached to the tail of the beam, one on each side, in the way formerly shown in fig. 394. It has no proper body-frame, but is merely a skeleton, the grubbing parts of it being the three tines or coulters *d*, *e*, *f*. The foremost of them, *d*, is set in a coulter-box in the beam, the two others, *e* and *f*, are continuations of the two wings, which are hinge-jointed to the side of the handles as at *g*, and where they are kneed downward at *h*, they are perforated for a quadrant bar, on which they are moved outward or inward, and are secured by the pinching-screws at *h*. The front tine terminates in a double spreading feather or duck's-foot point of about 11 inches in length, and 8 inches in breadth at the heel; the two back tines are flat on the outward sides, and feathered inward; their effect on the soil is therefore somewhat similar to that of the scuffler, fig. 394, paring and undercutting; but the implement is furnished with an appendage in the attached harrow *i*, which completes the operation at one turn. The harrow consists of two bars jointed to the middle of the quadrant-bar which sustains the back grubber tines, and are suspended by a small quadrant attached to each of the bars *i*, from the first stretcher of the handles at *k*, and each of the harrow-bars carries three common harrow-tines, but somewhat longer than usual. The harrow is, besides, capable of adjustment to depth by means of its suspenders, and to breadth by means of its two small quadrant-bars. The regulation of depth is aided by the wheel *l*, which may be from 8 to 10 inches in diameter, hung in the sheers *n*, which is jointed to the beam at *a*, and is capable of being shifted up or down upon the cross-head *o* of the beam, and fixed by a bolt at *n*, passing through the perforations of the cross-head, to which also a shackle and hook are attached for the draught.

(2126.) It requires no demonstration to show that the principle of this instrument is good—grubbing or scarifying to undercut all weeds, which are immediately brought to the surface by the action of the harrow, to wither and die—but it is believed that defects of construction exist in it that in some measure mar its utility. In stiff soils the broad-feather shares will with difficulty be kept in the ground; and, from their great length and breadth, will have the effect of consolidating that part of it which they pass over, into a hard crust. The harrow is an important part of the implement, but adds considerably to the draught; and the implement, upon the whole, is too heavy for one horse being able to produce efficient work with it: by lightening the entire structure, and altering the form of the tine, it might be rendered a very useful horse-hoe. Its general dimensions, as constructed by Mr. Wilkie, may be shortly stated. Length of beam from cross-head to coulter box 2 feet 10 inches; thence to quadrant of the back tines 1 foot 10 inches, and thence to end of handles 4 feet 6 inches; hight of beam at coulter-box 16 inches, at quadrant 14 inches, and at the point 18 inches. The depth of the beam at the coulter-box is 2½ inches, and its breadth 1 inch, from which point it tapers off forward and backward; the handles are 1¾ inches in depth by ¾ inch in breadth. The length of the harrow-bars is 2 feet 9 inches, and the length of the tines 10 inches; the weight is 145 lbs.; and the price of the implement is £4 15s.

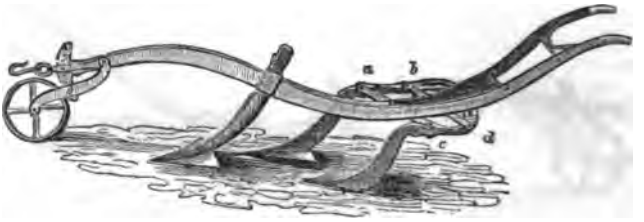
(2127.) The foregoing constitute a series of green-crop horse-hoeing implements, that possess all the principal points requisite for this operation; but there are numerous varieties of all the types here exhibited, though all are referable to one or other of them. It is, or ought to be, an essential point in all implements of this kind, that they possess a principle of expansion and contraction, to suit the different widths of drills; and, with few exceptions, this is the case. In many of those in use, however, the mode of expansion is attended with an inconvenience arising from the shortness of the expanding wings, which throws the coulters or tines out of parallelism, and thus proves detrimental to their perfect working in the soil. This inconvenience is more felt in those implements which have their tines formed like those of fig. 396, and least of all when the scuffling-tines are employed as in fig. 394. Mr. Wilkie, with his usual ingenuity, has invented, some years ago, an implement of this class, in which the expansions and contractions are effected by means of a parallel motion applied to the tines, as exhibited in the following figure.

(2128.) Fig. 397 exhibits Mr. Wilkie's *horse-hoe* with parallel motion; it is very similar in figure to the last, but the two back tines have their tails jointed at *a*, *b*, *c*, *d*, to two transverse parallel bars, which traverse, to a small extent, upon pivots placed in the middle of their length, attached to the tail of the beam. By moving these bars upon their pivots, from the position of a right angle with the central line of the beam, the one tine is pushed forward and the other backward, which must cause the points *a*, *b*, *c*, *d*, to approach the central line, and along with these the points of the tines, preserving a perfect parallelism, and capable of being secured at any required

* Agricultural Report for Banffshire.

width by pinching-screws. This is the most perfect mode of adjustment for the tines of a hoe of this construction—three-tined—but it does not apply to those with more than three, and is, withal, perhaps, too refined for a field implement. The self-cleansing form of the tine which is exhibited

Fig. 397.



WILKIE'S HORSE-HOE WITH PARALLEL MOTION.

here, and in fig. 396, in the two back tines of each, has been often dwelt upon as of much importance; but the truth of the matter seems to be, that though that particular form is beneficial in the great field-grubber, it seldom occurs, and ought never to be the case, that a drilled field-crop is so overrun with weeds as to require a self-cleansing tine.—J. S.]

29. HAY-MAKING.

"—— as they rake the green appearing ground,
And drive the dusky wave along the mead,
The russet hay-cock rises thick behind,
In order gay."

THOMSON.

(2129.) Hay is made both of sown and of natural meadow-grasses. The sown grasses are employed for hay in Scotland, and of these the hay consists of red clover (*Trifolium pratense*), and rye-grass (*Lolium perenne*); for although the white clover (*Trifolium repens*) is sown along with the seeds of the other two, it scarcely forms a part of the first year's grass, and constitutes no part of the hay, which is always taken from the grass of the first year. As hay is thus taken from the first year's grass, it matters not whether the rye-grass made into hay is annual or perennial. The annual yields the heavier crop, but the perennial the finer quality of hay. The natural grasses constitute the hay of England and Ireland. These two sorts of hay are certainly very different in appearance, the sown grasses showing the strong and stiff stems of the red clover and rye-grass, and especially when the rye-grass is annual, while the hay from the natural grasses is soft and woolly to the feel, and more odorous to the scent, because the sweet-scented vernal-grass (*Anthoxanthum odoratum*) always forms a component part. In so far as their nutritive properties are concerned, if both are equally well made, there will probably be no material difference; but this fact has been established in Scotland, that the sown grasses are more nutritive for young stock, both sheep and cattle, than natural grasses, and for that reason we may hold it as true that their hay will also be more nutritious for young stock; and in like manner the hay of natural grass should be more nourishing to old stock than from that which is sown; and hence natural hay is best for cows.

(2130.) I have heard farmers express the opinion that sown grasses require a different treatment on being made into hay than natural grasses. If the object is to obtain rye-grass seed while hay is being made, then, of course, the two processes should be different; but if the object is to make

the best hay from both the substances, then I cannot see why the processes should be different. On the contrary, the nature of all the plants employed being the same, the same treatment should produce in all the same results; and as the art of hay-making is merely to expel the water which the plants contain without injury to their texture, the only danger to be apprehended is excessive fermentation, which is easily excited in warm weather, and will proceed to a destructive extent, if not subjected to control. Still hay-making varies according to the means used for conducting it; for if manual labor alone is employed, one process should be adopted, but when mechanical assistance is received, the process should be modified accordingly.

(2131.) First, then, as to *hay-making with manual labor alone.* The implements required for the purpose are few and simple. The grass is cut with the common scythe, fig. 361; and the cutting is either let to laborers by the piece, or the plowmen of the farm do it, should there be spare time from horse-labor between the sowing of the turnips and the hay-harvest. The grass will be better and more expeditiously cut down if let by the piece, as the contractors will exert themselves more, and work more hours, than plowmen who have charge of horses can be expected to do. The usual cost of cutting grass for hay is 2s. 6d. or 3s. per imperial acre. On commencing to cut a field, the direction toward which the clover leans, or, should it be thin and upright, the quarter of the wind, which always influences the direction of thin grass, should be attended to; and in both cases the grass should *lean away from the mower.* It always makes the best work for the grass to be mowed *across* the ridges. It is fair work for 1 man to mow 1 acre every day; and I may here remark, it is no good sign of the weight of the crop if the mowers go over more ground every day. The other implements used in manual hay-making are forks and rakes. Forks are shown in fig. 279, and rakes are figured and described below; and of the two kinds I prefer the right-hand figure, as being the neatest and lightest.*

(2132.) Let us next consider the making of hay with the *aid of horse-labor and suitable implements*, the employment of which makes a considerable difference in the process. The tedding-machine, represented in Plate XXXI. fig. 368, is used to ted hay, and which it best does by passing across the swathes, taking up and teasing and scattering them on the ground in the most regular manner. It is alleged that this machine is only suited to ted natural grass, but why so is not obvious, for its structure is capable of laying hold of any kind of grass. It would indeed shake rye-grass too much that is intended for seed; but I have already said it is impossible to obtain good hay and good seed from the same crop. If the object be merely to ted grass, this machine will doubtless ted sown grasses as well as natural, when they are cut at the proper age. After the grass has thus been tedded, it is allowed to dry in the sun and wind all the forenoon. In the afternoon the hay-rake, whether the common horse-rake or American hay-rake, both of which are represented and described below by Mr. Slight, is employed to rake the tedded grass into a windrow across the 4 ridges which intervene between every fifth ridge which contains a row of cocks. Where the crop of grass is very thin, the horse-rake might carry the grass into a windrow over more than 4 ridges upon the fifth ridge; but with an ordinary crop it could not, perhaps, accomplish this, and much less with a heavy crop. After the grass, therefore,

[* Here follow minute directions for hay-making, not applicable to our country, from various circumstances, which the reader can imagine. The difficulty with us is to get the grass or the ground. The process of curing is simple enough. *Ed. Farm. Lib.*]

has been withdrawn across the 4 ridges, manual labor is employed to put it into grass-cocks, as in the case with manual labor. It will be observed that few people, and especially women, are required to conduct hay-making in this way, the heavy part of the duty consisting of making the cocks as often as requisite, which is best done by men.

(2133.) A large oblong hay-stack should be *built* in this way: In the first place a dry stance should be chosen, for a damp one will cause the destruction of several stones of hay at the bottom of the stack. The *stance* should be raised 1 foot above the ground with large stones inscribing the circumference, and the interior filled up with stone shivers or gravel beat firmly down. Upon this space the stack should be built by 2 men, who are supplied with armsfull of hay by a number of field-workers, whose duty is not merely to carry the hay but to tramp it under foot in a regular manner from one end of the stack to the other. The 2 men, each occupying a side of the stack, shake and build up what is called a *dace* of the hay before them as high as their breast, from one end of the stack to the other; and after half its length is built up in this manner, the women go upon it and trample it, and if they hold by one another's hand in a row their walking will prove the more effective. The breadth of the stack is a little increased to the eaves. The hay is forked from the ground by 2 or 3 men, and when the stack has attained an inconvenient hight for this purpose, there are 2 or 3 modes by which hay may be carried to greater hight; one is by placing short ladders against the stack, and a man on each, some way above the ground, with his back to the ladder, where he receives the forksfull of hay from the forker on the ground, and raises the load above his head upon the stack. Another mode is for men to carry back-loads of hay up long ladders, and empty them on the stack. A third is to erect a scaffolding of planks upon a couple of tresses of 6 feet in hight, and to fork the hay off the scaffolding to the stack as it is forked upon it from the ground. Of the 3 modes, the last of the scaffold affords the most secure footing to the men at an elevation from the ground, and in the end is the most expeditious; and in all the modes 4 men will be amply employed in forking up the hay to keep 2 builders in work. The hay is forked off the ground instead of the cart, as the latter mode would hinder the horses too long to make them stand till the cart is cleared of its hay by forking. The hay is, therefore, thrown down upon the ground from the cart, and if the cart is constructed to tilt up, the deposition of hay is easily effected; and even from a whole-bodied cart hay is easily thrown off by the forkers sticking their forks under the load along one side of the cart, and pushing upward and from them to the other side, one person holding by the wheel nearest the men to prevent the cart upsetting. The position in which the load is thrown upon the ground requires to be considerately chosen. The load should be thrown away *from* the spot upon which the men stand to fork, when the hay will easily come away with the fork, because each stratum of hay, as it was forked on the cart, then lies toward the men; whereas, when the load is thrown *toward* the forkers, the inclination of the hay abuts against them, and every forkfull must then be pulled away by main force. A hight of 12 feet is enough for the body of the stack, and a breadth of 15 feet is convenient for a hay-stack, and with these fixed dimensions, the length may be made more or less, according to the quantity of hay to be stacked. With these dimensions a *new-built* stack of 40 feet in length will contain about 2,000 imperial stones. After the body of the stack has attained 12 feet in hight, the heading is commenced by gradually taking in the breadth on each side to the ridging, which is elevated half the

breadth of the stack above the eaves, and the ends are built perpendicular. One man and one woman will only find room at the finishing of the top of the stack. A few straw ropes are thrown over the stack to prevent the wind blowing off its new-made top. The stack is left for several days to subside, and unless it has been slowly built and firmly trampled, it may subside in the body to the extent of 2 feet. Very probably heat may be indicated in some part of the stack a few days after it is built, by a leaning toward that part, because heating causes consolidation of the hay. A prop of wood placed against the place will prevent the stack subsiding much farther, and the handle of a rake pushed in here and there into the stack, will indicate whether the heating is proceeding upward or to a dangerous extent. A gentle heating will do no harm, but rather good, by rendering the quality of the hay uniform, and horses do not dislike its effect. Salt has been recommended to be used in hay, and when hay is in a damp state in consequence of the weather, it is an excellent remedial measure against mouldiness, and it may be sown by hand upon every *dace* of hay laid down by the two builders. The proper quantity of salt is to be used, according to the state of the hay, has never been correctly ascertained, and must, therefore, be left to your own judgment according to circumstances. Salted hay is very much relished by all kinds of stock, and especially by cattle.

(2134.) When the hay has fairly subsided, and the heat, if any, is no longer felt, the stack should be *thatched;* and as a preparatory operation, the sides and ends are neatly *pulled* straight from angle to angle of the stack, with a small increase of breadth to the eaves. This operation simply consists of pulling out the straggling ends of the hay, which give a rough appearance to the sides and ends, in order to render them smooth; and its use is to save the hay pulled out which would otherwise be bleached useless by exposure to rain, and to prevent rain hanging upon them about the stack. The heading or thatching consists of straw drawn straight in bundles, held on by means of straw-ropes. When a hay-stack is to be thatched, the drawn bundles of straw, and the straw-ropes, should, of course, be prepared in time; and yet it is a matter not of unfrequent occurrence for farmers to allow the hay-stack to stand unthatched until the corn harvest, for want of straw; or even to allow the hay to be left in ricks on the field till just on the eve of harvest. Straw, in some instances, may indeed be scarce, but in that case rushes and other tall-grown wild plants form an excellent substitute, both for thatch and ropes. Ferns and heath are good materials for thatch. The thatching should be carried on both sides of the stack simultaneously by 2 men, and begun at the same end. The men being mounted on the head of the stack, the bundles of straw are handed up to them on a fork one by one as they are needed, and each bundle is retained in its place on the roof, beside the thatcher, by leaning against a graip stuck into the hay. The straw is first placed over the eaves, handfull after handfull from the eave to the top of the stack, each length of the straw being overlapped by the one immediately above it. When the thatcher feels a hollow or soft part with his feet in the head of the stack, he makes up the part by some of the hay that was pulled out of the stack, to save the wasting of thatch straw in filling up such hollows. The straw is thus laid from the eaves to the ridge of the stack to a breadth as far as the thatcher can reach at a time with his arms. When the men on both sides meet at the ridge, straw is laid along the stack upon the ridge, to cover the terminal ends of the thatch on the sloping roof, and to support the ropes which keep down the thatch. When this breadth, of perhaps 3 feet, or a little more, of the thatch is laid down, its surface is

switched down smooth by the thatcher with a supple willow rod, and then a rope is thrown across the stack at its very end, and another parallel to it at 18 inches apart, and made fast at both ends, in the mean time, to the sides of the stack. Other ropes, at right angles to the first, are fastened 18 inches apart to the hay at the end of the stack, and supposing the side of the roof to be 11 feet along the slope, 6 ropes running horizontally will be required to cover the depth of the slope, leaving a space of 9 inches from the ridge for the place of the uppermost rope, and the rope at each eave is put on afterward. Each of these horizontal ropes is twisted once round every perpendicular rope it meets, so that the roping when completed has the appearance of a net with square meshes. As every subsequent breadth of thatch is put on, the roping is finished upon it, the advantage of which is, that the thatching is finished as it proceeds, and placed beyond danger from wind or rain, or disturbance from after work. If the stack stands N. and S., the E. side should have a thicker thatching than the W., as being most liable to damp, and the thatching of both sides should be thicker toward that end of the stack which is farthest from the steading, as it will stand longest, and the process of thatching should terminate at the end which will be first broken upon, that is, nearest the steading, because the thatch will come away more freely when removed in the opposite direction from which it was put on. The horizontal ropes at their termination are fastened into the hay at the end of the stack. The eave is finished by laying a stout rope horizontally along the line where the roof was begun to be taken in, and twisting it round each perpendicular rope as it occurs; when each perpendicular rope is broken off at a proper length and fastened firmly to the hay immediately under the eave, and after the eave-ropes have thus been fastened down, the projecting ends of the thatch over the eave are cut straight along the stack, and give to the heading a pretty finish. Another mode of roping the thatch is to place the ropes in a diagonal direction across the stack, and when one set of ropes cross the other diagonally, the effect is lozenge-shaped, which looks well; but roping in this fashion requires the thatcher to place all the straw upon the roof before he guides the ropes over the ridge of the stack, to do which he must stand upon the ridge and step backward upon it—a plan which allows the wind to have liberty to blow off the thatch before it is roped at all, and also obliges him to trample down the ridge straw to a certain degree.

(2135.) On the other hand, when the stack is built under cover of a *rick-cloth* or *shed*, the hay may be led in by a cart-load at a time, employing only 3 hands, for the builder forks the hand-cocks in the field to the cart, and the carter forks the hay to the builder off the cart, while the same field-worker who rakes the bottoms of the hand-cocks in the field carries the hay to the builder on the stack, each forkfull of hay, in this case, being thinly scattered over the stack, is easily trampled down, and has time to subside before another load is put over it on the following day. Where the rick-cloth is used, the stack should be thatched on its removal; but where a shed is erected, no thatching is required.

(2136.) Hay is sometimes built in *round stacks*, which are kept of a cylindrical form for 7 or 8 feet from the ground, and then terminated in a tapering conical top, and thatched. Such stacks contain from 300 to 500 stones of hay. This form of stack is convenient enough when a whole one can be brought at once into the hay-house, but should the stack be of such a size as to be necessary to bisect it perpendicularly, the remaining half is apt to be blown over; or should its upper half be brought into the

hay-house, the under part must be protected by a quantity of straw kept down by some weighty articles, and in such a case it is seldom that these are put on with sufficient care to keep out rain and resist wind. Upon the whole, the oblong form of stack admits of being most conveniently cut for use, and left at all times in safety; because a section of any breadth can be cut from top to bottom to fill the hay-house.

(2137.) The rule for ascertaining the number of stones of hay in oblong stacks is simple enough, but not so for conical stacks. To find the weight of hay in an oblong stack:—To the hight from the ground to the eaves add one-half of the hight of the top above the eaves for the mean hight, then multiply the mean hight by the breadth, and then multiply the product of both by the length. Divide the gross product by 27, and the dividend will give the number of cubic yards in the stack, and that number of yards multiplied by the number of stones of hay in a cubic yard, will give the weight of the stacks in stones imperial. It is not easy to state the exact number of stones of hay in a cubic yard, as that must vary according to the compressed state of the hay, the weight actually varying from 5 stones to 9 stones per cubic yard, according to the age and size of the stack, and the part of the stack from which the hay is taken; but perhaps 6 stones may be near enough the mark of the weight in a new stack, 7 stones in one that has stood for some months, and 8 stones in one that has stood over years. The contents of a round stack with a conical top may be ascertained in this way:—Take the hight of the round part from the ground to the eaves, and add to it one-third of the perpendicular hight of the conical top above the eaves for the mean hight of the stack. Take then the mean girth, which, if the stack is wider at the eaves than at the ground, is ascertained by taking the girth at the eaves, and also at the ground, and dividing their sum by 2. Square the mean girth, and multiply the product by the decimal .0795, which will give the area of the base of the stack. Then multiply the area by the mean hight, which will give the contents of the stack in cubic feet, divide the contents by 27, which will reduce them to cubic yards, and then multiply the yards by the supposed number of stones of hay in the yard, and the capacity of the stack will be found in stones. To know the contents of a conical stack or coll, take the girth at the ground in feet, find the area of the circle in the ordinary way, and multiply the area by one-third of the hight. The contents thus found in feet reduce to yards, and then multiply by the number of stones in a cubic yard. But the simplest plan in all such cases is to use any of the Tables which are published for the purpose of saving tedious calculations, such as those of Anslie or Strachan, the latter of which, however, are not extended far enough to comprehend stacks of the largest dimensions.

(2138.) A crop of hay varies from 150 to 300 stones per acre, according to the season and the nature of the soil. On light gravelly soils the crop is never heavy, but its quality is generally fine, and on good clay it is usually heavy, and the plants large and strong, the clover predominating. For quantity and quality combined, a deep mellow clay loam may be regarded as the best texture of soil. On thin clay, and on thin light soil resting on retentive clay, the clover is frequently thrown out by frost in spring, and the hay then consists chiefly of rye-grass, and on the same soil the same effect is produced by severe drouth in May. Good hay should consist of equal quantities of clover and rye-grass, feel pleasant to the hand, and smell fragrantly, and, when well prepared, possess a light brownish-green color; but as it is commonly prepared, the color is usually light brownish-yellow. Hay of natural grass, when well prepared, is darkish green in color, feels soft, is generally of fine quality, and highly fragrant. Grass usually loses two-thirds of its weight on being made into hay.

(2139.) Of 3060 grains of white clover, as much as 2430 grains were water, 100 grains nutritive matter, and the remaining 470 grains were insoluble matter. The nutritive matter in the 100 grains consisted of 77 of starch, 2 of sugar, 7 of gluten, and 14 of bitter extract and saline matter.* "When green grass or clover, approaching to maturity," says Professor Johnston, "is first cut down, it contains a considerable proportion of starch, sugar, and gum still unchanged into woody fibre, as it would mostly be were the plant allowed to become fully ripe." Here you see the propriety of cutting down grass for hay before any of its seed approaches to maturity, because latterly it contains woody fibre instead of the nutritive ingredients just mentioned. But even when succulent grass is "left to dry in the open air, the circulation proceeds to a certain extent, and, under the influence of light, woody fibre continues to be formed in the upper part of each stem, until it becomes completely dry." And "it may even be a matter of doubt whether the process of change does not often proceed after the hay has been carried off the field and stacked."† All which considerations tend more and more to prove that the longer grass is allowed to stand after the plant has attained its full stature, the less digestible or nutritious the hay will become; and more than this, the longer the process of making the grass into hay is delayed, the more woody, and, of course, the less nutritious the hay will be. Every quick process of converting grass into hay is, therefore, better than any slow one. There is a very quick mode practiced in Saxony, which is this:—The grass that has been cut down during the day is put into large cocks late in the afternoon. A very strong fermentation soon ensues, which continues all night until the morning, when the work-people return to the field, by which time the cocks have contracted much in bulk, and the steam rises briskly from them. They are then thrown down and scattered on the ground, and their contents allowed to remain all day exposed to the sun and air, and by the afternoon the hay is so dry and won as to be fit to be stacked, and accordingly it is gathered from the ground and carried to the stack. The new-mown grass of the day is put into large cocks in the evening, to be treated the next day in the same manner. This mode of hay-making might be followed in this country, provided we could trust our climate; but should the next morning prove a rainy or even a damp one, the contents of the cocks would inevitably be rotted. The modes of

* Sinclair's Hortus Gramineus Woburnensis.
† Transactions of the Highland and Agricultural Society for October, 1843.

hay-making, both manually and mechanically, which I have described above, are both expeditious as are also the modes described by Mr. Little, Carleagill, and Mr. Miller of Forest, both in Dumfriesshire.*

(2140.) As hay is usually made in a thriftless manner, and as grass is more nourishing to stock than hay, and as good food can be cooked for horses in winter without hay, I have often thought it a loss to farmers to make hay at all. The grass would pay better on being grazed, and the land would be retained in better heart. In the vicinity of large towns, it may be expedient to make hay, and yet when the crop proves heavy the price is low—the average may be stated from the tramp-rick at 8d. per stone of 22 lbs. I have seen the price as low as 4d. and as high as 1s. 4d. per stone; but when the price is high, the crop is deficient, and the quality of the hay bad. Taking the heaviest crop of 300 stones at 8d., it will yield £10 an acre, but 220 stones is nearer the mark, and yet grass lets for cutting £12 or £14 per acre in the neighborhood of Edinburgh, without incurring any trouble to the farmer. I am sure if half the labor spent in making hay were bestowed in winter in cooking food for the horses, farmers would derive a profit from the exchange.†

(2141.) [Of the *hay-making* implements, the scythe (2615), and fig. 361, and the hay-fork, fig. 279, having been already alluded to, I have now to notice a machine which is extensively employed by the English farmers in the preparation of *meadow*-hay, or hay prepared from the mixed natural grasses, in contradistinction from the artificial, or rye-grass and clover hay.

(2142.) The English hay-tedding machine, which is represented in perspective in Plate XXXI. fig. 368, consists of a skeleton carriage, having a series of revolving rakes occupying the place of the body. The carriage is composed of the transverse bar *a*, 6 feet in length, into which the horse-shafts *b b* are tenoned. An iron stay-bar *c c* on each side connects and supports the shafts, and the stays are continued backward, and attached to the center of the box that carries the axle of the carriage-wheel on each side. The length of the bars *c* from *a* to the center of the axle-box is 2 feet 10 inches, and the bars are 2½ by ½ inch. The carriage-wheels *d d* are 3 feet 10 inches diameter, and turn upon arms cast on a circular box, into which the nave of the wheel, armed with a ratchet *e*, is received. The ratchet-wheel *e*, thus attached to the nave of the carriage-wheel, takes hold of the spur-wheel *f* by means of a pall, and carries it round when the machine advances, but slips hold on backing or turning. The spur-wheel *f* works into the pinion *g*, which is mounted on the end of the hollow shaft *h*, extending from side to side of the machine; and though in the figure, for the sake of distinctness, the spur-wheel and pinion are exposed to view, they are in the machine closely boxed up in a cast-iron casing, which, for perfect and safe working is necessary to prevent entanglement from the hay falling between the wheel and pinion. A bar of 1¼-inch round iron passes through the hollow shaft *h*, and has its end fitted tightly into the outward side of the case that contains the pinion *g*, and there fixed firmly with a screw-nut on the outside of the case; and the hollow shaft and pinions being firmly connected by thin flanges (which are left out of the figure), they revolve round the central rod or shaft as one body, the rod having turned bearings where the pinion embraces it. The two rake-wheels *i i* are 2 feet 8 inches diameter, and of very light construction; they have eyes sufficiently large to pass over the end flanges, of about 7 inches diameter, of the hollow shaft, to which the pinions *g* are attached by means of their flanges; and, to fill up the large eyes of the rake-wheels, the shaft *h* is swelled out at the points of bearing. The rake-wheels, fixed dead upon the shaft *h*, are now armed with the eight rakes *k k*; these are wooden bars 5 feet 6 inches long, and 2½ inches square, each carrying 10 light iron teeth about 7 inches in length. The rakes are attached to the wheels by a tumbling joint *m m*, &c., and are held to the work by the springs *l* only; by which arrangement, when any undue resistance is opposed to a rake, such as a stone or other obstruction, the rake falls back till the obstruction has been passed, when the springs immediately return it to its working position.

(2143.) It will be observed that there is no thorough axle in the machine, as the revolution of the rake occupies the place where that member should exist; hence the axle-arms or heads are simply studs projecting from the box which contains the machinery *e, f, g*, and hence also the necessity for the connecting-bar which passes through the hollow shaft; that, together with the

* See Prize Essays of the Highland and Agricultural Society, vol. xiv.

[† We have before us a letter from Henry Ancrum, of Ashley, Missouri, in which he says:—"I have tried a great many experiments on animals. I have kept 20 Durham cows, 7 horses, and other stock, in a situation where hay was $25 a ton, in the highest health and condition without a blade of hay; and the result of my investigations and trials is, that cooked food in winter is the cheapest and most wholesome,

I have found that it is pretty indifferent as to the quality of the food by which the alimentary canal is filled, if ample, provided a certain quantity of concentrated food is given containing nitrogenous substances, and a small quantity daily suffices. No animal can be brought easily and readily to his highest pitch of perfection on one kind of food alone. The great secret is to keep up the animal heat in the winter. Where this is strictly attended to, any inferior food at discretion, and given with stated regularity, will make an animal fat. I have seen oxen of the largest size made completely fat with a moderate allowance of hay, with cabbages of the Anjou kind; but these animals were fed with the greatest regularity, carried, kept extremely warm, and the chill taken off the water in cold weather. How many millions are lost in the United States by not keeping up the animal heat in the winter?"

These suggestions, sustained by modern experiments on the nature and action of food, we consider important, as going to show that good hay is not so indispensable as may be imagined by those who have it not within their reach or to whom it would be very costly. *Ed. Farm. Lib.*]

bar *a* and the longitudinal bars *c c*, being the only parts which constitute the framework of the machine. Besides the capability of backing, without turning the rakes, there is provision for disengaging them when the machine is advancing. To effect this, the pall which is attached to the spur-wheel *f*, for the purpose of deriving its motion from the ratchet-wheel of the nave, is held in action by means of a spring pressing on the tail of the pall, and the disengagement of the whole machinery from the carriage wheel or first mover, is effected by a small tumbling lever affixed also to the spur-wheel, and fitted to bear upon and throw the pall out of gear with the ratchet of the carriage-wheel nave. The machine is also furnished with the means of elevating and depressing the center of the revolving-rake, and, of consequence, bringing the rake-teeth nearer to, or farther from the ground, and this is effected by turning round the circular boxes that contain the gearing to the extent required, which is then fixed by means of a quadrant bolted to the bars *c*, *c*; a small portion of this quadrant, which is a part or flange of the gearing-box, is seen with its bolt-holes at *e* on the left, and at *i* on the right of the figure. When in operation the machine is drawn by one horse, or sometimes two horses, and the result of the combination of the gearing is that the revolving-rake makes 4½ revolutions for one of the carriage-wheel. The latter being 3 feet 10 inches diameter, will pass over 12 feet or thereby in one revolution, and the rakes being 4 feet 6 inches diameter over the extreme points of the teeth, will describe a circle of about 14 feet in circumference, and this revolving 4½ times for one of the other, the points of the teeth, will pass through 63 feet while the carriage has moved over 12 feet, and as there are 8 rake-heads, there will be 8×4·5=36 contacts with the substance which is to be lifted, in a space of 12 feet, or one at every 4 inches. From this calculation it will be seen that the hay under the operation of this machine will undergo a process of teazling or tedding of the most perfect description; it will be separated and tossed about until no two stems of the plants will be left in contact, and by this exposure the drying process is effected in a period greatly shorter and more effectually than could be done by any number of hands. Thus, if we suppose the horse to walk 2½ miles per hour, and the machine to cover 6 feet in breadth, we have a surface of 1½ acres nearly covered in an hour.

(2144.) The following machines, though not confined to the hay-field alone, but are also employed in the grain harvest, are very frequently employed in hay-making, for the sole purpose of collecting the hay into heaps after the tedding process has been gone through.

(2145.) The *hand hay-rake* is an implement of great simplicity, but though almost elementary in its construction, it has been subjected to numerous variations, chiefly in one point, with a view to improve its construction. It consists of a head *e d*, fig. 399, *g k*, fig. 398, of from 24 to 27 inches in length, made of hard wood 1½ inches broad in the middle, tapering a little to each end, and from 1 to 1½ inches thick. The head is armed with twelve or thirteen wooden teeth *a* or *e*, made of oak or ash ¾ inch in diameter, and, when first made, about 3½ inches long. They ought to be formed

Fig. 398.

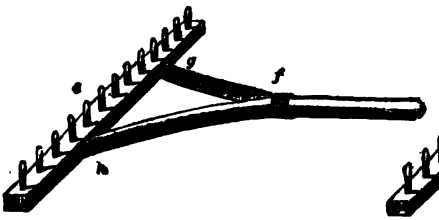


Fig. 399.

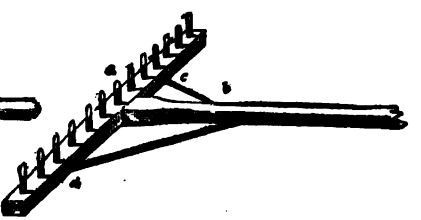


THE HAND-RAKES.

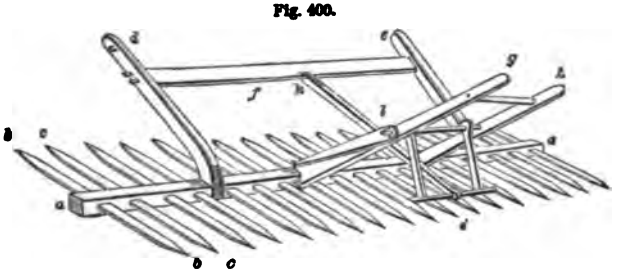
with a slight swelling in the middle, or rather towards one end, the shorter end being adapted to fit into holes previously bored at 2 inches apart centres; and when the teeth are driven into their holes the swell on the tooth fills up the hole tightly, giving the tooth much greater strength than if it were quite cylindrical. The teeth are then properly secured by wedging, and the wedges and ends dressed off; the points of the teeth are likewise dressed off to a uniform length, 2½ inches or thereby, and sharpened off from the back. The shaft or helve, which is 5½ feet long, is usually made of ash, but as lightness is an object, its thickness ought not to exceed 1¼ inches, dressed neatly smooth and round except where it enters the head; here, and for a length of 12 inches, it is usually kept square. This part of it is either let into the middle of the head by a tenon, as in fig. 399, or it is split as in fig. 398, and enters it by two tenons. It is in this point of the construction that the variations have occurred, and from the slightest consideration it will be evident that the single tenon alone, as in fig. 399, is defective and weak; hence the grounds for the variation, to afford some additional support to the simple tenon, and fig. 398 exhibits one mode of accomplishing the object; the helve is split with a saw from the end backward to *f*, at which point it is prevented from splitting farther by the application of a rivet put through the termination of the split part, or, what is much better, an iron ferule, as in the figure, is drawn tight upon it; the fork is then opened, the ends adapted to the respective mortises and secured into the head of the rake. This is apparently a very simple mode of accomplishing the object, but it is not by any means a perfect one. Were it possible to make the two parts *f g* and *f k* free of curvature, the object would be attained; but as this cannot under the circumstances be done, the head and the helve will have a very unstable attachment to each other, and a consequent weakness of parts; neither is it less expensive than other and better methods, though the rake of this form is always light in hand, which is its only commendation. A semi-circular bow of bent ash wood has been often applied, passing through a hole at *b*, fig. 399, and entering the head at *c* and *d*, but this, by reason of its curved figure, is also especially defective, besides weakening the helve. Equally so is a light iron bow of the same curvature, but, instead of passing *through* the helve, it is simply attached to

it, and to the head with a nail at each of these points. This will be better in degree than the last, from the greater rigidity of the iron, but is not better in principle. The true and only mode of applying the bow is that exhibited in fig. 399, where the parts *b c* and *b d* are perfectly straight, and formed of very light iron rod; it need not exceed ¼ inch diameter, flattened at the two extremities and at the point *b* into a small flat palm, and fixed to the helve and the head by a screw-nail at each point. This part of the rake is called the stay or brace, and in the last described form is as perfect as the case will admit of.

(2146.) To have said so much on an implement so simple and of such small intrinsic value may appear trifling, but the hay-rake is not so much the object here as the development of the principle, on which depends the strengthening and supporting the parts of any form of frame-work, whether of wood or iron, by the aid of diagonal stays or braces. This single member in all constructions is of such importance that no opportunity should be lost in impressing the principle on the mind of all, whose business or interest lies in those departments of Mechanics where its application is required.

(2147.) The *American hay-rake*, is so called from its having been an importation from America. This implement is represented in fig. 400, in perspective, and lying in the working position. It

Fig. 400.



THE AMERICAN HAY-RAKE.*

consists of a beam or head *a a*, 9½ feet long and about 4 inches square; it is perforated with 18 square mortises, into which the transverse bars or teeth *b b*, *c c*, &c. are firmly fixed. These teeth are about 3 feet 10 inches long, or 21 inches on each side of the head *a a*, and are about 1½ inches square on the body, slightly tapering to each end, where they are rounded off to a blunt point, but chiefly upon that side which is to lie next the ground, and this constitutes the body of the rake. It is drawn by a horse yoked to the draught-frame *d e*, of which *d* and *e* are two naturally-bent bars of wood about 3½ feet long and 4 inches by 2½ inches at the butt-end; at the butt they are worked out to the end in a semi-circle half embracing the head *a a*, which is here dressed into a cylindrical journal, and the bars *d e* are secured to the journals by a strap of iron passing round each and nailed or bolted upon the bars, leaving them freedom to traverse upon the journals. The stretcher-bar *f* is mortised into *d* and *e* at a distance of not less than 2 feet from the head *a a*. The handle-frame by which the implement is guided has the two bars *g* and *h* 4½ feet long and is 2½ feet apart; the bars being attached to the head in the same manner as described for *d e*. The two bars *g*, *h*, are also connected by 2 stretchers, and upon the lower one is appended the light pendent and movable frame *i*, the depth of which from the stretcher, to which it is appended, to the bar *i* is 10 inches, and is jointed to swing freely on the stretcher. The bar *i* of this last frame is put in connection with the draught-frame, by means of the connecting-rod *i k*, which is jointed movable at both ends on round journals, and strapped as before. The stretcher on which the frame *i* is appended is prolonged at each end to receive the catch-bars *l*, on the outside of the frame *g h*, one of which bars is seen at *l*, jointed on the prolonged stretcher, the position of which is 2 feet 3 inches from the journal of the head *a*. The catch-bars are 3½ inches by 1½ inches at *l*, but diminish forward to 1½ inches square at the point, where they abut upon an iron stud, which is presented at two of the opposite corners of the rake-head, at each side of the handle-frame, serving an essential purpose in the management of the implement.

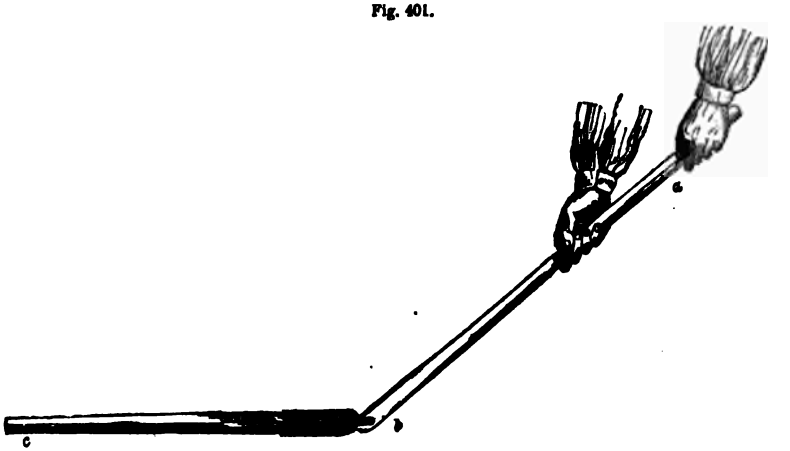
(2148.) In the working of this rake, it lies nearly flat on the ground, and when the draught-frame is at its proper hight, the connecting-rod *i k* keeps the hanging frame just within the extremity of the teeth that are then behind, and nearly bearing upon them. In this position also, the point of the catch-bars *l* is quite free of the studs of the head or beam, and by pressing down the handle-frame, the pendent *i* will come down upon and depress the teeth that are looking backward, raising at the same time those in front, such as for the purpose of passing over any obstruction. When, on the contrary, it is wished to depress the front teeth, the handle-frame is raised till the points of the catch-bars press against their studs, which will depress the front-teeth; and by continuing to elevate the handle-frame, the connecting-rod, from change of position in the bars *i k*, *i l*, and *l f*, will push the pendent *i* beyond the extremity of the teeth behind, when, the front teeth taking the ground, and nothing to resist the rising of those behind, the rake will immediately tilt over, the fore and hind teeth changing places; but, in other respects, everything will be the same as before. The effects of the motion and tilting, it is evident, will be, that in the progressive state the rake collects the hay or straw upon it chiefly in the front part; and when the attendant sees that the rake is filled, he raises the handles and tilts the rake as above described, leaving the collected mass at the spot where the tilt occurs.

[* Invented by Moses Pennock of the Society of Friends, in Delaware. Men's names have been immortalized by acts of much less public service. *Ed. Farm. Lib.*]

(2149.) A slight consideration of this implement will show the effectual and convenient manner in which its work is performed; but it will also probably occur to the observer, that, for progressive motion, it is by no means so well adapted as for collecting and depositing the products. The heavy transverse bar, or head of the rake, is drawn forward in the worst possible position, or what is called broad-side on; and it appears very obvious that this defect could be removed by simply applying a pair of low light wheels to the ends of the head; their diameter need not exceed 8 inches, and they should be very light. Perhaps it may be owing to this defect that the American hay-rake has of late years not been in such high repute as formerly.

(2150.) The *Flail*, fig. 401, is an implement of considerable antiquity, and of very extended application. Till about 80 years ago, it was the sole implement employed in Britain, and to this day is nearly so over a great part of Europe, for threshing out the grain from the straw. Though falling rapidly into disuse in England, it is nevertheless an important implement in many others, and therefore claims our attention in common with those of higher pretension. The flail consists of two parts, the *hand-staff* or helve *a b*, and the *supple* or beater *b c*; the first is a light rod of ash about 5 feet in length, slightly increased in breadth at the lower extremity, where it is per-

Fig. 401.



THE FLAIL.

forated for the passage of the thongs that bind the beater to it. The beater is a rod of from 30 to 36 inches in length, frequently also made of ash, though a more compact wood, such as thorn, is better adapted for it. If not properly applied, the ash beater will very soon separate into thin plates, which are portions of the concentric layers of the wood, and their separation arises from the beater falling upon the flat or convex side of these annular layers—or the reed of the wood, as vulgarly called. To prevent this disintegration of the wood, the beater should be constructed to fall upon the *edge* of the segmental portions of the *reed*, which is easily accomplished in its formation. The usual form of the beater is cylindrical, but frequently thickened a little toward the extreme end, the diameter being from 1¼ to 1½ inches. For the most part, it is attached to the hand staff by a strap of leather, or more frequently of hide untanned; when mounted in this manner, the beater is formed with two projecting ears, standing at right angles to the side on which it is intended to fall, and about 1½ inches from the end by which it is attached, serving the purpose of retaining the end of the beater within the strap. The strap is about 8 inches long and 1½ inches broad; it is bent over the end of the beater, and the tails brought to embrace the sides of it beyond the ears. The strap being previously perforated with four holes in each tail, it is bound by a thong of leather laced through the holes and round the neck of the beater; the upper turn of the lacing thong catching the ears, prevents the strap from slipping off. The strap, thus applied, forms a loop standing about 1 inch beyond the end of the beater; and through that, and the perforation in the end of the hand-staff, another and stronger thong is passed several turns and secured, forming thus a kind of loose swing-joint that allows free action to the beater in its gyration round the head of the thresher, and its descents upon the threshing-floor. Another mode of mounting the beater is by applying a strap of iron in place of leather, which is fixed to the wood by riveting, leaving a loop as before, which must be nicely rounded and smooth, to prevent the too rapid chafing of the thong by which it is bound to the hand-staff, in the same manner as described above. The figure here described exhibits the iron strap. In constructing a flail, a very general practice prevails, which is, to have the beater club-shaped, or thickest at the farthest extremity *c*—intended, no doubt, to give the better effect to the blows; but when we consider the effects arising from the manner of wielding the instrument, any additional weight at the extremity seems misapplied.—The greatest amount of useful effect will be produced by the beater when every point in its length strikes the floor with an equal amount of momentum or force; but there will be a constant tendency to a larger amount of momentum at the extremity *c* than at any other point, and a club-shaped beater will always augment this tendency, for the greater velocity of the extreme end, during the gyration of the instrument, multiplied by its greater weight, must give an undue preponderance of effect to that part of the beater, thereby lessening the general effect upon the work

under performance. The opposite mode, which is also practiced, to make the beater thinner toward the extremity, as exhibited in the figure, is more consonant to the laws of dynamics, and there can be no doubt that its practical effects will be equally favorable as compared with those of the club-shaped beater."—*J. S.*]

30. SUMMER-FALLOWING, AND LIMING THE SOIL.

"The bare fallow brings to teeming foyson."
MEASURE FOR MEASURE.

(2151.) Although summer-fallow occupies the same division of the farm as green crops—turnips, potatoes, tares—yet it may most characteristically be regarded as the first preparation for the crop of the following year; it is a transferrence of a portion of the land, with the labor bestowed upon it, from one year to another; it forms the connecting link between one crop and another. But although the preparation of the soil for a part of the crop of two consecutive years are conducted simultaneously by means of summer-fallow, yet the crops which occupy the soil thus simultaneously prepared are committed to it at very different periods—the green fallow crops being sown early in summer, while the sowing of the fallow crop on the summer-fallow is delayed to autumn; so that before the latter makes its appearance above ground, the former have almost advanced to maturity. Since the crop on summer-fallow is delayed to autumn—till the eve of commencing another agricultural year—the practical effect of the delay is to dispense with a crop for a whole year on that part of the fallow-break which is summer-fallowed, and, on this account, such a fallowing is commonly called a *bare*-fallow. As an entire crop is dispensed with, bare-fallowing should impart such advantages to the land as to compensate for the rest and indulgence which it receives; and so, in fact, are its advantages felt on some sorts of soils. But the truth is, after all, that bare-fallowing is a necessitous operation in soils that will not carry green or summer crops; and if such soils will not carry them, they must be operated on so as to be made suitable for a crop which they will not only bear to perfection, but will pay the expense of the operation. The sort of soils alluded to are heavy clays; and why will *they* not bear green summer-crops? A satisfactory reason cannot be given; but the fact, as developed by experience, is, that their nature is unkindly to the growth of plants commonly used in a green state; and their heavy, wet and obdurate nature prevents them, at any rate, from being prepared in time for sowing such plants.—Could clays be altered in their nature by any means, they might be employed in raising summer crops as well as the naturally more kindly soils; and such a change has been effected on many clay soils which were formerly incapable of rearing them; and the change has been effected by ameliorating their texture by thorough-draining, skillful tillage, and liberal manuring and liming. In this way the bounds of bare-fallow have been much circumscribed, and those of green crops as much extended. Still the heavier class of clays—the deep alluvial clays—have not yet been ameliorated to the degree of bearing green crops profitably, so they must continue to be bare-fallowed; but more than this, part of even the ameliorated

[* This implement is still much used in the Eastern States. Col. Chapman, President of the Saratoga Agricultural Society, still uses it on the ground of employment to the poor men who do the work. *Ed. Farm. Lib.*]

soil of almost every farm is necessitated to be bare-fallowed, for want of an adequate supply of farm-yard manure. Farms in the vicinity of large towns may be amply supplied with extraneous manure, to make up for the deficiencies of the farm-yard; but as most farms are beyond the reach of such assistance, it may be alleged that bare-fallowing, to some extent, is practiced every year upon every farm; though the limits of compulsory fallowing have been much circumscribed of late years by the purchase of extraneous manure from distant sources, which are easily conveyed, and sold at prices that afford a profit. Those manures—and I only allude to them here—are bone-dust and guano. These, superadded to draining and deep-plowing, have afforded the power to cultivate green crops upon soils which were naturally unfit for them; and, without such auxiliaries, soils suitable for their growth would be obliged to be bare-fallowed, to allow time to collect the requisite quantity of manure to support their fertility. Until manure is, therefore, obtained in sufficient quantity, bare-fallow must exist; but whenever that desideratum shall be accomplished, many farms will dispense with bare-fallow altogether. But there is a natural obstacle to the increase of manure in farms themselves; for it so happens that the greatest quantity of straw, which is the great source of fertilizing manure, is afforded by land the least fitted for green crops; and, on the contrary, land best fitted for green crops affords the least quantity of straw. Turnip-soils cannot supply as much straw as to manure, to the degree and in the state it should be applied to green crops, little more than ½ of the fallow-break; whereas clay soils afford as much straw for manure, in the state in which it may be applied to them in bare-fallow, as sufficiently to manure the fallow-break.

(2152.) The land subjected to bare-fallowing should have the strongest texture; be foulest of weeds, if any there be; and be situate farthest from the steading, that the carriage of turnips may be rendered as short as practicable. The winter treatment of the fallow land is the same as that for the summer crops, and this has already been described in preparing the soil for potatoes (1870) and turnips (1953). If one furrow—that of two-out-and-two-in, or of four-out-and-four-in—has been given to the fallow-break after cross-plowing, it will be as much as time can afford from working the potato and turnip land; and when it is found that the fallow-break will not likely be worked for some time to come, it is better to let it lie in the rough state left by the plow, than to render it smooth with the harrow; because, should dry weather ensue, the air will more easily affect rough than smooth land; or should it prove wet, the rain will less likely render rough land tough, than land in a compact and smoothened state; and, in strong soil, rain most advantageously moulders down rough clods.

(2153.) When leisure is again afforded to pay attention to the fallow-break from the advanced working of the turnip-land, the *state* of the fallow-soil should be particularly examined. Should the weeds in the soil consist principally of fibrous and fusiform-rooted plants, they will be easily shaken out by the harrows in dry weather; but should the running roots of weeds be found to have threaded themselves through hard, round clods, these will not be so easily detached, and it requires considerable skill in the farmer to conduct his operations so as to detach them with the least application of labor. It is inattention to *these states* of the weeds which causes so much unnecessary work in the subsequent part of summer in cleansing fallow land. If clods containing portions of the running roots of plants are knocked ever so much about in dry weather, they may be broken into smaller fragments; but the roots in them will be subdivided into as many pieces as there are broken clods, and the land will be as far

from being cleaned of weeds as ever; nay, the greater number of parts in which the roots are divided, so many more chances have the weeds of being disseminated over the land.

(2154.) In such a case, which is of frequent occurrence on strong land, the best plan is to allow the roots to grow for a time, and the force of vegetation will have sufficient power to break the clods, or will render them easily so by the roller, to reduce the clods by rolling after such a shower of rain as shall have nearly penetrated them. A precaution in the use of the roller should, however, be here observed. When most of the soil is in a mouldy state, rolling the hard clods found on it, will only bury, not break them. Rolling, with a view to breaking large clods, should therefore be performed when the soil is in a firm state, against which the clods will be reduced to powder. After such a rolling, the land should be harrowed a double tine, first one way and then across another way. The weeds and weed-roots will then be seen upon the surface. It is not expedient to gather weeds immediately on their being collected by the harrows, as a good deal of fresh soil adheres to them. A day or two of drouth should intervene, and the weeds will then be easily shaken free of soil by the hand. It has been recommended by writers to gather the weeds of fallow land by a raking implement, such as the American hay-rake, fig. 400; but every instrument of the kind will rake together clods as well as the weeds adhering to them, and if these are carried away with the weeds, the land will be impoverished by the loss of its finest soil; whereas the hand which throws the weeds into convenient heaps, can at the same time shake them free of soil. In collecting weeds, the field-workers should be ranged in a row as when weeding corn, every two throwing the weeds into the same heap; and the rows of heaps should be placed as far asunder as to allow a cart to pass between them, and take away 2 rows at a time. Many writers recommend the weeds to be burnt on the ground. No doubt, weeds will burn readily enough when dry, and the ashes of weeds constitute good manure, but, for my part, I never saw heaps of weeds thoroughly burned, and have seen their remains scattered, again to render the land foul. I agree with Lord Kames, that it is better to make a vegetable compost with weeds, than to destroy them by incineration, and with him readily demand, "What better policy than to convert a foe into a friend?" It is impossible to determine beforehand how many times fallow land should be plowed, harrowed, grubbed, and rolled, to render it clean; but it should be borne in mind, to incur the least expenditure of labor in accomplishing the object fully. It was once the practice to work fallow land until it was reduced to the state of meal; but experience has long established it as a fact, to be better for the ensuing crop of wheat to preserve a good-sized clod upon the surface of the ground in winter, however much the ground may be otherwise pulverized. The land must have been very foul, the weather very unpropitious, or much time wasted, if the fallow land is not ready for the manure by the beginning of August, before the chance of harvest interfering with the process of manuring.

(2155.) The usual mode of *laying dung on fallow land* is to feer the ridges (660), cart on the manure in heaps, spread them, and plow the manure in. So far as I have observed, the manure is spread over a large portion of the surface some time before it is plowed in, when, of course, much of its moisture will be evaporated. I very much prefer another mode of plowing in the dung, which is, to *angle-drill* the land in preparation for the dung; that is, to set up the land in *single* drills (1735), and fig. 323, from the flat without any feering, beginning at one corner of the field,

and terminating at the opposite one: the plow making the drill in one bout, the cart depositing the manure for 3 drills, 4 women spreading it immediately after the cart, and the plow following and covering up the dung in one drill in another bout (exactly as represented in potato-planting, fig. 344), is a process which so quickly and completely covers in the dung, while in possession of its moisture, that it should be universally adopted. The land remains in the drilled state until prepared for the wheat seed in autumn.

(2156.) Fallow land is not dunged so heavily as that for green crops, not so much from fallowed soils not bearing heavy manuring, as from want of manure. From 12 to 15 tons the imperial acre is an ordinary manuring for fallow. The manure need not be so well fermented as for green crops, as there is usually sufficient time for its fermentation in the ground before the wheat is sown. If there is not sufficient time, it should be fermented before its application, as it is not expedient to sow wheat to stand the winter in soil rendered hollow by rough dung. In strong carse clay, the manure is often applied in a state little removed from wet straw, and yet it seems to answer well in such a soil.

(2157.) While treating of fallow, it is necessary to notice the *liming* of land, as lime is commonly applied at that period of the rotation of crops, though by no means applied every time the land is fallowed. It has always been a favorite practice with farmers to apply lime in as caustic a state as practicable; because, perhaps, it is then in the state of finest powder, and easily commixes with every species of soil. When obtained from the kiln or from shipboard, it is in lumps, light in weight, and is technically called *lime-shells*. There is a difference in the practice of disposing of lime-shells while in preparation for the soil. Some lay down the shells in small heaps upon the feered ridges, while others lay them in large heaps along a head-ridge. It is clear that shells cannot be laid at once upon the land, unless the land had previously been sufficiently fallowed; and as land occupies a considerable time in being fallowed in a proper manner, it is also clear that no considerable quantity of lime can be driven, after the fallow is ready, unless the kilns are situate very near; and, at any rate, it is unnecessary to lay the lime upon the land, but at a short period before the wheat is sown. Besides, when shells are placed in heaps on the ridges, they must remain a considerable time there till reduced to powder by the air, when the lime will have lost a considerable portion of its causticity by union with the carbonic acid of the air, unless a good deal of rain shall have fallen to hasten its slaking. To preserve the shells intact, till needed, they should be put in large heaps, the outer surface of which may become neutralized by the action of the air, but the interior of which will not be so affected. Meantime the land is worked as opportunity offers, while the heaps occupy a head-ridge.

(2158.) A week or so before the lime is applied, water is poured on the large heaps of shells, in order to reduce them to a state of impalpable powder. The water will all be absorbed by the lime, which will, nevertheless, continue quite dry, thereby indicating that the water has disappeared by reason of its chemical union with the lime. A great quantity of heat is evolved during the time the lime takes to fall to powder; and when that last has been accomplished, the heaps will have swelled to more than three times their former size, when the lime is said to be *slaked*, and is then in its most caustic state. While the slaking is proceeding, the land that was manured in drills is cross-harrowed a double tine, to make it flat; after which the ridges are feered; and the lime is then spread along the feered ridges. The lime is spread in this way: The frying-pan

shovels, fig. 176, are the best implements for filling carts with, and spreading lime on land. A *calm* day should be chosen for the purpose, but should there be an air of wind, the single-horse carts should be so placed at the heaps as that the lime-powder which floats in air should be blown away from the horses and men. Powdered lime is heavy, but all that can lie upon a shovel is so light that one plowman takes a heap, and with one of his horses in a cart, for a yoking at a time, fills his own cart, and spreads the lime from it upon the land, with the shovel. The liming should be conducted against the wind; and when a number of men take from different heaps, they should so arrange themselves along the feered ridges as that the cart farthest down the wind takes the lead in spreading. In spreading lime, the man walks along the middle of the feered ridge, and casts the shovelsfull right and left from the middle toward the feering furrows, which will, of course, become, by plowing, the crowns of the future ridges. The man who can cast the shovelsfull with either hand will spread lime better than one who is right or left handed only. The lime should be spread *evenly over the surface*, but it may be spread thicker on one part of the field than another, according to the nature of the soil. On light knolls it may be spread thinner than in hollows, where the soil is either deeper or stronger. Progressively as the lime is spread, ridge after ridge, it is harrowed in and mixed with the soil; and immediately on the entire field being limed, the ridges are plowed with a *light* furrow, to bury the lime as little as possible, and which constitutes the seed-furrow of the future crop. It will be observed, from what has been said on the manuring and liming of fallow land, that the lime is spread above the dung, and some time after its application. This relation between the two substances is held, because it is conceived that, as dung has a natural tendency to rise to the surface, and lime to descend, this is the proper relation they should bear in the soil. Whenever rain falls, the liming should be discontinued.

(2159.) It is proper to put a cloth over the horse's back and the harness, and the men may cover their face with crape, to save its orifices being cauterized by the quicklime. The horses, when loosened from work, should be thoroughly wisped down and brushed, to free them of every particle of lime that may have found its way among the hair; and, should the men feel a smarting in their eyes or nose, a little sweet thick cream will be felt as an agreeable emollient; and the same application will prove useful to the horses' eyes and nose.

(2160.) The *quantity* of lime that should applied depends on the nature of the soil, the lighter soils requiring the less, and the stronger soils the greater quantity. On light turnip-soils, some think 120 bushels to the imperial acre sufficient, while I have used 150 bushels with benefit. I have seen as much as 510 bushels applied to the imperial acre, wheat-land, with manifest advantage. But perhaps from 150 to 240 bushels may be considered fair average quantities, according to the nature of the soil. On weak moory soils, 75 bushels are, perhaps, enough to commence its improvement with. The sort of lime should determine the quantity applied, the stronger being used in less quantity than the weak. The English lime is much more caustic than the Scotch. It is not customary to apply lime often to land, a farmer not thinking it expedient to apply it oftener than once in a lease of 19 years, on account of its expense. Its common price is 3s. per boll of 6 bushels; consequently its entire cost, at those quantities, will be from £3 15s. to £6 per acre for the best sea-borne English lime, exclusive of carriage; the Scotch sells for 10s. per cart-load of 4 bolls, including carriage for 10 miles.

(2161.) Lime is applied at different periods of the year, according to the state of the land. On summer-fallow it is applied immediately before the wheat is sown in autumn. It is also used immediately after taking up the potato crop in autumn. It is applied to the land cleared of turnips by sheep, just before the sowing of the barley-seed in spring. It is also applied before the turnip-seed is sown in the beginning of summer; and it may be applied to lea immediately before being plowed for oats in early spring. I do not say that it is immaterial to the proper use of lime to choose the season in which it is applied, convenience often determining that point as much as propriety; but experience has taught that it is used to manifest advantage when spread on land in summer-fallow, and for barley-seed immediately after the ground has been cleared of turnips by sheep.

(2162.) Lime is usually procured in summer and autumn, as the kilns are only kept in activity in those seasons, so when it is intended to apply it in spring, it is necessary to procure it in autumn, and keep it all winter; and to preserve it in the desirable state in winter, the heaps of shells should be covered with a thick coating of earth, and every crevice that appears in it should be immediately filled up. I am quite aware of the opinion of some farmers that lime is equally efficacious in the soil in the effete as in the caustic state, and Lord Kames was of that opinion; and, therefore, precautions to preserve it in a caustic state in winter may, by them, be deemed unnecessary; but as the general opinion runs in favor of quicklime, and which opinion I support, I have treated the subject accordingly, until experience shall instruct us better. There is this advantage, however, in using quicklime, that it is much more easily spread upon, plowed into, and mixed with the soil than effete lime.

(2163) It is supposed that light and heat, together with cleansing and working, have a beneficial effect upon soil. That these agencies promote fertility in some way, perhaps by affording facility to the union of oxygen with the soil, appears certain, for a smaller quantity of manure will raise as large a crop with bare-fallow as a greater quantity without it; and yet this particular result is only obtained from a peculiar class of soils—namely, the strong cla.s, for all turnip-soils actually become more fertile by the overshadowing of a luxuriant crop of leaves than by bare-fallowing.

(2164.) The action of lime upon land seems generally well understood by farmers. They conceive that lime operates in two ways upon soil, namely, mechanically and chemically. *Mechanically*, it subdivides the adhesive portions of obdurate clay; hence it was customary in the Carse of Gowrie, when the high price of grain remunerated the outlay, to apply lime to the land every time it was bare fallowed, that is, every 6 or 8 years, according to the rotation of crops pursued. I suspect that liming is not now so frequent there as it was wont to be. *Chemically*, lime unites with vegetable matter, and assists in its decomposition; hence it has been found to act *very* beneficially on all *deaf* soils. It renders loose soils more firm. In strictly chemical language, quicklime acts as an alkali, and this property has led some writers to assert that green vegetables are not decomposed, but rather preserved, by caustic lime—a result which cannot be experienced by the practical farmer in the soil; because, as caustic lime very soon becomes a compound of a hydrate and a carbonate in the soil, the property of this latter state is to accelerate rather than retard the decomposition of vegetable matter. As the consideration of this subject would lead us into a long discussion, I must content myself with quoting only a part of the account of the theory of its action by Professor Johnston, in order to show that the opinions of farmers is not far astray on this subject, which, in some respects, is yet but obscurely understood. "Lime acts in two ways on the soil," says the Professor. "It produces a *mechanical* alteration, which is simple and easily understood, and is the cause of a series of *chemical* changes, which are really obscure, and are as yet susceptible of only partial explanation. In the finely divided state of quicklime, of slaked lime, or of soft and crumbling chalk, it stiffens very loose soils, and opens the stiffer clays; while in the form of limestone gravel, or of shell-sand, it may be employed either for opening a clay soil, or for giving body and firmness to boggy land. These effects and their explanation are so obvious to you that it is unnecessary to dwell upon them. The purposes served by lime, as a chemical constituent of the soil, are at least of four distinct kinds. 1. It supplies a kind of inorganic food, which appears to be necessary to the healthy growth of all our cultivated plants. 2. It neutralizes acid substances which are naturally formed in the soil, and decomposes, or renders harmless, other noxious compounds which are not unfrequently within reach of the roots of plants. 3. It changes the inert vegetable matter in the soil, so as gradually to render it useful to vegetation. 4. It causes, facilitates, or enables other useful compounds, both organic and inorganic, to be produced in the soil, or so promotes the decomposition of existing compounds as to

prepare them more speedily for entering into the circulation of plants."* In conclusion on this subject, when we consider that 1 ton of limestone is reduced in weight to a little more than 11 cwts. of shells by burning, we cannot but admire the simple art which renders so valuable a material available to the purposes of the farmer, even when it is situate at a considerable distance from his farm.

(2165.) As fallowed land is usually manured along the feered ridges by depositing the loads into heaps, I might here give a Table showing the number of heaps each cart should afford in manuring an acre with a given number of cart-loads; but as *heaps* of manure are so indefinite a standard of measure, such a table would practically prove of little service. A much more accurate plan is to number the ridges on an acre in each field, and at every part of a field where the ridges are changed in length, as I have recommended before (386), and try and lay down the manure on the first ridge in the proportion it is proposed to manure the acre, and by the time the second ridge is gained, the man who hawks out the dung, fig. 343, will have found out how close the hawksfull should be laid down, and how large the heaps, if any, should be made.

(2166.) [Of the pulverizing implements used at all seasons, there have been already described the grubber, Plates XXIX and XXX, brake (1797), and the common land-roller, fig. 327; but there remains a class of implements of the same nature, which, though not numerous, are yet of considerable importance; they come also under the denomination of rollers, but are peculiar in their construction, and are particularly adapted for being used in summer-fallowing. The object of these machines being to break down the more indurated clods in clay soils, they are fitted to act either by abrasion, or by disintegration, or both combined. One of the simplest of them is the common plain roller, armed with strong and broad iron spikes, the latter splitting the clods, while the weight of the roller produces their farther abrasion: this implement, however, stands low in the scale of efficiency when compared with others which I have to notice.

(2167.) Crosskill's *clod-crushing roller* is one of the most efficient implements of this class, and is here represented in fig. 402, which is a view of the machine in the working state; but to convey any idea of its construction we must exhibit it somewhat in detail. With this view, fig. 403 is a side elevation of one of the individual wheels or plates that go to form the body of the roller, and consists of a ring or web of 30 inches diameter over the extreme points; the web is 2½ inches broad and ⅝-inch thick, formed into angular-pointed teeth. The ring is supported on the four feathered arms, and an eye formed in the center 3 inches in depth and 2½ inches diameter, fitted to move easily on the axle of the roller. Corresponding to each tooth of the wheel, studs are cast on each side of the web, which project 1 inch from it, as seen in fig. 404, an edge view of the wheel, where *a a a a* are the projecting studs, and *b* the eye, showing also the feathers of the arms. The wheels thus formed are threaded, to the number of 28, upon a round axle, 2½ inches diameter, upon which they are at liberty to turn separately, making up the body of the roller *a a*, fig. 402, to a length of 6 feet. A cast-iron end-frame *b* is then placed on each end of the axle, and these are bolted to the wooden transverse bars *c c*, and to these last also the horse-shafts *d d* are bolted. The axle is prolonged at each end *e* to an extent of 4 or 5 inches, forming the arm on which the carriage-wheels are placed for the removal of the roller from one field to another. The carriage-wheels are also of cast-iron, 3 feet diameter, plain of course on the sole; and when these are to be placed or removed, a hole is dug in the soil under each wheel, until the wheel turns freely round and can be moved on or off the axle, the roller then resting on the ground; but when the carriage-wheels are shipt on the axle and brought on level ground, the whole weight is borne by them, while the body is 3 inches clear of the surface. In this state it is traveled from field to field, and, when about to be worked, the carriage-wheels are removed by the process just described.

Fig. 402

* See the whole of the xviith Lecture of Johnston's Lectures on Agricultural Chemistry, for a careful examination of the properties of Lime in reference to its effects on the soil. This, in my opinion, is the most valuable monograph on Lime, as a material used in Agriculture, that has ever appeared.

(2168.) The effect of such a roller upon rough clay land may be easily conceived, and that where such a great number of *points* are brought into contact with the indurated clods, the result must be their reduction to a state approaching to the granular, especially if the operation is repeated. The effect is entirely different from that of the plain roller, for with it, if a clod does not crumble at once with its pressure, it is forced downward into the soil in a still solid state; whereas, with the one now described, the numerous points, acting like so many wedges, will almost infallibly split such a clod into numerous fragments, and repetitions of the process will produce a well pulverized surface."

31. BUILDING STONE-DYKES.

"It is by artificial calms that fields
Are warmed; and WALLS but slightly check
The sweeping blast."
GRAHAM.

(2169.) After the general principles upon which inclosures should be made have been explained, it is unnecessary to dwell on the subject of field-fences when treating of *stone-dykes*, but describe at once the best mode of constructing them. It may be premised that many dry stone-dykes in this country are constructed on erroneous principles, the stones being laid in an irregular manner, and more with a view to give a smooth face than a substantial hearting to the wall. The coping, too, is often disproportionately large for the body of the wall, which is not unfrequently too narrow for its hight. I suspect that many dry stone-dykes are built by ordinary masons, who, being accustomed to the use of lime-mortar, become regardless of bedding the loose stones of a dry dyke as firmly as they should be, and, of course, are unfitted to build one. It is true that a proper form of stones is a great assistance to the builder of stone-dykes—flat, thin stones being the best: but flatness and thinness are not the only requisites; they should also have a rough surface, by which they may adhere to one another in the wall; and no material, on this account, is so well adapted for the purpose as those derived from sandstone-boulders of gravel deposits, which split with the pick into flat stones of requisite thickness when first taken from their matrix, and, on being exposed to the air, become dry and hard. A builder of dry stone-dykes should, therefore, be brought up to the profession; and, when he has acquired dexterity, he will build a substantial wall, at a moderate cost, which will stand upright for many years.

(2170.) Dry stone-dykes are measured by *quarters*, that is, quarters of a yard of 9 inches each. A 5-quarter dyke is the usual hight of a field-fence—that is, 45 inches, or 3 feet 9 inches to the under side of the cover upon which the cope-stones stand—the cover and cope-stones usually measuring 12 inches, so that the dyke stands altogether 4 feet 9 inches in hight. The dyke, when finished, is measured by the rood of 36 square yards upon its face under the cover, so that every 30 yards of a 5-quarter dyke will be 1 rood in length. The usual thickness of such a dyke is 2 feet at the base, and 15 inches under the cover. But the best way to contract for the erection of stone-dykes is by the rood of 36 cubic yards, when every temptation on the part of the builder to contract the breadth, and

[* A very simple and most useful contrivance, not generally known, for pulverizing cloddy land is a "*drag-log*" of say 12 or 14 inches square, according to the hight of the wood and the work to be done, and 5 feet long, more or less, with tongue or shafts fastened on the top of it. This, dragged over the surface by a yoke of oxen or other suitable force, will at one operation produce a degree of pulverization of which few would have any idea who had not witnessed its effect. Any, the roughest, carpenter can make it. *Ed. Farm. Lib.*]

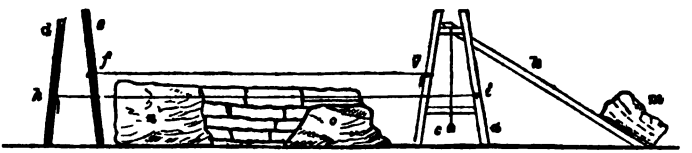
make the heart of the dyke hollow, will be removed. A dyke that has 2 plain faces is called a *double-faced* dyke; and one with 1 face, as when built against a sunk-fence, is called a *single-faced* dyke. A double-faced 6-quarter dyke requires 1 ton of stones for every square yard of its face—so that 36 tons of stones are required for every rood of 30 yards long.—The expense of quarrying that quantity of stones is about 10s. the rood; the carriage of them at a reasonable distance beyond 1 mile is also 10s. the rood; and the building is commonly undertaken, when the stones are good, at 10s. a rood also; so that such a dyke costs 30s. the 30 yards, or 1s. for every yard in length. The tools of a dry-stone dyker are few and inexpensive, consisting only of a mason's hammer, a frame as a gauge for the size of the dyke, and cords as guides for the straightness and thickness of the dyke. A dyker cannot continue to work in wet or in very cold weather, as handling stones in a state of wetness is injurious to the bare hand; on which accounts, dry stone-dykes are commonly built in summer.

(2171.) The line of fence being determined on, it is marked off with a row of stakes driven firmly into the ground. The upper soil, to the depth it has been plowed, is removed from the line to form the foundation of the dyke, and it may be driven away, or formed into a compost with lime near the spot for top-dressing grass. When driven away, it should be so immediately, and not lie to annoy the builder. When the surface consists of old firm sward, especially of moory turf, the dyke may be founded upon it; but, in forming foundations, it should always be borne in mind that dykes are apt to sink into *soft* earth of every kind to the injury of the dyke, not merely in curtailing its hight as a fence, but in twisting its structure and causing it ultimately to fall: so, when the soil consists of vegetable *mould*, it should be removed altogether, and its intrinsic value in a compost will amply repay the trouble of removing it. After the foundation has been formed by the removal of the earth, the stones should be laid down on both sides *as near the line of foundation as practicable*, for it is of considerable importance to the builder that the stones be near at hand. Indeed, when stones are laid even as far as 2 yards from the foundation, the builder incurs loss of time in throwing them nearer; but, on the other hand, no stones should be thrown into the foundation, as they will have to be removed by the builder before he commences operations. Where large boulder-stones exist, they form excellent material for the foundation of stone-dykes, and should be laid close to the foundation before the building stones are brought. The simplest mode of conveying large boulders is upon a sledge, shod with iron; and it is better for putting on and taking out than a common cart, the bottom and sides of which are apt to be injured by such boulders. Indeed, when many stones of ordinary kinds are intended to be driven for buildings, the carts should receive an extra temporary bottoming and lining with deals of common Scots fir, or deals of willow, which are better, as being softer and less liable to split. A pair of horses, yoked as in a plow, will draw a very heavy boulder upon such a sledge.

(2172.) Every preparation being thus made, the builder proceeds to his work—or rather 2 builders together, as they make the best work, and assist each other with stones which one would be unable to manage. They begin by setting up the frame *a*, fig. 405, in the foundation of the proposed line of dyke. The frame is made of the breadth and hight of the proposed dyke under the cover; and it is set in a perpendicular position by the plummet *c*, attached to it. A corresponding frame should be placed beyond the point at which the dyke commences; or 2 stakes, such as *d* and *e*, driven into the ground, having the same inclination as the sides of the

frame, answer the temporary purpose of an auxiliary frame. In uneven ground, a space of ½ a rood, or 15 yards, between the frames, is a sufficient stretch of building at a time; but, on even ground, a rood may safely be

Fig. 405.



THE FRAME AND COMMENCEMENT OF BUILDING A STONE-DYKE.

taken in. The cords *f g* and *h i* are then stretched along the space between the frames, and fastened to each frame respectively, to guide, as lines, the side of the dyke straight, and to gauge its breadth. The frame is held upright and steady by a stiff rail *k*, having the nail projecting through one of its ends *l*, being hooked on to the top-bar of the frame, and a stone *m* laid upon its other end.

(2173.) When the dyke has a scuncheon for its end, a large boulder, such as *n*, should be chosen as the foundation-stone; and if no boulders exist, a large stone should be selected for the purpose; for no better protection can be afforded to the end of a dyke than such a foundation, especially if the scuncheon forms at the same time one side of a gateway to a field. Another boulder, or large stone, should be placed at a little distance from the first, as at *o*, and the smaller stones are used to fill up the space between them, until the space is raised to the hight of the boulders. There is a great art in laying small stones; and it is, in fact, this part of dyke-building which detects the difference between a good and bad builder.—In good dry building, the stones are laid with an inclination downward, from the middle of the dyke, toward each face, as seen at *a* to *a*, and *b* to *b*, fig. 406. This contrivance causes the rain which may have found its way down through the top of the dyke to be thrown off by both sides; and, to sustain the inclination of the stones, small stones must be packed firmly under their ends in the very heart of the dyke; whereas stones, when laid flat, require no hearting to place them so, and may receive none, to the risk of the dyke bulging out in both faces. It tends much to the stability of a dyke to have what is called a *thorough-band* stone *c d*, placed across it at such a hight from the ground as represented in the figure. In like manner the cover *e f* acts as a thorough-band at the top of the dyke; but in laying the cover, the *leveling* of the dyke to form its bed should not be made of very small and very thin stones, as is too often the case, as these have little stability, being easily shifted from their position, easily broken, and, of course, constantly endanger the safety of both cover and cope. Thorough-band stones are frequently left projecting from one or both sides of the dyke by some builders, merely to indicate that they are thorough-bands; but the practice is objectionable, inasmuch as projections serve as stepping-stones for trespassers to climb over the dyke. Fig. 407 shows how a scuncheon should be formed of in-band *a a a*, and of out-band stones *b b b*, hammer-dressed,

Fig. 406.

SECTION OF STONE-DYKES, SHOWING HOW THE STONES SHOULD BE LAID.

and firmly bedded upon one another. The covers *c* should project 1 or 2 inches beyond the face of the dyke, to protect the top. They should be 2 inches in thickness, and without a flaw throughout their length, which should be 2 feet at least, that their weight may keep them firm, and their size cover a large space of building. In forming the cope, a large stone should be placed at the end, as *d*, in order to keep down the cover, and act as an abutment against which the smaller cope-stones may be wedged. Other large stones, such as *e*, should be placed at short distances from each other, and upon the joining of two covers, to keep them both secure. Thinner stones should then be placed between these on edge, and wedged firmly, with small stones driven between them with a hammer; but the *wedging* should be delayed until a considerable length of coping is finished, which will be the better able to resist its force. Fig. 407 shows how the stones should be laid in the body of the dyke, those placed uppermost covering the joinings of those beneath them; and small, thin stones are introduced here and there in the finishing to act as wedges between the large ones. The cope-stones should be nearly all of the same hight.

Fig. 407.

SCUNCHEON, COVERS, AND COPE OF A STONE-DYKE.

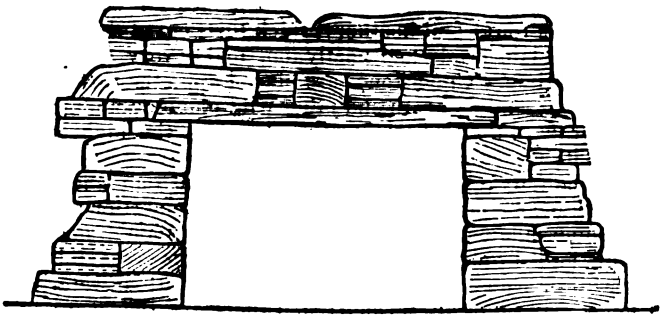
(2174.) In building a stretch of dyke, such as the rood above referred to, it is customary to carry up the building at both ends, as well as at the middle, of the stretch to the leveling of the top, before the intermediate spaces are built up, because those parts being built almost independently, act as pillars in the dyke to support the intermediate building plumb; and they are convenient for pinning the cords into while the intermediate spaces are being built.

(2175.) When a few stretches of a dyke have thus been finished, the surplus stones, if any, should be removed, and laid where they are wanted; but should there be a deficiency, stones should be immediately brought, to allow the builder to finish one stretch before he proceeds to another. The debris of stones caused by the hammer should be removed either to drains or roads.

(2176.) These are all the particulars to be attended to in building dykes for ordinary purposes; but there are a few modifications which require attention in order to render dykes, as a fence, convenient. 1. The first I shall mention is an opening left for the passage of sheep from one field to another, where the access between them by road is at a distance. Fig. 408, though a mere elevation, obviously shows how such an opening is made. A bunch of thorns or whins, or a board, closes the opening when no longer needed. Such an opening gives sheep access to pasture banks, or to a grass-field from their turnip-breaks in wet weather in winter, and it allows ewes to go to a turnip-break for a few hours every day from the grass-field they are grazing in. For such purposes, an opening of from 3 feet

to 3½ feet will suffice. 2. Another convenience is seen in fig. 409, consisting of a gap near the top of the dyke, which map be useful as a stile in the line of a foot-path, or a gap at the side of a cover, for hounds and

Fig. 408.



THE OPENING IN DYKES FOR SHEEP.

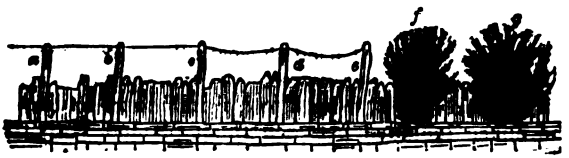
huntsmen to enter with ease; and here the whipper-in may stand on the out-look for a burst. When not constantly in use, such a gap is easily fenced with a bunch of thorns or whins.

Fig. 409.

THE STILE OR GAP IN A DYKE.

(2177.) Dykes such as I have been describing, namely, of 5 quarters in hight, will fence horses, and cattle, and Leicester sheep, but will not confine Black-faced sheep. For these, higher walls must be built, or expedients used to make ordinary dykes confine them. Some of these expedients are shown in fig. 410, where part of an ordinary dyke with its cope

Fig. 410.



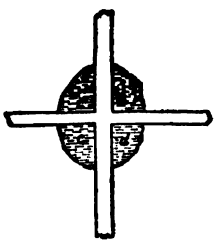
SOME EXPEDIENTS FOR INCREASING THE HIGHT OF STONE-DYKES.

is seen; and the expedients consist, 1. Of cope-stones *a*, *b*, *c*, *d*, and *e*, set on edge to a considerable hight, say 9 inches or 1 foot, above the ordinary cope-stones. In one case, such as that of the stones *a*, *b*, *c*, fillets of wood are laid along notches formed on their top, and wedged into them. In the case of the stones *c*, *d*, *e*, a strong rope of straw, laid somewhat loosely over the notches, and dangling occasionally with the wind, form a suffi-

cient scare to sheep. 2. Another expedient, where the dyke is built against rising ground, consisting of plantation or of cultivated land, is to sow a few seeds of whin or broom in the soil behind the dyke, and cause their shoots to push forth between the cope-stones, and grow into bushes, *f* and *g*, in front of them. 3. Where good stones for covers are scarce, and where turf is tough and heathery, thick turfs cut of the size of the top of the dyke, and laid firmly and neatly on, make very good covers, and will last a long time. Cope-stones are placed upon the turfs, which afford them a firm bed; and as heath and other wild plants, including the grasses, continue to grow in the turf, they serve to raise the hight of the dyke, and enhance its appearance as a fence.

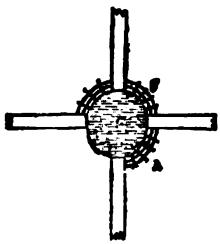
(2178.) When dykes run at right angles into one another, and are erected simultaneously, they should be built in connection; but where a new dyke comes against an old one, the old one should not be touched, and the new built firmly beside it. Where 2 dykes cross and the place is naturally wet, or water may be easily brought to it, a watering-pool to serve 4 fields may be easily formed; and there are two ways of making such a pond:—When the ground is firm, and the water shallow, the 2 dykes may cross, as in fig. 411, and allow the water to pass through them, and form a watering-pool in each field, such as *a*, *b*, *c*, and *d* out of a single pond. Where a pond *e*, fig. 412, already exists, and its water is too

Fig. 411.



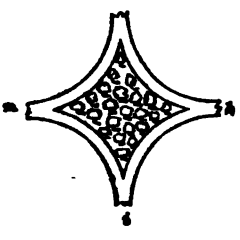
HOW TO FORM A WATERING-POOL TO FOUR FIELDS.

Fig. 412.



HOW TO FORM A WATERING-POOL COMMON TO FOUR FIELDS.

Fig. 413.



A CLUMP OF TREES AT THE MEETING OF DYKES.

deep for dykes to traverse, the dykes must terminate at its edge and convert the pond into a watering-pool common to 4 fields. When the pond is used by only 1 field at a time, it should be fenced from the other 3 fields by means of hurdles, as *f*, *g*, and *h*; but when it is used by more than 1 field at a time, a fence should be run across the pond, beside the hurdles in the fields not occupied by stock. Where the ground is firm, and there is no prospect of obtaining a site for a watering-*pool*, the dykes should be made to cross, and a well sunk in a corner of one of the fields, with a pump in it of such hight as to supply all the fields with water in tanks by means of a spout. This expedient I used successfully on one occasion. Where the ground is firm, and no water wanted at that spot, the dyke should be built curved, as from *i*, to *k*, from *k* to *l*, from *l* to *m*, and from *m* to *i*, fig. 413, and the space included between them planted with trees for ornament and shelter. There will be here little waste of land, even should it be of the finest quality, as the corners of 4 adjoining fields always contain ground that cannot be reached by the plow, while the plow can pass along such curves as near as to a straight fence. In building curvatures in dykes, builders charge ½ more per rood than for plain work.

(2179.) A stone-dyke is in the highest perfection as a fence immediately from the hands of the builder; but every day thereafter the effect of the atmosphere upon the stones, at all seasons, and the accidents to which

they are liable by trespasses of individuals, and the violence of stock, render it necessary to uphold their repairs frequently; and this consideration should cause the best suited materials to be selected for their original erection.

---

32. BREAKING-IN YOUNG SADDLE-HORSES.

"Which with a snaffle you may pace easy."
ANTONY AND CLEOPATRA.

(2180.) As I have mentioned how your saddle-horse should be groomed (1398), I would wish to say a few words on *breaking* him *in*. And, in the first place, I may remark that, judging by the conduct of roadsters one meets with every day on the public roads, we may fairly conclude that the profession of horse-breaking is not well understood in this country; and the conclusion need create no surprise, when we observe those who become horse-breakers to be generally cast-off grooms unable to procure a permanent situation, just as we occasionally see a discarded plowman become a spadesman, to save himself from starving; but it ought to excite even wonder to see farmers, who ought to be somewhat acquainted with the nature of horses, employ such persons to break-in their saddle-horses, merely because they demand a small fee, and undertake to finish a horse in all his paces in the course of 2 or 3 weeks. In fact, the farmer grudges the time, beyond a few days, any horse requires to be broke-in, and acts as if he conceived the animal should know the art of carrying him by instinct, when he himself may have been practicing horsemanship all his days, and never perhaps become a horseman after all. Notwithstanding the folly of employing inexperienced men, I am convinced were men of experience, address, and character to undertake horse-breaking in a perfect manner, they would receive encouragement from the farmer. No miracle is required to break-in a horse; he is naturally docile, and may be *taught* to do anything, as those who have witnessed the evolutions of the late Ducrow's stud with wonder and delight can believe; but the horse is naturally fearful, and, endowed with an undying memory, he never forgets any circumstance, however trivial, which may have aroused his fears. If the breaker, therefore, proceeds on the principle of subduing what he calls the horse's *temper*, by a constant endeavor to curb him, he may tame him for a time, but will never break him in; and even this subjection will only last as long as the horse finds he cannot obtain the mastery over his rider, who, on some occasion, may be a timid one; whereas, were it shown to the horse that no irritation awaits him in the stable, or on being ridden, he will place confidence in his rider, will regard him with attachment, and will take him everywhere, even through danger, by the gentlest touch of the rein, or exhortation of the voice. Why should the Red Indian of North America never put a bridle on his horse's head, and only have a piece of cord round the under jaw, by which to pull him up in a gallop, and guide him, with the greatest nicety, in the hottest pursuit after buffaloes, by the palm of the hand against the side of the head; as much so as to enable him to point the arrow with unerring aim into the heart of his prey? Why should the Arab's horse come into his tent like one of his family, lie down and rest, and never think of running away from his master when his services are required? Does the horse of the accomplished European display the least degree of such confidence in his rider?

Is it possible that a savage knows better how to break-in a horse than an European? The difference between the cases can be explained in a few words; the savage makes his horse his companion and friend, the civilized man treats his as his slave. And can any doubt, were the same gentleness, kindness, attention to his wants, which secure to the savage the willing assistance of his horse, bestowed by the civilized man on his horse when young, would also inspire him with confidence? Every one has felt the satisfaction of riding a horse one knows thoroughly. It should also be borne in mind as an incentive to kind treatment, that were horses generally well broke-in, they could not be spoiled by even bad riders, for their paces would be so pleasant the rider would have no inducement to try and mend them.

(2181.) The age of 3 years seems an excellent one for breaking-in a saddle-horse. The colt should be set to grass in the end of May, and taken in to break by August at latest, by which time the grass will have operated beneficially upon him as medicine, and there will be sufficient time to teach him his paces and put him in working condition before the fall of the year, when horses are apt to become soft, and catch cold; but were he kept longer at grass, his condition might become so fat as to endanger his constitution, were it suddenly reduced to working order.

(2182.) The first thing, in bringing a horse into the stable, to which he should have been accustomed from his foalhood, is to give a gentle dose of medicine to clear the bowels of a load of grass. A second dose may be repeated in a week. A little new-made hay with oats is the best food as a transition from grass to hard food. The first treatment with the cavesson and bridle being the same as that described from (1909) to (1911) for breaking-in the draught-horse, I need not repeat it here. I may mention, however, that much lunging in a circle is not advisable for a young riding-horse, though horse-breakers are very fond of giving him this sort of exercise, because it saves themselves a good deal of traveling; the motion round the circle being apt to cause the colt to contract a long step and a short. The circle is of most use in training to *canter*, when a leading foot is requisite to be used in that sort of action. The first tuition should be a straight-forward pace, as on a lea-field, and the *only* pace a *walk*, which should be taught to be both free with an easy head, and short with a tight rein. During the period of the walking-tuition, a great many useful lessons should be taught the colt, such as turning off you and to you—backing, whether quickly or slowly—leading, whether by the side of the head with the hand on the bridle-bit, or in front with a slack rein—standing still, whether for a short or long time—suffering to be tied to any object, such as a gate or tree—passing objects of terror, or of uncertainty, causing the animal to become acquainted with everything it does not seem to recognize—becoming accustomed with the crack of the long, and the touch of the short whip—lifting the fore and hind legs when desired—and suffering the groom to go about him and arrange the breaking-harness. With all these matters the young colt will become much sooner *familiarized*, by the breaker going constantly about with him on foot as a companion on the road and the field, than when mounted on his back. In the stable, too, the same system of tuition should be followed out, such as suffering a person to go up on either side, and in any way—suffering to be groomed, and rather liking it than opposing it, as is too often the case—drinking out of a pail in the stable and at the pump, or out of a trough or a brook—taking up with a dog in the stable or on the road—bearing, without a startle, the fall of the pail-handle, the broom, or anything else—lifting the feet at the pail to be washed—being led by the forelock to the door, or

the pump, or anywhere. These and many other things, the colt can be taught to know in and out of the stable before he is mounted at all. Thus familiarized, he will allow himself to be mounted without any trouble; and all the assistance of boys with whips, and of men to hold down the opposite stirrup, recommended by Mr. Youatt, dispensed with.* Tom Middlemiss, the horse-breaker whose name I mentioned before (1910), never required any assistance to mount a young horse, nor did any person ever see him mount one for the first time. The truth is, no fuss should be made about the colt; but when a number of persons are about him when anything is done, there cannot be but fuss, and he cannot fail to become apprehensive. He will soon confide in one person, the breaker who is constantly about him, but he will not confide in a number of persons at the same time, nor will he confide even in his breaker, when others are engaged along with him; and hence no considerate horse-breaker will permit any one to be near him, to distract the attention of the colt, when he is subjecting him to tuition of any kind. When mounted, the colt should bear his rider in standing for some time before he is urged to walk, as it will habituate him to stand at all times when mounted until his rider is ready to move. Every one must have felt the annoyance of mounting a horse that will not stand. His first pace should again be a walk, which having accomplished well with a rider, the trot should be taught. It is said that trotting is not a *natural* pace for a horse, he either walks or starts off at a canter. However this may be, trotting is an indispensable pace on our roads. On teaching trotting, horse-breakers are very apt to degenerate the pace into a jog, the most dangerous of all paces for a young horse in causing him to trip, and the most difficult to break a horse from, when contracted. A short, hitching walk, ready to break into the jog alluded to, is as bad as the jog itself, and is a favorite pace with horse-breakers in chewing off their wards as fast walkers; but in such a pace a young horse is almost sure to dig a toe into the ground, and if a stumble is *not* the consequence, it is not the *man's* fault. Let the walk be a sound walk, and a trot a fair trot, and let no bastard pace be permitted to spoil both. It is not easy to teach a young horse to canter from a trot in a straight line, as he is more apt to start off to the gallop; but a few lessons in the circle will give him an idea of a canter, as he will there learn to point the leading foot. There is some risk at first in making a young horse reduce a canter into a trot, the actions being so very different, he seems at a loss what to do, and would rather halt. The tightening of the rein by degrees is the only way of reducing the pace in safety, as it likewise is from a fast to a slow trot. A sudden halt might throw the colt upon his haunches, and irrecoverably bring him over upon his back, and such an accident as this the colt will never forget, and, in fear of it, may become restive when pulled up suddenly at any time afterward. Every maneuver that may occasion any sort of accident to the colt should be avoided by the rider with care, and counteracted with firmness. Thus day by day the young horse acquires experience in the management of himself on the road, or in the field, but this series of experiences is a work of much time to both man and horse—of much patience and perseverance to the man—of much endurance and irksomeness to the horse; and more than all this, much of the benefit derived from the horse-breaker will be in a manner lost, if the future rider of the horse does not guide him in a similar manner, and with equal care for some time to come. If considerations such as these do not induce the owners of horses to employ only men of skill and character in breaking them in, I do n't know what stronger motive can be placed before them to do it.

* Youatt on the Horse, edition of 1843.

AUTUMN.

"Ye balmy breezes! wave the verdant field;
Autumn! all your bounties, all your lustre yield;
That fruits and herbage may our farms adorn,
And furrowed ridges teem with loaded corn."
Ferguson.

In contemplating the nature of the different seasons, we have seen Winter the season of *dormancy*, in which all Nature desires to be in a state of repose—Spring, the season of *revival*, in which the returning power of Nature inspires every created being with new vigor—Summer, the season of *progress*, in which Nature puts forth all her energies to increase and multiply her various productions—and, now, we see Autumn, the season of *completion and of consequent decay*, in which Nature, in bringing the individual to perfection, makes provision for the future preservation of the kind. While, therefore, the natural action of spring and summer is single, that of autumn is of a compound character. "Thus, if we follow out the study of the autumn in a proper manner, it leads us to all the revolutions that have taken place in the surface of our planet; and in this way, a plant of which we can, in a few months, see the beginning, the perfection, and the decay, becomes to us an epitome of the system of growing Nature in its widest extent, and through its most prolonged duration. This is the grand advantage while studying the productions of Nature in their connection, and the events and occurrences of Nature in their succession, has over the mere observations of the individual substance and the passing moment; and it is this which gives to the law of the seasons so high a value above all the beauties of the seasons taken in their individual character."

Autumn brings fruition, in which the toilsome labors of the husbandman, for the preceding twelve months, find their reward. It is the season in which hope is lost in the possession of the thing hoped for, and because of a harvest of plenty, it is the season of gratitude. "It is this which makes the principles of seasonal action thicken upon us as the year advances, and the autumn to become the harvest of knowledge, as well as the fruits of the earth. Nor can one help admiring that bountiful and beautiful Wisdom which has laid the elements of instruction most abundantly in the grand season of plenty and gratitude." But grateful as the husbandman must always feel for the bounties of Providence, so much labor is bestowed, so much anxiety is felt by him, as regards the effects of the vicissitudes of the seasons, before "he gathers his wheat into the garner," that the reflections which the consummation of harvest is calculated to give rise to are, I fear, narrow, and even selfish. "For as the annual harvest which we obtain from the earth is received by us as resulting from that in which we have a right of property, a merit in labor, or both united, we are apt to forget the part which Nature has in the productiveness of the year, and look upon the whole produce as the return of our own capital and our own skill, just as we do in any mechanical work or mercantile speculation. That this is the true state of the case is proved by the habitually proverbial fact that the cultivators of the ground, for what purpose soever they may cultivate, are always complaining of

the weather, as the grand enemy by which all their labors are frustrated, and all their products diminished. They are nowise at fault themselves, but the 'weary weather' never will be obedient to their dictates. What with rain, what with drouth, what with heat, what with cold, each thrusting itself forward at the time when its opposite would have been by far the more beneficial, the crop they get is always 'below a fair average,' and what they do get is got in in spite of the weather, and not by means of its coöperation. It is in vain that the fable of the farmer—into whose hands Jupiter gave the management of the weather, and who, by having rain, and drouth, and sunshine, and snow, when and where he wished, brought his land into a state of such utter sterility, that he was fain to plead more earnestly than ever that so dangerous a power might be taken out of his hands—has stood on the record against them from remote antiquity; for the majority contend stubbornly that all the merit is their own, and that all the blame falls upon the weather, which, notwithstanding all the examples which have been set before it, and all the experience it must have had, 'will not understand and obey the rules of good Husbandry.'"*

The colors displayed by the autumnal setting sun are exceedingly rich; one form of the phenomenon not uncommon at that period is attempted to be penciled in Plate XIV; but a far finer picture is to be seen in these words of a revered bard, who can feel intensely as he can describe beautifully:

"A cloud lay cradled near the setting sun;
A gleam of crimson tinged its braided snow.
Long had I watched the glory moving on
O'er the soft radiance of the lake below.
Tranquil its spirit seemed, and floated slow;
E'en in its very motion there was rest;
While every breath of eve that chanced to blow
Wafted the traveler to the beauteous West.
Emblem, methought, of the departed soul,
To whose white robe the gleam of light is given;
And, by the breath of Mercy, made to roll
Right onward to the golden gates of Heaven,
Where to the eye of Faith it peaceful lies,
And tells to Man his glorious destinies."

WILSON.

Objects in the horizon—trees, houses, and ruins—are projected in bold relief against the clear, deep sky of a calm autumnal evening at sunset. Such a scene as this—if gemmed, moreover, with the radiant and lustrous evening star—affects the mind to thoughtful meditation, not untinged with melancholy.

The temperature of autumn is high—August, in Scotland, affording the highest average of the year, on account of warmth in the night as well as the day, though the sun is not more hours above the horizon than in March—but Autumn follows the radiance of Summer, while Spring just escapes from the frigidity of Winter. Such is the heat that it is no uncommon occurrence for reapers to be seriously affected by it in the harvest-field.

The labors of the field partake of the compound character of the season itself. Just as one crop is reaped from the ground, part of the succeeding one is committed to the earth; the autumnal wheat of two successive years being sown and reaped about the same time. The toil endured in harvest is almost incredible. Only conceive the entire bread-corn sufficient to support the population of such a kingdom as this to be cut down and carried, in minute portions, in the course of a single month! The usual season of reproduction among the animals of the farm is spring; but the most useful animal of all, the sheep, forms an exception to the rule, Autumn being the season in which the ewes are drafted, and the tup is allowed to

* Madie's Autumn.

go with them. There seems in autumn a tendency in the animal frame to disease; sheep are liable to hepatitis, calves to quarter-ill, the horse to colic and even inflammation in the bowels, and stallions and geldings become dull in spirit. Perhaps the feeding nature of aftermath, on which all animals live in autumn, may cause a tendency, in the animal system, to predominant secretion of one of the fluids, and thereby predispose the system to particular complaints. If there is probability of truth in this surmise, preventive measures should be sought for and obtained; and oil-cake seems to possess this property. One preventive remedy against annoyance from parasitic insects and from cold to sheep, is bathing or smearing.

The sports of the field all commence in autumn. The long-contemplated gatherings in the hills, on the noted 12th of August, in quest of grouse—game, *par excellence*, of which our country should be proud as its only indigene—cause every sheiling to afford shelter to many who, at other seasons, indulge in the far different enjoyments of urban luxuries. Partridge-shooting comes in September, sometimes even before the corn is cut down, and is followed by hare-hunting in October; and after all the fields are cleared of their valuable produce, the inspiring "music" of the pack is heard to resound through hill and dale.

The great event of autumn—the harvest—naturally claims a preponderating share of the husbandman's solicitude; and until this important issue of all his toil is secured beyond danger, he cannot rest in quiet. He looks around him, night and day, regarding the "face of the sky," and acts with circumspection. He sees his whole year's bread at stake, and feels that its safety depends on his own skill; and should he fail to exercise this aright, he would never cease to blame himself. None is more anxious to follow this advice than he:

"The wind, the rain, the sun,
Their genial task have done.
Wouldst thou be fed,
Man, to thy labor bow,
Thrust in thy sickle now,
Reap where thou once didst plow—
God sends thee bread."
MONTGOMERY.

When every straw is safe in the stack-yard, and the stack-yard gate closed for the season, then, and not till then, is he satisfied of his task being finished, and enjoys undisturbed repose.

Now that we have surveyed all the seasons as they present themselves in this country, we must own our climate to be anything but genial. The frequent changes to which it is daily susceptible render the culture of the soil always a difficult, and not unfrequently an irksome occupation. Those vicissitudes, no doubt, sharpen the intellect of the farmer, and perhaps have been the chief means of eliciting the high skill which is so universally acknowledged to be exercised in the Agriculture of this kingdom. Such skill will always have a field for exercise, for our insular position will subject our atmosphere to perpetual changes dependent on different conditions of heat and moisture produced by the state of the surrounding ocean. Notwithstanding the farmer is held to his task by a frowning climate, he would rather wish to have a smiling one, and sometimes envies the bright skies which he hears illumine the Continent. There is much truth in the desire expressed in the following observations, lightly as they are put together, for no one but enjoys fine weather, which is, indeed, always the source of gratulation when it occurs: "It may be very well for a lover to declare in the presence of his mistress that

"All seasons and their change
All please alike;"

but to common mortals, occupied with the ordinary affairs of life, there is no truth in it. Who in his senses ever affirmed that the fogs of November were as delightful to him as the balmy breath of May? If any one has, as I have, a horror of icicles, and who would never have the mild temperature of the air interrupted by the presence of a hoar-frost, let him migrate with the climate. Let him spend the month of January in Portugal; February in the Madeiras; March in Spain; April in Sicily; May in Lapland; June in Italy; July in Switzerland; August in France; September in England; October among the forests of America; November in Crete; and December in the islands of the Cape de Verd. By this rotatory motion he may enjoy a delicious temperature, and revel in honeysuckles and roses all the year round."*

33. PULLING FLAX AND HEMP, AND THE HOP.

"Now pluck up thy flax, for thy maidens to spin;
First see it dried, and timely got in."
TUSSER.

"Lo! on auxiliary poles, the hops,
Ascending spiral, ranged in meet array!"
PHILLIPS.

(2183.) I propose here merely to speak of flax as to its *treatment in summer*, and the *mode of harvesting it*; for as to its treatment afterward as an article of manufacture, that is beyond my province. The only care required by the growing crops of flax in summer is *weeding*, and in its early stage of growth it will be much injured if weeds obtain the mastery. To obviate this inconvenience, and, indeed, to save altogether the trouble of weeding, it has been recommended to sow the land at the time of sowing the flax-seed with grass-seeds, or to sow the flax-seed in drills; but neither expedient is so suitable for flax itself as land kept clean by weeding a broadcast crop; for as equality of fibre is of the utmost importance to the value of flax, sowing it in drills admits the air unequally to the crop, and the fibre of the plants on the outside of the drills would thereby be much coarser than that of those in the interior.—And as to sowing grass-seeds, even the low-growing white clover among flax, it should make no difference to the flax-plant whether it was choked by a valuable or a worthless plant, since both would equally be *weeds* in reference to it.

(2184.) Besides the common weeds which infest the soil, according to its nature, there are others specially found among flax; of these, one is the common gold-of-pleasure, *Camelina sativa*, the seed of which is imported among flax-seed; and the plant may be known by its attaining from 2 to 3 feet in hight, having small yellow flowers, and very large pouches on long stalks. But a more troublesome weed than this is the flax-dodder, *Cuscuta Europæa*, inasmuch as it adheres parasitically to the flax plant, and, of course, injures its fibre; while the gold-of-pleasure may be pulled out before the flax is ready. The habits of the flax-dodder are these: "It is a plant which germinates in the ground, and sends up a slender, thread-like stem, which, twisting itself about, soon touches one of the stems of the flax among which it is growing. As soon as this takes place, the dodder twists itself round the flax, and throws out from the side next

* Note-Book of an Oxonian—*John Bull*, for 5th August, 1843.

to its victim several small processes, which penetrate the outer coat or cuticle of the flax, and act as suckers, by which *the parasitical dodder appropriates to its own use the sap which has been prepared in the flax, upon which the growth of the flax depends.* The dodder then separates itself from the ground, and relies solely upon the flax for its nourishment, producing long, slender, leafless stems, which attach themselves to each stem of flax that comes in their way. Thus large masses of the crop are matted together, and so much weakened as to become almost useless. This plant produces great quantities of seed, which is usually threshed with the flax-seed, and sown again with it in the succeeding year. Several years since I took considerable trouble to ascertain if all foreign flax-seed was mixed with that of the dodder, and was led to the conclusion that the American flax-seed is nearly free from this pest, and that that from Russia, and especially Odessa, is peculiarly infested with it."* . The weeds, when very young, are picked out by hand from the flax by field-workers; and, in doing this, the kneeling down upon the flax does it no harm. If weeding be once effectually and timeously done, the weeds will not again much trouble the crop; and, though it should cost several shillings the acre, the increased value of the crop will repay it all. Before leaving the subject of weeding, I may remark that, though the American flax-seed be free from dodder-seed, it is far inferior in giving a crop to that imported from Riga, the Riga-kind, which also bears the name of Belgian seed, from the Belgians sowing it. And I may also remark that sowing flax on clean land will save much of the cost of weeding—that is, after a green crop, as turnips and potatoes, the cleansing of which will have rendered the soil comparatively clean for flax. If flax be thus cultivated in lieu of a corn-crop, its culture may be practiced without much deterioration to the land; but if it is determined to regard flax as a green crop, and cause a corn-crop to follow it, the land will in time assuredly feel the scourging effects of such a system, and oblige its cultivators to abandon it altogether.

(2185.) The pulling, steeping and drying of flax are simple enough, and are processes generally well understood; but Mr. Henderson's account of managing the crop, whose sample of Irish flax obtained a gold medal from the Agricultural Improvement Society of Ireland, at their meeting at Belfast, in August, 1843, being the most practical, and at the same time succinct, I have met with, I shall transcribe it. 1. And, first, as to test of *ripeness*, Mr. Henderson says: "I have found the test recommended by Mr. Boss to ascertain the degree of ripeness that gives the best produce, with the finest fibre, perfect. It is this: Try the flax every day when approaching ripeness, by cutting the ripest capsule on an average stalk across (horizontally), and when the seeds have changed from the white, milky substance which they first show to a greenish color, pretty firm, then is the time to pull. The old prejudice in favor of *much ripening is most injurious*, even as regards quantity; and the usual test of the stalk stripping at the root and turning yellow should not be depended on. Where there is one man that pulls too green, five hundred over-ripen." 2. When properly ripened, flax should be *pulled* in this way: "I use the Dutch method —say, catching the flax close below the boles; this allows the shortest of the flax to escape. With the next handful the puller draws the short flax, and so keeps the short and the long each by itself, to be steeped in separate ponds. It is most essential to keep the flax even at the root end, and this cannot be done without time and care, but it can be done, and *should always be done.* The *beets* should always be small, evenly sized, straight,

* Gardeners' Chronicle and Agricultural Gazette for 16th February, 1844.

and even, and should never be put up in stooks or windrows, but taken to the pond the day they are pulled, or the day after at longest, especially in bright weather; for *the discoloration produced by the sun on green flax will never be removed till it goes to the bleacher, and will give him some trouble also.*" 3. Next comes the *steeping*, which is a most important process, and is the one least understood by growers of flax in this country. You, perhaps, require to be informed of the object of steeping the flax-plant.—The stem of flax consists of two parts possessing very different properties: the one, the outer, is fibrous, and affords the substance of flax; the other, the interior, is pithy, and is got rid of by fermentation in steeping, loosening its hold of the fibre. There is also much mucilage to be got quit of; and the sooner flax is put into steep after being pulled, the more mucilage will be dissolved from it. If steeping is so long continued as to affect the texture of the fibrous coating, the flax will be injured; and should it not be as long applied as the pithy matter may be easily loosened, much labor will be afterward incurred in getting quit of it. Proper steeping, then, is an essential and delicate process, and on this account Mr. Henderson's instructions are valuable: "Flax is subject to injury from neglect in every process, but in this especially. The water brought to the pond should be pure from all mineral substances, clean and clear. The water of large rivers is generally to be preferred; but spring-water, which has run some hundred yards, becomes soft, and will have deposited any mineral impurities it contained; immediately from the spring it seldom does well. If the water be good and soft, it is injurious to allow it to stagnate in the pond before steeping. I put in two layers, each somewhat sloped, with the root-end of each downward: one layer at a time is said to be safer, and, perhaps, is so, though I have tried both and seen no difference. The flax should be placed rather loose than crowded in the pond, and laid carefully straight and regular. Having an abundant supply of water, I do not let any into the pond till the first layer is in. I cover with moss-sods (from the turf-banks) laid perfectly close, the shear of each fitted to the other.—Thus covered, it never sinks to the bottom, nor is it affected by air or light. It is generally watered in 11 or 13 days. A good stream should, if possible, always pass over the pond—it carries off impurities, and does not at all impede due fermentation; flood and all impure water should be carefully kept off. The Dutch test of being sufficiently watered is certain and perfect; at least, I never found it otherwise. It is this: Try some stalks of average fineness, by breaking the woody part in two places, about 3 inches apart, at the middle of the length; catch the wood at the lower end, and if it will pull (downward) for those 3 inches freely, without breaking or tearing the fibre, it is ready to take out. This trial should be made every day after fermentation subsides, for sometimes the change is rapid.—Flax is more frequently injured by too little than too much of the water. Great care and neatness are necessary in taking it out. Broken or crumpled flax will never reach the market. Spread the day it is taken out, unless it is heavy rain—light rain does little harm; but, in any case, spread the next day, for it will heat in the pile, and that heating is destructive.—The most particular cause of injury in steeping is exudation of water from the sides or bottoms of the pond. Stripe and discoloration are mostly imputed to the quality of the water brought to the pond; while, in 9 cases out of every 10, the water oozing from the sides and bottom of the pond itself is the cause. Even if such water were pure, which it seldom is, it is injurious; but when impregnated with iron or other materials, it does immense harm. If such ponds must continue to be used, the injury may be partially amended by draining around the sides and ends, at 6 or 8 feet

distance, and 18 inches deeper than the bottom of the pond, and filling the drains with stones. No other thing I know of does such extensive injury as this springing of water within the pond." 4. Flax "should be *spread* even, straight at its length, not too thick, and well shaken, so that there shall be no clots; indeed, if possible, no 2 stalks should adhere. I have ever found it injurious to keep it long on the grass; it is in the steep the wood is decomposed; on the grass the fibre is softened, and the wood little, if at all, affected. I rarely let it lie more than 5 days, sometimes only 3; this year it had only 3 days, and I never had better flax. It should never, if possible, be spread on the ground flax grows on—it claps down, and the clay and weeds discolor it; clean lea, or lately cut meadow, is the best." 5. "*Lifting*, like all other operations, requires care and neatness to keep it straight to its length, and even at the roots. This operation is too frequently hurried and coarsely done." 6. If the steeping and grassing have been perfect, flax should require no fire; and, to make it ready for breaking and scutching, exposure to the sun should be sufficient; but if the weather be damp, the flax tough, and must be wrought off, then it must be fire-dried. Such drying is always more or less injurious; but, if it be put on the kiln in a damp state, it is ruinous—it is absolutely burnt before it is dry. All who can afford it should keep such flax over to the ensuing spring or summer, putting it dry into stacks—then it will work freely without fire-heat." 7. In the concluding remarks of Mr. Henderson, there is much good sense: "The proper culture and preparation of flax require more care, exertion and expense than the old, slovenly method; and those who will not give those requisites would do wisely to abstain from growing flax altogether. Any other crop will abide more negligence. So much has been said and written of late of the advantage of flax-culture, that it is to be feared some may be led to carry it to an undue extent, and sow it on land not fitted for it; indeed, this is already often done, and I know of nothing more injurious to the farmer. Flax is proverbially either the very best or the very worst crop a farmer can grow."*

(2186.) The crop of flax, after it is dried, is bulky for its weight; and yields from 3 to 10 cwt. per imperial acre of dried plants. From 30 to 40 stones, of 14 lbs. each, the acre, of *dressed* flax, is considered a fair crop, and if *fine* quality, will fetch perhaps £90 a ton; that is, from 4 to 5 acres are required to furnish 1 ton of flax, and a return obtained of from £18 to £22 per acre, exclusive of the expense of preparing it by beetling, scutching, and hackling, and may still leave from £10 to £15 an acre of profit, which is a large one; but should the flax prove coarse by improper management, or be injured in drying, much waste will be occasioned in dressing it, and the profit reduced to perhaps ¼ of these amounts. So the observation of Mr. Henderson, of flax being either the best or worst crop for the farmer, thus receives corroboration; and it should also be borne in mind that flax, like the potato crop, leaves no straw for manure to the land.

(2187.) *Hemp* is a crop scarcely cultivated in Scotland, and its culture in England is confined to the southern counties, being a plant indigenous to the south of Europe and India. Being tall of growth in comparison to flax, it receives no injury from weeds, but, on the contrary, smothers by overtopping them. This plant is best cultivated in drills. The crop is pulled and watered, and dried like flax, the weight of produce dressed being little more than flax, from 40 to 45 stones the imperial acre, and the profit derived from it, after deducting expenses, seems

* Dublin Farmers' Gazette.

to be from £5 to £6 per acre, though Lord Somerville, in sanguine expectation of extending the culture of this plant in England, estimated it at £8. The dried refuse of the stems of hemp, after the fibre has been separated, is used as fuel, and may be converted into charcoal fit for gunpowder. The seed yields about 3 quarters per acre, and from it is expressed an oil "employed with great advantage in the lamp, and in coarse painting. They give a paste made of it to hogs and horses to fatten them; it enters into the composition of black-soap, the use of which is very common in the manufacture of stuffs and felts; and it is also used for tanning nets." The common hemp is raised in India, not for the sake of its fibre, but for the intoxicating quality of its seeds when eaten green and fresh; the hemp of commerce of that country is derived from a different plant.*

(2188.) The *hop* is not cultivated in Scotland but as an ornamental plant in the shrubbery, because the climate is not sufficiently warm to develop its cones, constituting the ripe fruit, which is its useful part. The culture of the hop is confined to the south of England, where, in 1835, the extent of ground occupied by it was 53,816 acres; and its culture is very different from that of usual field-crops. When a new hop-garden is formed, the ground is trenched to the depth of 2 feet; and as the plants occupy the ground several years, their roots strike to a considerable depth, where the more of better soil they find near the bottom of the trench, the better they grow, for as to the surface soil, it can be manured at any time, and in many ways. The plants, previously raised from seed, as being more hardy in constitution than raised by cuttings, are placed in quincunx order, at 5½ feet distance each way, which give 1,440 plants to the imp. acre. The hop-plant being dioecious in its nature, that is, having different sexes on different plants, 1 male is planted among every 10 female plants. The female plants only bear fruit, which has the form of solitary cones or strobiles, ovate and pendulous, composed of membraneous scales of a pale-green colour, each containing one round flattish seed of a bay-brown color, surrounded with a sharp rim, and compressed at the top. Being climbers, as the plants shoot up, they are tied to and trained along poles pushed endwise into the ground beside them; and in the first year's growth of the bine the poles used may be short; but afterward, when shoots spring from the old stock, 3 bines are preserved from each shoot and trained up upon 3 poles placed around each plant-hill, with their upper ends divergent, that the air and sun may find their way into the centre of each cluster of plants; and the poles are, besides, so set as to allow the forenoon sun to reach the plants, and also to receive as little injury as possible from the prevailing wind of the district. The poles are from 16 to 18 feet the longest, and 14 the shortest; and as 3 are required for every hill, 4,320 are wanted for every acre. The best poles are of yew, next of chestnut, then larch, ash, willow, oak cut in winter, Scots fir, birch alder, beech, in the order enumerated. They last from 3 to 5 years, according to the wood, and cost 1s. per foot per 100 poles; that is, poles 18 feet long will cost 18s. the 100, or nearly £39 per acre; and as about 500 poles are wanted every year to keep up the stock, their wear and tear costs about £4 10s. the acre. In order to lessen this great annual expense, it has lately been suggested to stretch a stout wire along each alley, to which the poles should be fastened. The advantages of this plan are said to be, that poles of much less value than those usually employed may be used, injury from gales of wind avoided, and the alleys being open to the influence of the sun and air, the mould,

* See Wissett's Treatise on Hemp, which contains all that can be said on the subject. Quarto edition, 1808.

that fatal disease of the hop, prevented; and it is said that a garden of 9 acres at Halling, near Rochester, is cultivated in this way. Poles are carefully laid aside at the end of every hop-season. The bines, as they shoot up, are tied to the poles by women, who use dried rushes for the purpose. The ground receives culture to keep it clean and open till the season of picking or gathering the flowers arrive, which is commonly the first week of September. The hop properly so called, is picked from the bine by the hand; and, to facilitate that process, the bines are cut over at 3 feet from the ground, and the poles raised and laid on their side in a convenient position and place for the pickers. Whole families of laborers are employed at picking, receiving 1½d. per bushel, at which rate a family of 5 will earn from 7s. to 10s. a-day. There being 1,440 hills in the acre, and allowing 1 bushel of hops to each hill, and 1½ lbs. to each bushel, the acre will yield 19 cwt. 32 lbs.; but the crop is sometimes not ¼ of that quantity. Indeed, so precarious is the crop of hops, that, at Binstead, in Hampshire, a farmer grew 4½ cwt. on 10 acres, in the year 1825, and in the following year, 1826, he realized 9 tons from the same land! This diversity of crop is greatly owing to the effects of insects, of which a considerable variety and in great numbers affect the hop-plant, and also of blight or mould, occasioned by damp or confined air. When ripe for picking, the hop is of a lightish-green color, and gummy to the feel when in the highest perfection. In a few days longer it becomes brown and strong-tasted. At Farnham, in Kent, the hops are always picked in the perfect state, and every injured flower is put into a separate basket; and, on this account, the Farnham hops always command the highest price in the market. This hop is eagerly sought after by pale-ale brewers; while the brown, stronger-tasted hop is better liked by porter-brewers. After being picked, hops are immediately subjected to artificial heat in a kiln to be dried, so that they may keep; and to show the value of a delicate-colored article in the market, the brown samples are strongly fumigated with sulphur, to give them a fairer and more equal appearance. It is surprising that purchasers who are judges of hops, and aware of such a practice, submit to it, unless they themselves employ it as a means of deceiving customers who never saw hops growing, and know not how they are treated. What would be thought of a corn-farmer, were he to fumigate the barley he had to dispose of with sulphur, in order to make the bright-colored, overripened, and stained samples look all alike? If light-colored hops are indispensable to the brewer, let *him* manufacture his commodities as he pleases, but let the farmer deal only in the genuine produce of the soil. If he must have fair-colored hops, let him pick them in due season, and exercise his skill in a legitimate way, and eschew every species of deception. The drying is effected with coke and some charcoal, the drying heat being 112° Fahrenheit; and costs, including every expense, 14s. the cwt. After being dried, hops are laid in a heap, to sweat and grow tough, and there they lie longer than merely to cool; for they must feel moist and clammy, and be squeezable in the hand, before they are bagged, when 5 lbs. of fresh hops will weigh only 1 lb. when taken from the kiln. A *bag* of hops weighs 2½ cwt.; and is fixed by statute 4 feet wide, 7½ feet long, and to contain 5½ yards of cloth, weighing 5½ lbs., which usually costs 6d. per yard. A Kent *pocket* is 3 feet wide, 7½ feet long, weighs 4 lbs., and contains usually 1¼ cwt., but 2 cwt. of Farnham hops. Such a pocket will occupy a man from 3 to 4 hours to tread the hops into firmly; and to tread 4 of them in a day, at 9d. per cwt., is a very good day's work; and in doing which he becomes covered with yellow dust, to which powder Dr. Ives ascribed the whole virtue of the plant.

Hops cannot be tread too firmly into the bags, for the more the air is excluded the better; and, for this end, the use of the Bramah hydraulic press is recommended. It is not an easy matter to keep hops when they shrink in the bags, and the air finds admission to them, and they then lose from 5 to 10 lbs. per cwt.; but the greater quantity of sulphur and saltpetre employed in the drying, the worse will hops keep. Damp is ruinous to them. In most cases, the price of old hops drops down to the half of that of new. Hops containing the most seed will retain their weight the longest.

(2189.) The [excise] duty on hops is 2d. per lb., and it amounted to £409,055 in 1835, on the produce of 53,816 acres, being 49,086,600 lbs., or 8½ cwt. per acre. Small as this impost appears, it made that year a direct tax upon the land on which the hop grew, of £7 19s. 6½d. per acre! I never could understand why hops should be subjected to direct taxation, when all other agricultural productions are exempt from it. I can see the plea upon which a duty on *malt* may be urged, of its truly being a *manufactured* article; but the tax on hops is a *direct* impost on the produce of the soil. Whatever benefit is derived from this impost to the revenue, from which nearly £4,000 a year must be deducted for its collection, is more than counterbalanced by the spirit of gambling engendered in speculators, who make purchases solely in accordance with the palpable amount of duty to be exacted. Offers made to farmers, resting on this contingency, lure them also into that vice, and frequently make them suffer; and they cannot avoid the temptation, for the casualties affecting hops are so uncertain, that the prospects of a crop may be blighted or secured in the course of a few days. Thus, in 1834, the hop was so much affected by the *aphis*, that the whole amount of duty was struck at about £100,000 over all the districts; but on thunder-showers falling and destroying the insects *just in time*, and the weather afterward proving very favorable to the growth of the plant, actually raised the duty, which was paid, to £329,936, thus indicating an increase in the value of the apprehended crop of more than 3 times. Were there no duty, the farmer would dispose of his hops, when he realized them, as he does any other crop. The expense of forming a new hop-garden is £15 13s. per acre, including a half-year's rent. The yearly expense of maintaining an acre of hops is, up to picking time, including rent, &c., £17 8s.; picking, drying, and including duty on 6 cwts., £15 2s.; together, £32 10s. It is not an uncommon practice to let the working of the ground, the poling of the hills, and the tying of the bines to the time of picking, to laborers at £3 10s. per acre.*

(2190.) *Flax (Linum usitatissimum)*, from the Celtic *Llin*, a thread, in the class and order *Pentandria Pentagynia*, of Linnæus, and in the natural order of *Lineæ*, is a native of many parts of Europe, as well as of Nepaul and North America, in corn-fields, and is said to be originally from Egypt. It has been cultivated for an unknown length of time in Britain, of which it is now considered a naturalized inhabitant; and it is cultivated both for its fibre and oil, and the husk of the seed, after the oil has been extracted from it, is employed in the fattening of live-stock.

(2191.) "Mr. James Thomson and Mr. Bauer," relates Dr. Thomson, "have shown that the *fibres* of flax are transparent cylindrical tubes, articulated, and pointed like a cane; while the filaments of cotton are transparent glassy tubes, flattened, and twisted round their own axis. A section of a filament resembles, in some degree, the figure 8, the tube, originally cylindrical, having collapsed most in the middle, forming semi-tubes on each side, which give to the fibre, when viewed in a certain light, the appearance of a flat ribbon, with a hem or border on each edge. The uniform transparency of the filament is impaired by small irregular fissures, probably wrinkles arising from the desiccation of the tube. In consequence of this difference between the structure of linen and cotton fibres, Mr. Thomson and Mr. Bauer were enabled to ascertain that the cloth in which the Egyptian mummies are wrapped is always linen, and never cotton. It is clear from this that the opinion entertained by some, that what is called in our translation of the Old Testament *fine linen* of Egypt, ought to be the *cotton cloth* of Egypt, is erroneous. We have

* See Lance's Hop-Farmer, edition of 1838, for a great deal of information regarding the culture of this interesting plant.

no evidence from the cloth wrapped about ancient mummies, that the Egyptians in those early times were acquainted with cotton." *

(2192.) Large quantities of flax-seed, commonly called linseed, are annually imported into this country. It is imported for the purposes of growing the flax-crop, and for crushing into oil. Vitality not being certain in the flax-seed raised in this country, it is necessary to receive a supply from abroad, and of all foreign kinds, that from Holland is the preferable for seed, while our own answers for crushing into oil. "Crushing-seed is principally imported from Russia, but considerable quantities are also brought from Italy and Egypt. Of 2,759,103 bushels of linseed imported in 1831, 2,210,702 were brought from Russia, 172,099 from Prussia, 106,294 from the United States, 105,448 from Italy, 98,847 from Egypt, 53,738 from the Netherlands," † &c. By the New Tariff, the duty on foreign linseed, and that from British possessions, is only nominal, being 1d. per quarter. The prices by the quotations in February, 1844, are from 50s. to 60s. per quarter for English sowing, and from 25s. to 37s. for Baltic crushing.

(2193.) Linseed contains a great proportion of mucilage, and, when converted into jelly, constitutes an excellent nutriment for stock. The process of making the jelly is this: "The proportion of water to seed is about 7 to 1. Having been steeped in water 48 hours previous to boiling, the remainder is added cold, and the whole boiled gently for 2 hours, keeping it in motion during the operation, to prevent its burning to the boiler, thus reducing the whole to a jelly-like, or rather a gluey or ropy consistence. After being cooled in tubs, it is given with a mixture of barley-meal, bran, and cut chaff; a bullock being allowed about 2 quarts of the jelly per day, or somewhat more than 1 quart of seed in 4 days; that is, about 1-16 of the medium allowed of oil-cake." ‡

(2194.) The mucilage of linseed does not belong to any of the genera of gums; but its nature has not yet been ascertained. Its general composition and elementary constituents were ascertained to be these, by Guerin-Varry:

General Composition.		*Elementary Constituents.*	
Soluble gum	52·70	Carbon	34·30
Insoluble	29·89	Azote	7·27
Ashes	7·11	Hydrogen	5·65
Water	10·30	Oxygen	52·78
Total	100·00	Total	100·00

The ashes contained carbonates of potash and lime, phosphate of lime, chloride of potassium, sulphate of potash, oxide of iron, alumina, and silica ‖

(2195.) The oil afforded by linseed is in the proportion of 22 per cent., that is, about 15 gallons of oil from 1 quarter of seed, at a weight of 7½ lbs. to the gallon; the remainder is *oil-cake*. The best oil is that which is cold-drawn; and I suppose that the best oil cake is obtained from this process, as having most oil in it. The warm-drawn oil is obtained by heating the seed by steam to a temperature of 200° Fahrenheit; and as the heat liquefies the oil, no doubt more is expressed from the seed, and the oil-cake cannot be so rich. Both the cold and heated seed are put into woolen bags, and pressed by means of the hydraulic-engine or a wedge, and the cake, on being taken out of the bag, is already quite firm; its weight at most is 8 lbs., and sells for £9 10s. to £10 per 1,000, or 1¼ farthings per lb., and the foreign from £5 to £6 10s. per ton, or 2¾ farthings per lb. From this difference in the price, it would appear that the foreign is the more valuable oil-cake, owing, perhaps, to its being manufactured by imperfect machinery, which cannot extract so much of the oil out of it as our own; but be this as it may, I am not aware that any experiments have ever been made on their comparative fattening powers. A substitute for oil-cake, or what is called Hutchinson's patent oil-cake, is compounded, I understand, of 3 cwts. of linseed-oil and 1 ton of barley meal, and is sold at £12 per ton. I have given the proportions of Mr. Warnes's compound, which is similar, in (1264).

(2196.) Oil-cake, independently as an article of food, is an excellent medicine for live-stock, preventing constipation in the bowels, and giving to the hide a *sweetness of coat* unattainable by other means. Mr. Wilson of Edington Mains, in Berwickshire, tells me that ever since he has given oil-cake to his calves after being weaned, they have not been affected with that fatal complaint the quarter-ill, already described in the latter part of (2001), and he has experienced this beneficial effect for 6 years without any external application of setons. By administering oil-cake to my cows after calving, I certainly prevented their being affected with red-water (1699).

(2197.) *Hemp (Cannabis sativa)* is in the class and order *Dioecia Pentandria* of the Linnæan system, and of the natural order *Urticaceæ*, or nettle tribe. Being a dicœcious plant—that is, having the sexes in different plants—it is necessary to have a mixture of both sexes in the same plot of ground, if seed is desired to be raised and collected; though, I presume, for the purpose of raising the fibre merely, that condition is not requisite; but, as apparently similar seed produces plants of different sexes, a mixture of the sexes cannot well be avoided in practice. The male plant is more slender and delicate in appearance than the female, which bears the seed; and, though this is the usual distinction of sexes in plants, yet, strange to say that, in speaking of the hemp-plant, most writers denominate the plant which *bears the seed* the *male*—owing, perhaps, to its more robust appearance, in comparison of the *true* male, which is, of course, barren of seed. On this misapplication of the sexes, it has been well remarked: "We are the more surprised that botanical writers should fall into the error, or rather copy this blunder from one work into another, for so many ages, without correcting a mistake that inverts the order of Nature." §

(2198.) The principal use to which hemp is applied is the making of cordage of all kinds, the fibre being both strong and durable. A first-rate man-of-war is said to require 80 tons of rough

* Thomson's Organic Chemistry of Vegetables. † M'Culloch's Dictionary of Commerce, art. *Flax*.
‡ Don's General Dictionary of Botany and Gardening, art. *Linum*, vol. i.
‖ Thomson's Organic Chemistry of Vegetables.
§ Phillips's History of Cultivated Vegetables, vol. i.

hemp to supply her with her necessary tackle. Taking 40 stones the imperial acre as a good crop, 4 acres are required, at that rate, to raise 1 ton; so that a man-of-war consumes at least one year's produce of 320 acres of hemp for an outfit of cordage! "By this cordage," says Coles, quaintly, in his Paradise of Plants, "ships are guided, bells are rung, beds are corded, and rogues kept in awe." Old cordage is converted into paper, and should, therefore, never be destroyed.

(2199.) The *Hop (Humulus lupulus)*, like hemp, stands in the class and order of Linnæus, *Dioecia Pentandria*, and natural order *Urticaceæ*. It is not a native of Britain, nor was its use known in this country till the reign of Henry VIII., in 1524,* when it was used in the composition of malt liquor—thus franking the truth of an old English distich, that

"Hops, Reformation, Bays, and Beer,
Came into England all in one year."

It had not become a favorite with the people for many years after that period; for Walter Blith records, in 1653, this remarkable popular error, only 200 years ago—and such errors are rife in all ages of the world—that "it is not many years since the famous city of London petitioned the Parliament of England against two nuisances; and these were, Newcastle coals, in regard of their stench, &c., and hops, in regard they would spoil the taste of drink, and endanger the people."† It would appear that this public expression of dislike against hops had prevailed in high quarters, for their use was forbidden by act of Parliament in the reign of James I., though the mandate was little attended to; and, by the time of Anne, public opinion had so entirely changed, that hops were considered so superior to all other bitter principle, that brewers were prohibited from using any other, under a penalty of £20. Hops had not thriven for some time after their introduction into England; and, even so lately as 1695, enough was not grown to serve the country, for 510 cwt. were that year imported from Flanders and Holland. For many years past this country has been able not only to supply itself, but to export hops, and few foreign hops are imported. In 1832 there were 703,163 lbs. exported, and only 11,167 lbs. foreign imported; but even this small importation was not required for home consumption, for in the same year the much greater quantity of 50,113 lbs. of foreign were exported. The English hop is accounted the best in the world. Hops may be used medicinally; a hop-pillow will insure sleep to a patient in fever, when all other expedients will prove ineffective. The tender shoots of the hop in spring may be used as a pleasant, bitter salad.

(2200.) The yellow powder of hops was named *lupulin* by Dr. Ives, which Messrs. Payen and Chavallier found, by analysis, to contain the following substances: Volatile oil 2, bitter principle 12.5, resin 52.5, silica 4, and of di-acetate of ammonia, gum, bi-malate of lime, traces of fatty matter, and some salts, unascertained portions of each. In another analysis, they found it to contain 13 per cent. of the weight of the cones, but, deducting 4 per cent. of foreign matter, there was left 9 per cent. of lupulin. When distilled with water, it gives about 2 per cent. of its weight of colorless volatile oil, to which hops owe their peculiar smell. This oil dissolves in considerable quantity in water, and it seems to contain sulphur.‡

34. REAPING RYE, WHEAT, BARLEY, OATS, BEANS, AND PEASE.

"Here, stretched in ranks, the swelled swaths are found
Sheaves heaped on sheaves here thicken up the ground.
With sweeping stroke the mowers strew the lands—
The gatherers follow and collect in bands;
The rustic monarch of the field descries,
With silent glee, the heaps around him rise."

POPE'S HOMER.

(2201.) We are now arrived at the most important of all field operations—that for which every other that has hitherto been described has been merely preparatory—the grand result, to attain which the farmer feels the greatest anxiety, and which, when attained, yields him the greatest happiness, because it bestows upon him the fruit of all his labor; but the fruit will be great or small, in proportion—all other things being alike—to the skill and industry he has displayed during the course of the preparatory year; for no adage conveys a stronger truth than this, when applied to the farmer, "As he has sown, so shall he reap." If he have dealt with the land in a penurious spirit, laboring with inadequate means, stinting manure, and grudging seed, he will reap a scanty produce, a deceitful crop, and grievous disappointment; but should he have done all that skill,

* Beckmann's History of Inventions, vol. iv. † Blith's Improver Improved.
‡ Thomson's Organic Chemistry of Vegetables.

industry and liberality could effect, he will assuredly reap a bountiful reward, for the earth is ever grateful of kindness. Not having yet experienced it, you can hardly conceive the difference between these two positions of the farmer; in the latter case, the very rustling of exuberant straw, while the crop is handling, is delightful to his ear, and his heart is made glad when he sees every one bestowing with heartiness the severe labor required in cutting down and carrying in a heavy crop. In the former case, on the contrary, the boneless straw is easily squeezed in the hand of the reaper—the light, scanty-grained heads are almost disregarded by him, and a single cart-load clears a large space of the field. Such a contrast is indeed lamentable, and unfortunately may be made every harvest; but it is true, nevertheless, that the contrast is becoming less striking yearly—for it is within my own recollection that 9 bolls, or 54 bushels, barley are now as easily raised as 7 bolls, or 42 bushels, were 20 years ago; and should the present spirit of inquiry continue, and lead to still more amended practice, it is certain that the range of comparison between former and present crops will be still more narrowed; and to the furtherance of this there is, besides, this great stimulus to improvement of poor soils, that the effect of amended practice is far more apparent on them than on better soils.*

(2202.) As harvest-work requires a greater number of laborers than usually live on a farm, it is requisite you should hire beforehand a band of reapers on whom you can rely on remaining with you all harvest, and not trust to the chance of a casual supply. No doubt farms in the immediate vicinity of large towns can obtain a great number of reapers daily, who go to their own lodgings in town at night; and the convenience of obtaining a day's work at good wages, within a few minutes' walk of their own homes, will tempt most of the inhabitants of towns to prefer farms near them; and this being the case, farms so situate may not require a hired band, but depend on the chance of finding reapers from day to day.—When harvest-work goes on in a regular manner through the country, this is an easy and simple mode of conducting harvest-work; but should a great proportion of the crop become sooner ripened than was expected, or the weather endanger the safety of the standing crop everywhere, the general demand for hands renders the farmers near towns no better off than those at a distance, for town reapers will then go anywhere for higher wages. The farmers near towns may, no doubt, then give higher wages as well as others; but the excitement of raising wages renders reapers unsettled, and their chief anxiety then is to inquire where the highest wages are to be obtained, not who the possessor is of the nearest farm. In such circumstances, the farmers near towns must put up with the services of the infirm, the young, and those who are burdened with household cares. The *safest* plan, therefore, for *every* farmer to follow, is to hire a band of reapers, proportioned to the extent of work to be performed, to remain with him all harvest, and to obtain auxiliary hands, as he wants them, on any hiring-day in the neighboring town.

(2203.) *Reaping-scythes* being of different forms, and having to be mounted in a peculiar manner, are figured and described hereafter, and the mode of using them I shall soon describe.

[* The same spirit of inquiry is producing like results in some parts of the United States; but there is no sort of industry that experiences as much difficulty in commanding the use of the capital necessary for its advancement—except it be in the New-England States, where facilities exist for the incorporation and loaning out of capital, and where consumers employed in every trade are close alongside the producers, ready to demand and pay for every species of the fruit of agricultural industry, from an onion to an ox. *Ed. Farm. Lib.*]

(2204.) Before proceeding to employ reapers in the field, it is requisite you should know when corn is fit to be cut; for if cut down too soon, or allowed to stand too long, loss of produce will be incurred. It may be laid down, as a general rule, that corn in a healthy state comes to maturity first in the ear, and then in the straw; and when it does not, that is, when the straw becomes matured first at the root, then, of course, the grain suffers premature decay. Whenever a crop is observed to be in the latter state, it need not be allowed to stand longer on the ground, as it can derive no more benefit from the soil, and its grain will won as readily in the stook as on foot; and so, in like manner, whenever the ear is observed to be sufficiently ripe, the crop should be cut down, as the straw will won more rapidly in the stook than standing on the ground. The only matter of doubt, then, in the case is, when the ear is sufficiently ripe. The most ready way of judging of this, in wheat and oats, is the state of the chaff, and of 2 or 3 inches of the top of the straw under the ear; if all these are of a uniform straw-yellow colour, and feel somewhat hard in the ear, in the oat, and absolutely prickly to the hand, in the wheat, when grasped, they are ripe; or the grain itself may be examined, and should it feel firm under pressure between the finger and thumb, it is ready for reaping; or should the neck of the straw yield no juice when twisted round by the finger and thumb. Barley should be of uniform yellow color in the grain and awns, and the rachis somewhat rigid; for as long as it moves freely by a shake of the hand, the grain is not sufficiently ripe, nor will it be of uniform color. It is not equally prudent to reap all sorts of grain in the same degree of maturity. When wheat is reaped before it is sufficiently ripe, it is apt to shrink, and have a bluish tint in the sample; and when too ripe, the chaff opens from the grain, which is apt to be thrown out by the least agitation of the air; and some sorts of white wheat are very subject to be thrown out by the wind, even before reaching the point of maturity. When very ripe, wheat bends down its ear, opening the chaff, and becomes stiff in the neck of the straw, indicating that Nature intends the grain to be shaken out. Red wheat is less liable to be shaken than white; but any kind will shake out when too ripe, provided the plant is in good health, and the grain of good quality; for as to immature grain, it is difficult to make it leave the chaff even when hardened, and the spelt wheat has so tenacious hold of its capsule, that it is difficult to be disengaged from it even by the blows of the flail, fig. 401. It may be supposed that, whenever the ear and the entire straw are of uniform yellow colour, the plant is no more than ripe, and so it is; but by the time the straw has fully ripened to the root, the ear will be rigidly bent, and ready to cast its seeds with the slightest violence. The same rule may be applied to barley as to wheat, that is, whenever the neck of the straw is ripe, it is time to cut, for when too ripe, the ear bends itself down, diverging the outward row of awns nearly at right angles with the rachis, and is apt to be snapped off altogether by the wind. In regard to oats, the same rule also applies; but there is much less risk of cutting oats unripe, in comparison to allowing them to stand till perfectly ripe, as they are easily shaken out by the wind,—the chaff standing apart from the grain. When bean-straw turns black, it is fit to cut, and so is pease-straw, when the pease become firm in the pod. In every case it is much safer for the crop to be cut before it is ripe than after it has become too ripe, as I shall show below.

(2205.) With all these preliminaries arranged, and with your mind satisfied that the crops are in a fit state for reaping, proceed with the reapers to the harvest field, and conduct the reaping in the best manner for each

respective sort of grain. And, in regard to this, I should remark that the harvest-field will not be properly conducted unless a person is appointed to superintend the reapers; for to none of the reapers can such a task be deputed, as his own occupation is sufficient to occupy all his attention. The steward is the person who should undertake this duty, unless you undertake it yourself. It is his duty to mark the time to commence work, and to leave it, and of the hours of meals and of rest; it is his duty to restrain the impetuous, to urge the slow worker, and to keep every one in the best spirit for work; and it is his duty to see the ground neatly cleared of the crop, and the crop itself judiciously handled. The man who fulfills all these duties as they should be during the entire harvest, accomplishes no easy task, either of body or mind. He should not be mounted on horseback, but be on foot, ready to keep everything right; for it should be remembered that a single minute's loss of work of a large band of reapers, causes a great loss in the gross amount of work. The farmer himself, when not superintending, may move about on horseback; but a horse is a troublesome companion to a man who has to move about close to workpeople in a harvest-field.

(2206.) Reaping with the *scythe* is a nice operation, and requires considerable skill. The scythes should be mounted as figured hereafter, and made fit for work some time before being wanted in the harvest-field. There should be a number of small articles always ready in the field in case of accident, the procuring of which wastes much time, when not at hand. These are, a small hammer for fastening the wedges of scythe-ferules and of rake-handles; bits of old sole-leather for bedding the tines of the scythes upon; pieces of cord for tying anything; small large-headed nails for fixing the stays to the snead of the scythes; a large coarse file for rubbing down the turned-up point of a scythe, when it happens to come against a stone; a sharp knife for cutting bits of leather, and for removing any raggedness upon the rakes or cradles.

(2207.) The various forms of scythes are the cradle-scythe, the straight-sneaded scythe, and that with the bent snead, fig. 361, already described; and the greatest favorite among mowers is the cradle-scythe, because it is easiest to wield by the arms, and does not twist the lumbar region of the body so much as the two common scythes; and I may remark that it is this last effect which forms the great objection against the scythes in ordinary use. And yet it is not easy to see why the use of the cradle-scythe, which is borne by the arms alone, in front of the body, and which does not admit of being balanced in one hand like the other scythes, should be less fatiguing to work with; yet there is no doubt of the fact, and on that account more work is done with it.

(2208.) In commencing to cut a field of corn with the scythe, that side should be chosen from which the corn happens to lie, if it be laid, and, if not, then the side from which the wind blows. The scythe makes the lowest and evenest stubble *across* the ridges, and then also most easily passes over the open-furrows. Other things being favorable, it is best to begin at that side of a field which is on the left hand of the mowers. If all these conveniences cannot be conjoined, as many as can should be taken advantage of. The ground should have been rolled, and all large stones removed in spring, otherwise the scythes will run the risk of being injured in the face by stones, and even by clods.

(2209.) I have already said that reaping with the scythe is best executed by the mowers being in what is called *heads*, namely, a head of 3 scythesmen, 3 gatherers, 3 bandsters, and 1 man-raker, or of 2 scythesmen, 2 gatherers, 2 bandsters, and 1 woman-raker. On a large farm the

heads may consist of the former, and on a small one the latter number. The best opening that can be made of a field for scythe-work, is to mow *along the ridge* by the side of the fence, which is kept on the left hand, from the top to the bottom of the field; and while one head is doing this, let another mow along the bottom head-ridge, the whole length of the field, and thus open up 2 of its sides. After this, the first head commences mowing at the lowest *corner* of the standing corn, across 6 ridges, or 30 yards, which is as far as a scythe will cut corn with one sharpening. Suppose all these preliminaries settled, the scythesman who is to take the lead first sharpens his scythe. In sharpening a scythe for cutting corn, the scythe-stone has to be put frequently into requisition, for unless the edge is kept keen, the mowing will not only be not easy but bad; and unless a scythesman *can* keep a keen edge on his scythe he will never be a good mower, and will always feel the work fatiguing to him. The sharpening should always be finished with the *straik* or strickle. The stone need not be used at every landing, the strickle answering that purpose; but whenever the scythe feels like a drag on the arms, the stone should be used. In mowing, it is the duty of the mower to lay the cut corn or swath at right angles to his own line of motion, and the straws parallel to each other, as at *a*, *a*, *a*, fig. 414, and to maintain this essential

Fig 414.

THE MOWING OF CORN WITH THE SCYTHE.

requisite in corn-mowing, he should not swing his arms too far to the right in entering the sweep of his cut, for he will not be able to turn far enough round toward the left, and will necessarily lay the swath short of the right angle; nor should he bring his arms too far round to the left, as he will lay the swath beyond the right angle; and, in either case, the straws will lie in the swath partly above each other, and with *uneven ends*, to put which even in the sheaf is waste of time. He should proceed straight forward, with a steady motion of arms and limbs, bearing the greatest part of the weight of the body on the right leg, which is kept slightly in advance, as seen at *b*, *b*, *b*. The sweep of the scythe will measure about 7 feet in length, and 14 or 15 inches in breadth. The woman-gatherers *c*, *c*, *c*, follow by making a band from the swath, and laying as much of the swath in it as will make a suitable sheaf, such as *d*, *d*. The gatherer

is required to be an active person, as she will have as much to do as she can overtake. The bandster *e* follows her, and binds the sheaves in the manner already described, and any 2 of the 3 bandsters, *f*, *f*, set the stooks *g* together, so that a stook is easily made up among them; and in setting them, while crossing the ridges, they should be placed on the same ridge, to give the people who remove them with the cart the least trouble. Last of all comes the raker *h*, who clears the ground between the stooks with his large rake *i*, described below, of all loose straws, and brings them to a bandster, who binds them together by themselves, and sets them in bundles beside the stooks. This is better than putting the rakings into the heart of a sheaf, where they will not thresh clean with the rest of the corn; and, moreover, as they may contain earth and small stones, and also inferior grain, from straws which may have fallen down before the mowing, it is better to thresh bundles of rakings by themselves. The figure exhibits the 3 kinds of scythes in operation.

(2210.) A scythesman will cut fully more than 1 imperial acre of wheat in a day. Many farmers affect to believe that the scythe is an unsuitable instrument for cutting wheat; but I can assure them, from experience, that it is as suitable as the sickle, and that mown sheaves may be made to look as well as reaped. No doubt mowing wheat is severe work, but so is reaping it. Of oats, 1 scythesman will mow fully 2 acres with ease. The oat crop is remarkably pleasant to handle in every way; its crisp straw is easily cut by the scythe, and being hard and free, and generally not too long, is easily bound in sheaf and set in stook. Nearly 2 acres may be mown of barley; but the gummy matter in the straw, which gives it a malty smell, causes the stone to be frequently used in mowing barley, and the straw being always free, the bands are apt to break when rashly handled in binding the sheaves.

(2211.) One mode of setting up corn to dry quickly is in *gaits*, that is, the band of the sheaf is tied loosely round the straw, just under the corn, as at *a*, fig. 415, and the loose sheaf is made to stand upon the lower end of its straw being spread out in a circular form, as *b* to *c*, and they are set upon every ridge. The wind whistles through the open sheaf, and even the rain passes through, and does not hang upon it. The expedient of gaiting, however, is only practiced in wet weather, and even then only should the crop, if allowed to stand, be endangered by a shaking wind. It is confined also to a particular kind of crop, namely, oats—wheat and barley never being gaited, because when wheat gets dry, after being cut in a wet state, it is apt to shake out in binding the gaits; and when barley is subjected to the rough usage of binding, after being won, the heads are apt to snap off altogether, and, besides, exposure in gaits would injure its color, and render it unfit for the maltster. Oats are protected by a thick husk, and the grain is not very apt to shake out in handling, excepting potato-oats, which are seldom gaited, the common kinds only being so treated. But, for my part, I would not hesitate to gait any sort of oats when wet with dew in the morn-

Fig. 415.

A GAIT OF OATS.

ing, or even when wetted with rain, rather than lose a few hours' work of reaping every morning, or at nightfall. Gaits, it is true, are very apt to be upset by a high wind; but after having got a set, it is surprising what a breeze they will withstand. After being blown down, however, they are not easily made to stand again, and then 3 at least are required to be set against each other; but whatever trouble the re-setting them should create, they should not be allowed to lie on the ground, and it will be found that a windy day dries them very quickly, and secures their winning.

(2212.) *Rye* may be reaped or mown in the same manner as the other cereal crops. Its straw, being very tough, may be made into neat slim bands. It usually ripens a good deal earlier than the other grains; and its straw being clean and hard, does not require long exposure in the field, and on that account the stooks need not be hooded.

(2213.) *Beans* in drills are reaped only with the sickle, by moving backward, taking the stalks under the left arm, and cutting every stalk through with the point of the sickle. When beans are sown by themselves straw-ropes are required for bands; but when mixed with pease, the pea-straw answers the purpose. Beans are always the latest crop in being reaped, sometimes not for weeks after the others have been reaped and carried. In stooking, bean-sheaves are set up in pairs against one another, and the stook may consist of 4 or more sheaves, as is thought most expedient in the circumstances for the winning of the crop, the desire being to have them won as soon as possible, to get the land sown with wheat. *Pease* are also reaped with the point of the hook, gathered with the left hand, while moving backward, and laid in bundles, not bound in sheaves, until ready to be carried, and are never stooked at all.*

(2214.) It will be observed, from the foregoing statements, that mowing is by much the cheapest mode of cutting down corn, and on that account should be universally adopted; for the item of harvest expenses is a heavy one in the farmer's books, and every legitimate means should be used to lessen it. Any plan that would deprive the inhabitants of a farm of work, I would hesitate to recommend; but when the farmer, as at present situated, is very dependent on the public market of labor to secure his whole year's produce, he is justified in the endeavor to make himself independent in this respect. It is scarcely practicable to render himself entirely independent of the market, without throwing his horses idle for a long time; and, as there is no economy in such a course, the only other left him is to economize on the usual cost of harvest-labor. Now, the scythe offers this advantage, and so efficient is that implement that whoever has tried it fairly, and for a whole harvest, has never relinquished it. I know a prejudice exists against it, on the ground that a mown stook does not look so well as a reaped one, and that is difficult to build a neat stack with mown sheaves. I own there is a roughness in the appearance of mown sheaves, but I can assure every one who has not discovered what I am going to state by his own experience, that that is no detriment to the corn, and the objection disappears as work-people become *accustomed* to the implement. Such a roughness would not exist were mowers careful to lay the swathes at *right angles to their line of motion*, and were gatherers to lift the swathes even, and lay them down in armsfull even in the bands; and though it is scarcely possible for work-people to bestow utmost atten-

[* Is there not, in many of the United States, an opening for experiment in an extended cultivation of the bean and pea crops? Indian corn, it is true, profitably supersedes various staple crops much relied on in Europe; but when we consider the very nourishing quality of beans and peas, we have room for surprise that neither should be even enumerated or alluded to in the decennial return of our agricultural produce. *Ed. Farm Lib.*]

tion at all times, yet practice makes great proficiency in this matter, which compensates, in a great measure, for want of constant attention. I found this effect produced after employing the same hands at the same work for successive years, and who at length became as neat and clever at their respective works as I could wish them. Besides the actual economy in employing mowers, only conceive the advantage of being able to carry in the corn after it has been exposed in the air to win only half the usual time. Reaped oats require to stand in the stook a fortnight before they will keep in the stack; mown oats, in the same weather, may be carried in a week.* Barley, when reaped, is scarcely fit for leading in less than 3 weeks; when mown, it may be put into the stack in safety in 10 days. And as for mown wheat, about 3 days will suffice to win it. It is an error to suppose, as is too commonly imagined, that a mown stook takes in rain: on the contrary, I have frequently ascertained that it takes in rain less than a reaped one. In one instance I remember of a field of potato-oats being finished cutting, that heavy rain fell the next day, and continued without intermission for 3 days, the last of which was very windy, and the wind had changed from E. to W., when it faired. About ¼ of this field had been reaped with the sickle, and the reason that implement was used in it all, was to give a little harvest-work at threaving to a few elderly men and women, cotters, and hinds' wives who, having to attend to young children, could not undertake the regular work of a harvest-field. Impressed with the common belief that a mown sheaf must take in rain, I went to the field after the rain had ceased, to ascertain the state the stooks were in, never doubting they would be soaked, while the reaped ones would be comparatively dry; but judge of my surprise when the fact was the very opposite, the mown sheaves not being wetted to the heart, while the east side of the reaped sheaves were soaking to the bands. On consideration, I accounted for the difference of the phenomena in this way: In reaped sheaves, and especially when cut by threave, the straws are straight and hard pressed, between which the rain finds its way into the heart of the sheaves; while the straws in the mown stooks, being somewhat bent and broken and interlaced on the surface, this texture prevents the rain penetrating, and is rather serviceable in throwing it off. Besides this property, mown sheaves are evidently more pervious to air than reaped.

(2215.) An advantage of another kind obtained in mowing corn should not be overlooked, which is the very short stubble left in the field, and the larger quantity of straw carried to the stack-yard. The following statement may be depended on, as being the result of experiment:

				Cwt.	qr.	lbs.
Weight of straw per acre, when cut to 2 inches of the ground.....				26	1	0
..	..	..	8 ..	..	23	1 6
..	..	..	12 ..	..	21	0 2

So that ¼ cwt. of straw is left per acre on every field by every 1 inch of stubble. When we know that the value of straw is commonly about 28s. per ton, or 15s. per load of 36 trusses, we cannot but feel surprised at the barbarous mode of using the wheat-straw in some places of England—in first reaping the ears of corn, and then mowing the straw.

(2216.) It is not easy to state, with sufficient accuracy, the proportion which the straw and grain bear to each other—nor, of course, the ratio realized by the farmer, which must depend on the mode of cutting adopted by him. I have received the following statement of their relative weights in the neighborhood of Edinburgh, from Mr. Andrew Gibson, of

[* Depending, of course, on climate and weather. *Ed. Farm. Lib.*]

the Dean Farm, whose good farming is well known: From a crop of wheat, of 40 bushels to the acre, or of 2,600 lbs., at 65 lbs. per bushel, the straw will weigh 9 kemples of 440 lbs. each, or 3,960 lbs., affording just $\frac{1}{3}$ more weight of straw than of grain. From a crop of barley of 60 bushels, weighing 56 lbs. per bushel, or 3,360 lbs. per acre, the weight of straw is 7 kemples, or 3,080 lbs., being $\frac{1}{10}$ more weight of grain than of straw.—From a crop of 60 bushels of oats, at 45 lbs. per bushel, or 2,700 lbs. per acre, the weight of straw is 8 kemples, or 3,520 lbs., being $\frac{1}{3}$ more weight of straw than of grain. These are all average quantities. In ordinary crops at a distance from towns, the proportion between the grain and the straw is *supposed* to be—for, I believe, it has not been satisfactorily ascertained by experiment—the grain $\frac{1}{3}$ and the straw $\frac{2}{3}$ of the entire weight of the crop.*

(2217.) There is another curious inquiry connected with this subject—namely, the proportionate weight of *roots and stubble left in the field after the crop is reaped.* In reference to the roots of natural grasses left in the soil acting as manure, Professor Johnston observes that "the same is the case, to a greater or less extent, with all the artificial corn, grass, and leguminous crops we grow. They all leave their roots in the soil; and, if the quantity of organic matter which these roots contain be greater than that which the crop we carry off has derived from the soil, then, instead of exhausting, the growth of this crop will actually enrich the soil, in so far as the presence of organic matter is concerned. No crops, perhaps, the whole produce of which is carried off the field, leave a sufficient mass of roots behind them to effect this end; but many plants, when in whole or in part eaten upon the field, leave enough in the soil materially to improve the condition of the land—while, in all cases, those are considered as the least exhausting to which are naturally attached the largest weight of roots. Hence the main reason why poor lands are so much benefited by being laid down to grass, and why an intermediate crop of clover is often as beneficial to the after-crop of corn as if the land had lain in naked fallow." The remarks here given are not all connected with our present subject, but they show the partial compensation which white crops return to the soil by means of their roots. The Professor then gives the results of some experiments of Hlubek, conducted on a small scale, with a view to ascertain the quantity of roots left in the soil by plants after their parts above ground had been removed; and though the experiments were made with a few of the natural grasses, after they had been made into hay, I shall transcribe them, as the results give the proportion between the roots and stems of gramineous plants.

[* Obvious as is the usefulness of facts thus exactly ascertained, how few farmers in our country have been at the pains to inquire after them for his own government. The relative weight of grain and straw will depend on various circumstances. On the fertile lands of Prince George's and other counties, where the soil is deficient in clay, and yields heavy crops, say from 40 to 60 bushels of Indian corn, you hear them complain that their wheat *runs to straw* In such cases the proportion of straw to grain would probably be much larger than is here designated. It is, however, obvious that every farmer should, in the commencement of his career ascertain these matters for his future government. Every farmer can make a near approach to the quantity of *grain* he makes on his estate; and having done that he will have the satisfaction to know how much provender he has for his stock, and how much of the fertilizing properties of his land has been carried and sold off in the grain crop, and how much remains to be returned to the land. This relative weight of grain and of fodder needs to be nicely and thoroughly ascertained as to Indian corn. *Ed. Farm. Lib.*]

English and Scientific Names of Grasses.	Produce in		Produce in Roots.		Weight of dry Roots to 100 lbs. of Hay.

"The fourth column of the above Table," observes Professor Johnston, "shows how large a quantity of vegetable matter some of the grasses impart to the soil, and yet how unlike the different grasses are in this respect. The sheep's fescue and perennial rye-grass—besides the dead roots which detach themselves from time to time—leave at the end of the fourth year a weight of *living* roots in the soil, which is equal to 3 times the produce of that year in hay. If we take the mean of all the above grasses as an average of what we may fairly expect in a grass-field, then the amount of living roots left in the soil when a 4-year old grass-field is plowed up, will be equal to $\frac{1}{6}$ more than the weight of that year's crop." The mean of the Table gives a weight of 121 lbs. for every 100 lbs. of crop; and if we take this as a rule for estimating the weight of roots left in the ground by the cereal crops mentioned above in reference to their weight of straw, and if we take their respective weights of grain and straw as given above, the following will be the entire weights grown of those crops:

			Tons. cwt. qrs. lbs.
Of Wheat,	Grain	2.600 lbs.	
	Straw	3.960 ..	
	Roots	4,779 ..	
		11,339 lbs. =	5 1 0 17
Of Barley,	Grain	3.360 ..	
	Straw	3,080 ..	
	Roots	3,726 ..	
		10,166 lbs. =	4 10 3 2
Of Oats,	Grain	2.700 ..	
	Straw	3.520 ..	
	Roots	4.259 ..	
		10,479 lbs. =	4 13 2 7

(2218.) Although it is perfectly true what Professor Johnston says in his concluding remarks on this head, that "this burying of recent vegetable matter in the soil, in the form of living and dead roots of plants, is one of those important ameliorating operations of Nature which is always, to some extent, going on where vegetation proceeds: it is one by which the practical man is often benefited unawares, and of which—too often without understanding the source whence the advantage comes—he systematically avails himself in some of the most skillful steps he takes with a view to the improvement of his land,"* it is, nevertheless, of greater benefit to the farmer to cut his crops as near the surface of the ground as possible, thereby putting it in his own power to return the straw to the soil in a state of manure best suited to the wants of the crop, than to cut the stubble high, merely because the soil will derive benefit from it, as an organic substance, when it happens to become decomposed in the soil.

(2219.) That one period of their age is better than another for reaping grain crops, has been proved by very careful experiments made by Mr. John Hannam, North Deighton, Yorkshire.—Without entering into the details of these experiments, it will be sufficient to give only their results. Of wheat reaped at various times, the following were the advantages and disadvantages derived:

* Johnston's Lectures on Agricultural Chemistry and Geology.

No. 1, reaped *quite green* on 19th August, and stacked 26th August, gave a return of £11 17s. per acre.

No. 2, reaped *green* on 19th August, and stacked 31st August, gave a return of £13 6s. per acre.

No. 3, reaped *raw* on 26th August, and stacked 5th September, gave a return of £14 18s. per acre.

No. 4, reaped *not quite so raw* on 30th August, and stacked 9th September, gave a return of £14 17s. 4d. per acre.

No. 5, reaped *ripe* on 9th September, and stacked 16th September, gave a return of £13 11s. 8d. per acre.

Hence a *loss* of	£1	14	8	per acre upon	No. 1	as compared with	No. 5.
.. ..	0	5	8	..	No. 2	..	No. 5.
.. *gain* of	1	6	4	..	No. 3	..	No. 5.
.. ..	1	5	8	..	No. 4	..	No. 5.
.. ..	3	1	0	..	No. 3	..	No. 1.

Hence, also, wheat reaped a *fortnight* before it is ripe gives an advantage on every point, viz:

In weight of gross produce, of	13 1-5	per cent.
.. equal measures, nearly	¼	..
.. equal number of grains, nearly	2¼	..
In quality and value, above	3¾	..
In weight of straw, above	5	..

Besides these, other advantages are, straw of better quality, a better chance of securing the crop, and a saving in securing it. On the other hand, wheat, reaped a *month* before it is ripe, gives an advantage of 22 per cent. in weight of straw compared with the ripe, but suffers disadvantage in every other point, namely:

In weight of gross produce	11 5-13	per cent.
.. equal measures, above	1·3	..
.. equal number of grains, above	13 1 6	..
In quality and value, above	4·5	..

(2220.) These may seem trivial advantages and disadvantages, when confined to the area of a single acre; but apply the particulars to the extent of ground under wheat culture in the kingdom, and the truth of the Scottish adage, "mony a little maks a muckle," will be clearly seen; for, as Mr. Hannam observes, "When we consider that there are in England and Scotland about 4,000,000 acres of wheat grown annually, producing 12,000,000 quarters of grain, of which ¾ are allowed to become ripe; when we consider that by cutting this sooner we should produce an increase of 15 1-7 per cent. of flour, and realize an increased value of 7s. 6½d. upon every quarter produced; and that we should produce food for 1,362,857 persons over and above what we now produce, and an extra annual income of £512,491: and when we consider that this increase would be so much added to the wealth of the country, that it is equal to the proceeds, at 3 per cent., of an estate worth £17,083,033; and that the increase of our population demands an increased supply of food, I would ask, what is our duty in this case?"*

(2221.) Upon one occasion I cut down a few stooks of potato-oats when quite green, though full in the ear, to allow carts to pass to a place destined for the site of a hay stack; and, after standing till the rest of the field was brought in, they were threshed with the flail by themselves, and the sample they produced was the most beautifully silvery grain I ever saw; but, not having made the experiment with any view to the crop, I pursued the investigation no farther, and cannot say what effect so very early reaping had produced upon the quantity and quality of meal.

(2222.) [The first and most important operation of the harvest season being the reaping of the crop, I have now to proceed with the description of the machines and implements used in that interesting operation. It is more than probable that, in the dawn of Agriculture, the tiny crop of grain was plucked by the roots from the earth without the aid of any instrument other than that most comprehensive one, the human hand; but the inconveniences attending this mode must have been soon superseded by the adoption of the reaping-hook, or sickle, which is coeval with the most remote history. It is believed that instruments or machines of a more complicated form than the sickle have been resorted to by some of the nations of antiquity: but of these we have no certain historical information; and when it is considered that, even in modern times, with all our advantages of mechanical knowledge, and the numerous appliances of mechanical experience and skill, we have, as yet, failed in producing a really effective reaping-machine, we are led to the conclusion that nothing of the sort in a perfect form had ever been achieved by the ancients. During the last sixty years, many attempts have been made to produce a perfect reaping-machine, but, with few exceptions, they have proved abortive, and the problem, in its fullest extent, remains yet unsolved; but, nevertheless, several of these attempts have been attended with at least partial success—a success which has extended to the reaping of grain when it stands erect, or even slightly inclined, if all in one direction—but have all failed in making satisfactory work when the crop has been lodged by rains, or contorted by winds. The step which has been made in achieving even this much is, however, of importance, and holds out a prospect of the probability that we shall yet see a reaping-machine adapted to the reaping of at least a very large proportion of our fields, in the situation in which they are found in general, when ready for the sickle. But as none of these machines can be considered perfect in their present state, I deem it unnecessary to enter into any minute details of their construction here, and will only give a summary

* See Quarterly Journal of Agriculture, vols. xii. and xiii., for the detailed particulars of Mr. Hannam's interesting experiments.

view of their principles, and the *leading* features of their construction, with a reference to writers whose more detailed information may be obtained by those who desire to prosecute the subject.

(2223.) The first reaping-machine that came before the public with any claim to efficiency was that of Mr. Smith, of Deanston, about the year 1814–15, when it was tried before a joint-committee of the Highland and Agricultural Society, and of the Dalkeith Farming Society, the latter having previously offered a premium of £500 for a perfect reaping-machine.* On that trial, the machine operated with very considerable effect; but though much approved of, in a general view, was not considered so complete as to warrant the committee to award the premium. Mr. Smith's machine continued for a number of years to be the only one at all effective; but, as it did not possess all the requisite qualities for perfect reaping, it did not come into actual use beyond a very limited extent. The cutting principle in Smith's original machine is beautifully simple, being a plain, smooth-edged, annular knife, of about 6 feet diameter, and 6 inches broad, attached by arms to an axle, with which it revolves with a velocity that makes one revolution for every 2 that the machine travels over the ground. The cutter was surmounted by a light sheet-iron drum, or rather frustum, of an inverted cone, about 3 feet in hight, which serves as the collector or gatherer of the machine; and this was attached to, and revolved along with, the cutter and its axle. The motion of the cutter and gatherer was derived from a pair of carriage-wheels fixed upon an axle, which carries a toothed bevel-wheel, and from this last by a pinion and horizontal shaft, and second pair of bevel-wheels, the last of which was fixed upon, and gave motion to, the cutter-shaft. The carriage-wheels, with their axle, bore all the framework and gearing of the machine, with a slight preponderance forward; and this preponderance was borne by a small roller, placed under the fore-part of the framework, near the center of the cutter, serving to preserve the uniform hight of the cutter from the ground—a pole projected backward from the body of the machine, to which two horses were yoked, one on each side, by a splinter bar, pushing the machine before them, and, as the pole projected a few feet behind the horses, it served as a rudder to the machine in the hands of the driver. The circular cutter here adopted is, perhaps, the most perfect method of performing the act of cutting the grain, which is done by it in a very successful manner—the machine being provided with apparatus for cutting higher or lower, as the crop may require.—The gathering process is less perfect—the cut grain is carried round by the motion of the drum to the left side, where, as soon as it is clear of the standing corn in front, it falls outward, forming a continuous swath at one side of the track over which the machine has passed.

(2224.) At a subsequent period, Mr. Smith effected various improvements on his reaping-machine; and in 1837 it was exhibited in operation at Ayr, before a committee of the Highland and Agricultural Society, where it performed to the satisfaction of all present, both in cutting and gathering; but, at the same time, it showed marks of unwieldiness, especially from its great length, which is about 20 feet, that still rendered its general application doubtful. The chief point of its improvement, at this trial, lay in the gathering-drum being now adapted to revolve separate from the cutter, with a velocity at its periphery equal to the progressive velocity of the machine; and in the drum also being armed with rakes, or wooden teeth inserted all over its circumference, which supported and carried the cut grain round to the proper point of discharge.

(2225.) The next machine of importance, in the order of time, is that of Rev. Patrick Bell, now minister of the parish of Carmylie, in the county of Forfar. It appeared in operation in 1827–8, and received the sanction of the Highland and Agricultural Society in 1829, by a premium of £50.† For several years thereafter this machine retained considerable repute, and a considerable number of them were made, and successfully applied in the counties of Fife and Angus, but after all this apparent success, it has also fallen into disuse, like its predecessor. Mr. Bell's machine acts upon the clipping principle, the cutter being a series of scissors, the upper blades of which are immovable, and of the form of isoceles triangles, whose hights are 10 inches, and bases about 4 inches, adapted to cut on both edges. The lower blades are of a similar form, each jointed upon a pin, in a position corresponding to the space between the upper blades, and their shank or handles are all jointed to a traversing bar, put in motion by a crank; there are ten pairs of such scissors, and by the above arrangement, the whole are made to cut simultaneously right or left. The motion of the cutter is communicated from the carriage-wheels, as in Smith's machine, there being two principal wheels for that purpose, and two minor wheels to bear up the cutters and fore part of the machine. The gathering process is accomplished by an endless web, which is placed above and behind the cutter, revolving either to right or left; it receives the grain as it falls from the cutter, and is regularly carried to one side, and dropped in a continuous swath, as before. To insure the falling of the cut grain upon the web, there is a light four-leaved vane placed in front of the machine, and is made to revolve by means of a band; the leaves of this vane press gently upon the yet uncut grain, gathering it toward the web, until it is severed below by the scissors, when the web carries it off. For several years this machine bid fair to become a favorite; the work was well performed wherever the corn stood upright, and that it would work among laid corn was not expected of it; yet it is now seldom seen in the field, and the only cause to which its failure can be attributed, is the complicated structure of the cutter. A cutter consisting of such a number of parts, each of which requires the most perfect adjustment to render it effective, being, besides, liable to unequal wear, renders it yet more liable to derangement; and, farther, as the derangement of a single blade of the cutter is sufficient to destroy the usefulness of the machine; and the rectification of the defective blade requiring a workman of superior talent, it must have become both troublesome and expensive to effect such repairs; and this added to the risks of delay in an important season, seem to have contributed to the gradual disuse of the machine.

(2226.) Soon after the introduction of Mr. Bell's reaping-machine, there appeared another competitor, Mr. Joseph Mann, Raby, near Wigton, Cumberland.‡ Mr. Mann's machine appears to have been constructed, after many years' labor, so early as 1826, but it was not exhibited in Scot-

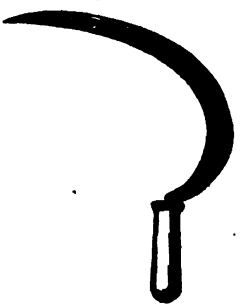
* Prize Essays of the Highland and Agricultural Society, vol. x. Preliminary Notice.
† Quarterly Journal of Agriculture, vol. i. ‡ Ibid., vol. iv.

land till 1832, at the Highland Society's Show in Kelso, where it was tried before a Committee with a success very similar to those that had gone before it. Though not affording entire satisfaction, it nevertheless possessed some points of considerable importance. In construction it was more compact than some of the previous machines; and, from the simplicity of its movements, would be less expensive. It was drawn by one horse, walking before the machine, and by the side of the standing corn, cutting a breadth of from 3½ to 4 feet, and would, therefore, cut nearly 10 acres in 10 hours. The cutter was on the revolving principle, but instead of being circular, it formed a polygon of 12 sides, each side of the polygon being a separate blade, easily removed and changed. The gatherer was the revolving cylindrical drum with rakes, afterward adopted by Mr. Smith, of Deanston, before alluded to; but in Mr. Mann's machine the drum revolves at a considerably higher velocity, making 26 revolutions in a minute, while the cutter makes about 200. In this machine, therefore, the velocity of the rake-teeth is 400 feet per minute, or nearly double that in Mr. Smith's improved form. This high velocity of the rake carries away the cut grain in a thinner layer upon the rakes, but it requires the application of a comb to strip the corn from the rakes, and thus secures its being always dropped at one point in the machine. The motion of the cutter and rake were obtained from one of the carriage-wheels as in the others; but here they were communicated by pitch-chains, and the front part of the machine was supported by a castor-wheel, to the stem of which the horse-shafts were attached, the castor-wheel running by the side of the standing corn. I am not aware of this machine having ever made farther progress; though I do consider that it possesses some advantages over any that have yet been tried, and, if fully matured, might have superseded its competitors.

(2227.) In viewing the subject of the reaping-machine, three things have to be specially considered. The expense of the machine, the expedition it may effect in reaping the crop, and the saving in expense that may be effected by it. The last described machine could certainly be procured at a price not exceeding £30. The same machine was, perhaps, not capable of reaping an acre per hour consecutively; its effect may, therefore, be restricted to 8 acres per day, being about 12½ days to every 100 acres. It will follow, therefore, that on a large farm two machines might be requisite, making an outlay of £60. To qualify this outlay, the expense of reaping (as ascertained, by Bell's machine,) has been estimated, including the expense of binding up the sheaves, at 3s. per acre; while the minimum expense of reaping by the hand is taken at 7s. per acre, and the maximum may run to 12s.,* but taking the mean at 9s., gives three times the expense of machine-reaping. For 100 acres, therefore, cut by hand, the expense would be £45, while that by the machine is only £15, giving a saving of the entire price of the machine in one year. But suppose the price of a machine could be saved even in two years, the advantages would be very great, under the supposition that an effective machine could be procured for £30. It is deserving of consideration, also, that although no reaping-machine is to be expected capable of cutting down the crops in every possible state, yet we may infer that, even on a farm of ordinary extent, such a breadth of crop may be found, in almost any season, capable of being cut by a machine, as would save half the expense of its purchase. To obtain an effective and durable reaping-machine is, therefore, yet an important object to the farming interest.†

(2228.) In the present times, it may be safely averred that the only means of reaping is by the *sickle* and the *scythe*. The first is a very simple, but, at the same time, so far as it goes, a very efficient instrument. It is employed in various states, not differing much in general form, though exhibiting marked differences in the detail; but these varieties are confined under two very distinct forms, the *toothed* and the *smooth-edged* sickles. Fig. 416 represents the *toothed* sickle, an instrument so well known that it requires little description here. The blade, in the common toothed sickle, is principally made of iron, but with an edging of steel; the teeth are formed by striking with a chisel and hammer, in the manner of file-cutting, the cutting being only on the lower side; but when the blade has been bent to the proper form, tempered, and ground on the smooth side, the serratures are brought prominently out on the edge of the blade; and as the striking of the teeth is performed in a position oblique to the edge of the blade, at an angle of about 70°, the serratures on the edge acquire what is called a *hook* toward the helve, thus causing the instrument to cut keenly in that direction when drawn through the standing corn. When the blade has been thus finished, a wooden helve of the simplest form is fitted upon the pointed tine formed at its root for that purpose. The toothed sickle is made with various degrees of curvature and of weight, but chiefly as represented in the figure, and it has been the subject of several patents, chiefly depending on the formation of the blade. One of these is only of two or three years' standing, and promises to be an important one. Messrs. Sorby & Son, of Sheffield, are the patentees; and the principle upon which their patent is based is a blade of rolled cast-steel swedged into a form that gives a sufficient degree of stiffness to the blade, without the increase of weight that accompanies the thick-backed or the other patent ribbed-back sickles. In the new patent, the advantage of a small quantity of the very best material—cast-steel—is combined with extreme lightness and a due degree of strength and stiffness, the latter arising from the swedged or moulded back.

Fig. 416.



THE TOOTHED SICKLE.

(2229.) The *smooth-edged* sickle, or *scythe-hook*, as sometimes called, differs from the former

† For practical remarks on the two most promising machines in use in the United States, see the letter from Mr. Bowling, of Virginia, in the present (March) Number of the Monthly Journal of Agriculture. *Ed. Farm. Lib.*]

* Quarterly Journal of Agriculture, vol. iv. (801).....25

in being broader in the blade, and longer withal, but in curvature it resembles the former; and its chief difference lies in being ground on both sides, to form a fine and thin sharp edge. Like the toothed sickle, the blade has undergone various improvements; and Mr. Sorby's cast-steel swedge blade is also extended to the smooth-edged sickle.

(2230.) In the formation of the sickle, the curvature of the blade is a point of more importance than to a careless observer may appear; and though the ordinary reaper is seldom qualified to judge in this matter, he may feel pleased to be informed that there is a certain curvature that will give to the muscles of his right arm the least possible cause for exertion, while there are other curves that, if given to the blade of the sickle, would cause him to expend a great amount of unnecessary exertion in the arm, and a consequent unnecessary fatigue would follow. Fig. 417 which represents the smooth-edged sickle, has a curvature approaching very near to that which, in this instrument, may be termed the *curve of least exertion*; and throughout that portion of the sickle that performs the cutting process, it possesses this peculiar property, from the following circumstance, that lines diverging from the center of the handle of the sickle at *a*, and intersecting the curve of the cutting-edge, all the diverging lines will form equal angles with the tangents to the curve at the points of intersection. This property gives to the cutting-edge a uniform tendency to cut at every point in its length, without any other exertion than a direct *pull* upon the helve; were the curvature less at any point, a pressure of the hand would be required to keep the edge to the work, and were the curvature greater at any point, or on the whole, the exertion to make the cut would be greater, as it would then become more direct, instead of the oblique drawing or *sawing* cut, which, in all cases, is the most effective, and productive of least resistance.

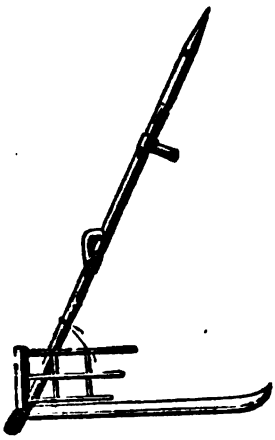
Fig. 417.

THE SMOOTH-EDGED SICKLE.

(2231.) A mode of using the smooth-edged sickle has of late years come into some repute, known in Scotland by the provincial term *dinging-in* (striking-in). In this process the sickle is not drawn through the straw, but is struck against it, somewhat in the manner of using a scythe; indeed, the practice originated in the attempt that was made some years ago to introduce the Hainault scythe in the harvest operations of this country, but without success. In the (dinging-in) practice, the left hand is employed, with its back toward the right, in slightly bending down the grain, and holding it to the blow of the sickle. A man practiced in this mode of working will do one-half more work than is usually done in the common way; but the stubble is left less regular, and, except by very expert hands, there is a want of tidiness in the process.

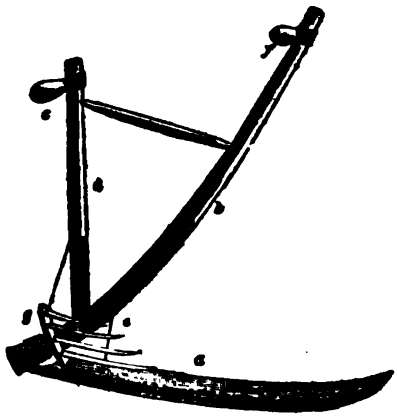
(2232.) The *scythe* is also extensively used as a reaping instrument, but more especially in England, and in some of the northern counties of Scotland, chiefly for the barley and oat crops, though in some localities, also, for wheat. The common hay-scythe is used for this purpose, in most cases, with the addition only of a very light rail or cradle, sometimes attached to the handle, and in other cases to the heel of the blade, as in the annexed cut, fig. 418, which is the common

Fig. 418.



THE COMMON REAPING-SCYTHE.

Fig. 419.



THE CRADLE-SCYTHE FOR REAPING.

scythe, fitted for reaping. In the scythe mounted in this manner, the use of the rail or cradle will be obvious, being the collecting of the swath into a compact body, and depositing the same in as regular a manner as possible, preparatory to the binding of it into a sheaf.

(2233.) For a considerable period, a scythe mounted in a different form has been in use for the purpose of reaping, and it is believed that its introduction can be traced to Banffshire or Aber-

doenshire, where the scythe is rather extensively used for reaping. About ten years ago this form of scythe came more prominently before the public,* and, for a time, gained considerable repute under the name of the *Cradle-scythe*. Of this form of mounting a reaping-scythe, there are many varieties; but they all agree in one point, that of having two short helves, the one branching out of the other, instead of the common long helve or snead. Fig. 419 is a view of the cradle-scythe in one of its most approved forms, wherein *a* is the scythe-blade, *b* the principal helve, to which the blade is attached in the usual way, the hook of the tine being sunk into the wood, and an iron ferule brought down over the tine, binding it firmly to the wood; but the blade is farther supported by the addition of the light stay *c*, termed by mowers the *grass-nail*. The minor helve *d* is tenoned into the former, and the two handles *e f* are adjusted by wedges in the usual way, to the hight and mode of working of the mower. The *cradle* or rake consists of a little wooden standard *g*, about 8 inches high, jointed to the heel of the blade, so as to fold a little up or down across the blade; into this are inserted three slender teeth, following the direction of the blade, and may be from 6 to 15 inches long; the head of the standard is supported by a slender rod of iron, which stretches about 18 inches up the handle, where it is secured by a small screw-nut, capable of being shifted up or down to alter the position of the standard and its teeth to suit the lay of the corn. The standard or rake-head was at one time recommended to be made in the segment of a circle,† for which there seems no good reason, either practical or philosophical; but the idea was seized upon, and the cradle-scythe mounted in that form was widely distributed; but instead of this supposed improvement tending to increase the favorable opinion of scythe-reaping, the practice seems rather on the decline; and there is good reason to believe that this malformation of the rake may have had no small share in producing a distaste for scythe-reaping as a practice; whereas, under proper management, and a judicious choice of implements, there can be no doubt of considerable advantages being attainable from scythe-reaping, as compared with the sickle.

(2234.) It is believed by very competent judges, that the figure here given of the cradle-scythe possesses all the advantages that are derivable from using this instrument; and, in addition to the details already given, I may add that the length of the blade is from 3 feet 4 inches to 3 feet 6 inches; the left or principal helve is about 4 feet, the other 3 feet, measuring direct from the heel in both cases; the distance between the helves, where the handles are applied, is 24 inches; and in setting the blade the following rule is to be observed: When the framed helves are laid flat on a level surface, the point of the blade should be from 18 to 20 inches above that surface, and measuring from a point on the left helve, 3 feet distant from the heel of the blade in a straight line, as at *b*, the extremity of the blade should be also 3 feet distant from the point *b*. Iron has, in many cases, been substituted for wood in the construction of the helves; but it does not, by any means, appear to be so well adapted to the purpose as the wooden helves; when constructed of iron, if they are made sufficiently light, there is too much elasticity in the fabric, which is fatiguing to the workman, by reason of the tremor produced at every stroke of the scythe.

(2235.) As essential appendages of the scythe, there must be kept in view the *scythe-stone*, with which it is kept in proper cutting order: a soft, fine-grained sandstone is the proper material from which it should be selected; and as for applying it, it were difficult in words to describe the proper mode of doing so, but the following may suffice to give the uninitiated some notion of the process. The scythe is placed on the left side of the mower, with the point of the blade resting on a small stone on the ground, the heel of the blade and helve being supported by the left hand; the scythe-stone, which is about 10 inches long, is grasped by one end in the right hand, and is thus applied, crossing the blade. The effect of the sharpening is produced by making sliding strokes with the stone along the blade on each side alternately, upward and downward; but the downward strokes only, or those *toward* the point of the blade, should be the effective ones, the returning stroke of the stone touching the blade but lightly. The object of this mode of treatment is based on the principle that the scythe cuts after the manner of a saw; though the teeth are not very prominent, still the fine serrature is there; and, to make it cut with the best effect, it must be *hooked* toward the point of the blade, or in the direction of its motion, when cutting; and the application of the stone, as above described, produces this direction of the minute teeth in the cutting-edge. The strokes of the stone cannot conveniently be carried over the whole length of the blade at one throw of the hand, hence the sharpening begins at the heel, and proceeds downward; but, from the position described, there still remain a few inches at the point untouched; and, to reach this part with the stone, the mower lifts up the blade, by seizing it about the middle with the left hand, and bringing it to a horizontal position—the helve still resting partly on the ground, and partly against his body, he is enabled to complete the process of sharpening. Throughout this operation, it is to be specially observed that, in applying the stone, it must always be held flat upon both sides of the blade; if this is not attended to, either the edge will not be improved, or it will be rounded off, and the consequence of this last effect will be that the scythe will speedily be unfit for cutting until it be re-ground.

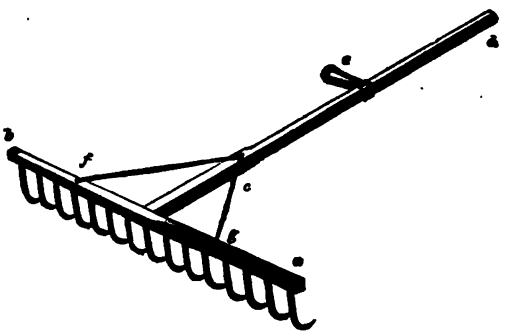
(2236.) The *strike* or *strickle*, which is also used in the sharpening of the scythe, principally for giving it a finer edge—though this is very frequently a mistaken notion—is formed of a piece of hard wood, about 15 inches long, one end of which is shaped into a handle; the body of it is sometimes 1¼ inches square, but in most cases it is about 2 inches broad, by ¾ inch thick. It is coated over with granulated emery, imbedded in a cement such as glue; and, to produce the best effects, the emery should be of a medium degree of fineness. The strickle being a light instrument, it is always attached to the helve of the scythe, and is, therefore, always at hand, ready to be applied in the event of any accidental injury to the edge of the scythe being sustained; while the stone, from its greater weight, can only be resorted to at the landings, where it lies in readiness.

(2237.) *The hand stubble-rake.*—The gleanings of the stubble is an object of considerable value, and, to secure it for the benefit of the farmer, different implements are employed.

* Quarterly Journal of Agriculture, vol. v. † Ibid., vol. vi.

The principal and the most effective of them is the horse-rake; but, in the absence of that machine, the hand-rake is found to serve a very good purpose. Fig. 490 is a representation of this rake, and it is of very simple construction, the form being precisely that of the hay-rake, but of enlarged dimensions. The head, *a b*, is 5 feet long, and should be made of good, tough ash, 2½ by 2 inches; the helve *c d* may be 6 feet in hight, of the same material, and furnished with a handle *e* that can be fixed in any desired position, by means of a ferule and wedge. The helve is tenoned into the head, and supported by the iron brace *f, c, g*. The teeth are of iron, 7 inches in length, and set at 4 inches apart, but formed in the lower part so that the bend rests on the ground, preventing the points of the teeth penetrating and mixing the earth with the gleanings. The best method of fixing the teeth is by a screw-nut, as in the horse-rake, as they are thereby easily removed in the case of being broken, without risk of injuring the head. It is also advisable to have the ends of the head hooped, to prevent splitting.—J. S.]

Fig. 490.



THE HAND STUBBLE-RAKE.

35. CARRYING IN AND STACKING WHEAT, BARLEY, OATS, BEANS, AND PEASE; AND THE CONSTRUCTION OF CARTS.

"Inwardly smiling, the proud farmer views
The rising pyramids that grace his yard,
And counts his large increase; his barns are stored,
And groaning staddles bend beneath their load."
SOMERVILLE.

(2238.) It is necessary that reaped corn remain for some time in stook in the field, before it will keep in large quantities in the stack or barn.—The length of time will, of course, depend entirely on the state of the weather; for if the air is dry, sharp, and windy, the corn will be ready in the shortest time—while in close, misty damp, it will require the longest time; but, on an average, for wheat 1 week, and for barley and oats 2 weeks, will suffice. In this respect, the superiority of the mown over reaped corn manifests itself—mown wheat being ready for the stack in 4 or 5 days, and barley and oats in 8 or 10—the chief cause of the difference being the loose and open state in which mowing leaves the straw in the sheaf.

(2239.) Mere dryness to the feel does not constitute all the qualities requisite for making new cut corn keep in the stack. The natural sap of the plant must not only be evaporated from its outside, but also from its interior; and the outside may feel quite dry, while the interior may be far from it; and the knowledge of the latter property constitutes the whole difficulty of judging whether or not corn will keep in the stack. There is one criterion by which whether or not a sheaf is fit to keep may be ascertained with almost certain success, which is, that if the sheaf feel quite dry, the straws be loose and easily yield to the fingers, and the entire sheaf feel light when lifted off the ground by the hand thrust through the middle of *the band*, the sheaf is ready; for if it present all these qualities at the band, where it is most compressed, the rest will be sure to be won. While win-

ning, it is as probable that the sap of the cereal grains is converted into woody fibre, as that of clover on being converted into hay (2139).

(2240.) The winning of corn is comparatively an easy matter, when the weather is dry; but, in windy and showery weather, the stooks are apt to be blown down and become wet, and incur the trouble of setting up again at the first moment of calm. When the air is calm, dull, damp and warm, every species of grain is apt to sprout in the stook before being ready for the stack. When much rain falls, accompanied with cold, the grain becomes sooner ready than the straw for the stack; and, to win the straw, the bands are not unfrequently obliged to be loosened, and the sheaf spread out to dry in the wind and sun; and in like manner the sheaf should be spread out, even in dry weather, when a large proportion of young grass is mixed among barley-straw. When barley is mown, it is quite practicable to get rid of much of the grass among it, by the gatherers shaking the grass out of the swathes by the corn end, before laying the corn into the bands. This extra process of shaking will, no doubt, lose some time, but it is probably better to lose a little time in the mowing than subject the corn to perhaps a week longer exposure in the field. It is scarcely practicable to shake out grass in reaping, as the hook would require to be laid aside while both the hands were engaged in shaking every handful; and to cut the stubble as high as the grass would be preposterous. An extra hand, therefore, would be required for this purpose among reapers on every 2 ridges. Corn wins in no way so quickly as in gaits, fig. 415.

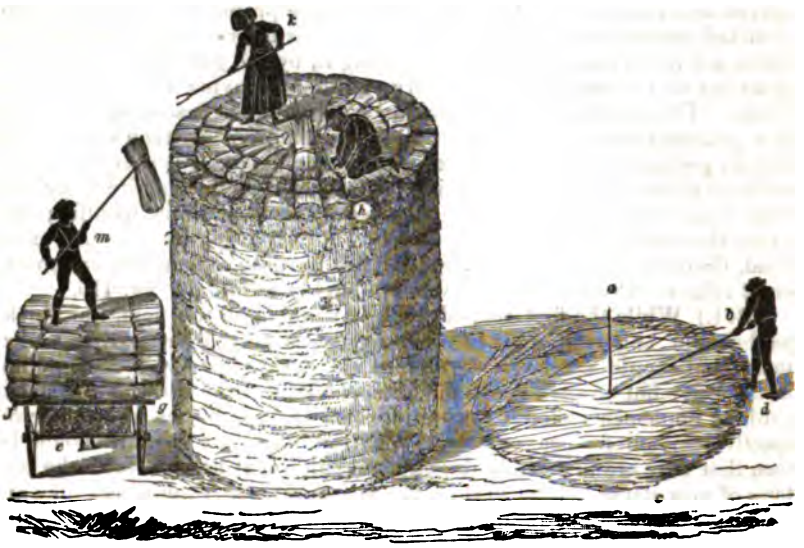
(2241.) While the first reaped corn is winning in the field, the stack-yard should be put in order to receive the new crop, by removing everything that should not be in it—such as old, decayed straw, weeds, implements, &c.; but no such use as the latter should ever be allowed of a stack-yard, as implements should be put into their proper places when their respective season for use expires. Where stathels are used, it should be seen that they are in repair; dry straw should be at hand to form the bottoms of new stacks, where stathels are not used; and, even where they are in partial use, straw is required for the stacks built on the ground, as stathels can only be placed round the utmost limits of a stack-yard, unless an inordinate space of ground is appropriated to it, with a cart-road between every 2 rows of stathels, as already commented on at (70). Straw-ropes should also be provided for covering the barley-stacks, in case of threatened rain.

(2242.) The description of a *stathel* or *staddle* is given in (70), and a perspective view in fig. 24, which is a framing of wood put together, to remain in a permanent form upon stone props, made up of 3 parts—a sole *b*, a pillar *c*, and bonnet *d*. It has been brought to my notice that a better form of stathel would be to have the frame in 2 pieces, to remove into a shed, and be protected from the weather, when not in use. Such a movable frame would answer the purpose as well as a permanent one; but, when removed, the props should require to be removed also, otherwise they will be driven over, and perhaps broken, or at all events disjointed, and their replacement would create a good deal of trouble when wanted; and this is a species of trouble, perhaps, more serious than the decay of the wood of a frame 1 year or 2 sooner than it would otherwise be. True, the props could be made of one piece of cast-iron, which they sometimes are; and, where stones are scarce, this material seems indispensable; but, where stones are plenty, they make cheaper props than cast-iron; and, although cast-iron ones would be easily removed, the soles on which they rest would still be liable to be broken, and the setting them again on a level would impose considerable trouble and expense. So that, on the

whole, such a stathel as is shown in fig. 24 will, in my opinion, answer well for ordinary farms. The framing is made heavy, the scantlings being 9 inches in the side—a size which the Scots fir easily attains, because it is to be permanent in its position, and to last a long time, remaining serviceable for a lease of 20 years; but, of course, where larch is abundant, smaller scantlings will be handier, equally strong, and last perhaps longer. Stathels require no straw to render them fit for building stacks upon.

(2243.) A *stool of straw for a stack* is made in this way: Stick a fork *a*, fig. 421, upright in the ground in the center of the intended site of the

Fig. 421.



THE FORMING OF A STOOL FOR A STACK; THE LOADING OF A CART WITH SHEAVES; AND THE BUILDING OF A STACK.

stack. Put a quantity of dry straw around the fork, and shake it up as you would do the litter of a horse, spreading it out to about the size and form the stack should occupy on the ground. Take a long fork *b*, with the radius of the stack marked upon its shaft—embrace the upright fork *a* between its prongs, and, holding its shaft at the specified distance of the radius, push in or pull out the straw with your feet, as seen from *c* to *d*, into the shape of the circle described by yourself in walking round the circumference of the stool.

(2244.) Having made these preparations, on the supposition that the corn is ready to be carried in and stacked, the first thing is to provide an efficient person to fork the corn in the field to the carts—a man being the best for the work, as he is able not only to wield the sheaves with ease, but possesses dexterity to place the sheaves in the position most convenient for the plowman to build them on the cart; for, throwing sheaves in any manner upon the cart makes the forking no easier for the forker, while it gives the plowman much additional trouble to turn the sheaves upon the load, where his footing is not very secure. A loss of 2 or 3 minutes incurred in this way in loading each cart makes a considerable loss upon the day's work. The steward should build the stacks, unless he is specially engaged with the reapers in the field, when another man should be hired

to stack; but on a large farm more than 1 stacker may frequently be required at a time. When more than 1 stacker is employed, each should have the same head of carts leading to him, even when both heads are leading from the same field, that the corn may be regularly supplied to him.

(2245.) The *cart* is the vehicle employed in carrying in corn. The common cart, mounted with a framing called *tops*, is used in some parts of the country; while, in others, the *corn*-cart, different forms of which are represented and described below by Mr. Slight, is employed, the body of which is put on the axle and wheels of the common cart, and provided with ropes to hold on the load. Of the two sorts of carts for this purpose, I prefer the corn-cart, as it carries the load lower to the line of draught; and it is provided with a plank, called the *lead-tree*, for the plowman to stand upon when forking off the lower part of the load.

(2246.) The horses are usually yoked *double* in leading time, as there is only one man to each pair of horses; and there may be inequalities in the fields and roads which require the force of 2 horses to surmount. As I have had occasion to mention the price of the harness required for the plow, I may here enumerate those for the cart. In addition to the collar and bridle, there are—

Saddle and girth	22 lbs.	weight,	worth	£1	2 0
Breeching	10	..	..	1	0 0
Two back-bands and girth	8	..	..	0	16 0
Cart-chains	14	..	at 7d. per lb.	0	8 2
Stretcher	..		..	0	3 0
Total	54 lbs.			£3	9 2

In Forfarshire the trace-horse is harnessed in a different manner. A broad strap is hooked to the back of the upper part of the collar, and terminates at the other end in a crupper, and a haunch-strap passes down in each side to support the trace-chain. This plan supports the stretcher well, and prevents it falling so low as the hocks of the horse in the turnings, but it confines the action of the horse by buckling the shoulder and tail together, and when the bearing-rein is passed over the harness, the horse's head is very much confined. Harness leather is best, in the long run, though dearest at first. Double cart-ropes measure 24 yards, single 12 yards, and cost 4½d. per lb. Hemp and Manilla reins cost 5½d. per lb. There should always be double reins used with the cart, whether the horses be yoked single or double. The double reins are connected at the end with a tie and loop to hang on any hook, or slip below any part of the harness. With the collar and bridle, the shaft-horse carries 58½ lbs. of harness, and the trace-horse 34½ lbs.

(2247.) In carrying the crop off the ground, the object is to do as little injury as possible to the land with the cart-wheels, especially to young grass; and for this reason, as well as forming an excellent guide, the horses should walk in the open furrow between the ridges in every alternate furrow, while the wheels pass along the furrow-brow of the ridge on each side. When corn is cut with band-won reapers, the stooks of 2 ridges being placed on 1, the cart clears the produce of 2 ridges, and the same may be the case with mown corn, provided the bandsters are instructed to set the stooks in the same manner upon the ridges while working across them. In threaving, the stooks being set on every ridge, the former is obliged to go from one ridge to another to clear 2 ridges, which occasions much loss of time.

(2248.) A corn-cart is loaded with sheaves in this way: The body *e*, fig. 421, is first filled with the sheaves lying with their butt-ends toward the shaft-horse's rump at one end, and the back end of the cart at the other. When the corn is on a level with the frame or *shilments* of the cart, the sheaves are then laid across the body of the cart in a row along both sides of the frame, with the butt-ends projecting as far beyond the frame as the band, as at *f* and *g*; the sheaf on each *corner of the frame* being held in its place by being transfixed upon a spike attached to it. Another row of sheaves is placed above the first, and the corner ones kept in their places by a wisp of corn, held fast by the band being placed *under* the adjoining sheaf. Sheaves are then placed along the cart with their butt-ends to both its ends, in order to hold in the first laid sheaves, and to fill up the hollow in the middle of the load. Thus row after row is placed, and the middle of the load filled up till as much is built on as the horses can conveniently draw, 12 large stooks being a good load. It should be ascertained that the load is neither back-laden nor too heavy upon the horse's back; and, indeed, if the cart has been evenly laden according to its form, there is no risk of either inconvenience being felt by the shaft-horse. A load thus built will have the butt ends of all the sheaves on the outside, and the corn-ends in the inside.

(2249.) The *ropes* are then thrown over the load to keep it from jolting off the cart upon the road, and in necessarily crossing gaw-cuts in the fields. There is usually a ring in the back-bar of the cart to which the rope is fastened by the middle, whence it is wound round each back-stay; but fastening the rope round the back-stays will answer without a ring. The ropes are then thrown across the load diagonally to the opposite angles in the front of the cart, and one end is made fast to each shaft, with as much force as the forker can exert on the ground, with the assistance of the plowman on the top of the load. The crossing of the ropes prevents the load splitting asunder over the sides of the cart, while it is jolted along the road. Some plowmen profess to show their dexterity in building loads of corn, and of bringing them to the stack-yard without the assistance of ropes; but there is no use of running the risk of losing time by breaking the load and strewing the road with sheaves. Such a fate attended the first load I tried to build even with the assistance of ropes. When the corn is mown, a woman is usually employed to rake the ground on which the stooks stood, because they were set upon the ground at the time of mowing before it was raked.

(2250.) When corn is fit for stacking, the carrying is continued from break of day to twilight, provided there be no heavy dew at morning or night. From a little after sunrise to a little after sunset, the corn may be taken in with great safety. It is customary, in some parts of the country, to keep the horses in the yoke when employed at leading, and feed them with corn from nose-bags, while the carter is taking his dinner, and to give them green food, such as tares, while the cart is unloading at the stack. In other parts the horses are taken out of the yoke, watered, and put into the stable, where they receive their corn while the men are at dinner. This is the best way for the horses, though it usually puts off one hour of the best part of the day before the horses again take the road, whereas half an hour in the other case is quite sufficient for the men to dine, and the horses to eat their feed of corn. Some horses are apt to take fright, owing, no doubt, to the mode in which they had been broke in, when the bridles are temporarily slipped off their head for the purpose of taking the bit out of their mouth, to allow them to eat the tares with freedom; and, to avoid such an accident with a horse known to be easily

frightened, its bit should be made to fasten with a small strap and buckle to the near side of the bridle.

(2251.) A load of tares is brought to the steading fresh in the morning for the horses. They are not fit for the use of horses until the pods are pretty well filled with grain, prior to which state they are apt to purge and weaken them, when subjected to much work in the cart, as in the time of carrying in corn. For cows it matters not how succulent tares may be, as they yield much milk on them; and, indeed, no other green food is so productive of milk.

(2252.) In setting a loaded cart to the stool or stathel of a stack, it should be studied to let the plowman have the advantage of any wind going in forking the sheaves from the cart. The stack should be built in this way: Set up a couple of sheaves against each other in the center of the stathel, and another couple against them in the other direction. Pile others against these in rows around the center, with a slope downward toward the circumference of the stathel, each row being placed half the length of the sheaf beyond the inner one, till the circumference is completed, when it should be examined, and where any sheaf presses too hard upon another, it should be relieved, and where there is slackness, another sheaf should be introduced. Keeping the circumference of the stack on the left hand, the stacker lays the sheaves upon the outside row round the stack, putting each sheaf with his hands as close to the last set one as he can get it, and pressing each sheaf with both his knees, as represented at *h*, fig. 421. When the outside row is thus laid, an inside one is made, with the butt end of the sheaves resting on the bands of the outside row, thereby securing the outside sheaves in their places, and at the same time filling up the body of the stack firmly with sheaves, as seen at *i*. A few more sheaves may be required as an inmost row still, to fill up and make the heart of the stack its highest part. It is of immense benefit to a stack to have its center well filled with sheaves, as it is the heart-sheaves which retain the outside ones in their places with an inclination downward from the center to the circumference; and this position of the outside sheaves is necessary to prevent the rain finding a passage along the straw into the very heart of the stack, where, of course, it would find its way easily, were the sheaves to lie with an inclination downward to the center of the stack, and where it would soon spoil the corn. The sheaves are then said to take in *pen-wet*. The number of rows required to fill the body of a stack depends on the length of the straw and the diameter of the stack. In crops of ordinary length of straw, such as from 4½ to 5 feet, a stack of 15 feet diameter is well adapted; and 1 inside row, along the bands of the outside one, with a few sheaves laid across one another in the center, will make the stack completely hearted. Where much wheat is raised, and which often reaches from 5 to 6 feet in length, the stack should be 18 feet in diameter, to give room for hearting. In a stack of 15 feet, the breadth is rather too much for the plowman to fork heavy sheaves across to the stacker, when the stack attains a certain hight, and when the load in the cart becomes low; and the stacker should always receive the sheaves within his reach, as he cannot rise from his knees to take them without much loss of time, and risk of making bad work. To expedite the building, a field-worker *k* should stand on the stack, to pitch the sheaves with a short fork to the stacker in the position they are wanted by him, to save him the trouble of turning them, as the sheaf *l* is shown in the cut. By a little management, the field-worker may receive every sheaf as the plowman pitches it from his fork upon her fork, and prevent it falling upon the stack until she throws it in its proper position beside the right hand of

the stacker; and in doing this she should not give him more sheaves than 1 by 1 as he builds them; nor should she receive them faster from the plowman than the stacker can build them, for no time is gained, but lost, in piling more sheaves upon the stack than the stacker can dispose of. The proper relative positions of the plowman *m* and the field-worker *l*, for thus giving and receiving the sheaves, are endeavored to be represented by those figures in the cut.

(2253.) As every cart is unloaded, the stacker descends to the ground, by means of a ladder, and trims the stack, by pushing in with a fork the end of any sheaf that projects farther than the rest, and by pulling out any that may have been placed too far in. It seems to be considered necessary to make the stack swell out as it proceeds in hight, if we may judge from common practice; but it is *not* necessary to swell it out in the building, in order to throw off the drops of rain from the eaves—for the spreading of the eaves by the stack itself, in settling down after it has been built for a few days, is quite sufficient to throw off the drops. The leg of the stack may, therefore, be carried up nearly perpendicular.

(2254.) As the stack rises in hight with cart-load after cart-load, the trimming cannot conveniently be done with a fork; a thin, flat board, about 20 inches in length and 10 inches broad, nailed firmly to a long shaft, is an appropriate instrument for beating in the projecting ends of the sheaves, and giving the body of the stack a uniform roundness. A stack of 15 feet in diameter should ultimately stand 12 feet high in the leg; and an allowance of 1 foot, or 1½ feet, for subsidence, after the top is finished, according to the firmness of its building, is generally made. The hight is measured with the ladder, and, allowing 2 feet for the hight of the stathel, a 15-feet ladder will just give the required measure of the hight of the leg before the top is set on. The eaves of the stack are formed according to the mode in which it is to be thatched. If the ropes are to be placed lozenge-shaped, the row of sheaves which forms the eaves is placed a little within the topmost outside row; and, after the top is fully finished, its slope will be the same as that of a roof—namely, 1 foot less of perpendicular hight than half the diameter. In finishing the top, every successive row of sheaves is taken as much farther in as to give this requisite slope; and the beveled bottoms of sheaves, as they stand in the stook, answer this purpose well—the hearting being particularly attended to in every row, till the space in the center of the stack is limited to an area upon which 4 sheaves can stand with their tops uniting, and their butt-ends spreading out to give a conical form to the top; and these sheaves are kept firm in their place against gusts of wind with a straw-rope wound round them and fastened to the sheaves below. If the thatching is made with heavy ropes, running from the top of the stack to its eaves, the eaves-row of sheaves is made to project 2 or 3 inches beyond the upper row of the body of the stack, and the slope of the top is formed from the point of projection of the eaves, and the top finished as in the other mode. The field-worker remains on the top as long as she has footing to hand the sheaves to the stacker.—Thus, as one stack is finished, another is founded on the adjoining stathel, and, as one is finished on a stool of straw, another stool should be ready to have another founded upon it.

(2255.) There is seldom leisure to thatch stacks as long as there is corn to carry in, and the finer the weather the less leisure will be found. A damp day, however, which prevents leading, answers very well for thatching, as the straw is not the worse of being a little damp; but in heavy rain it would be improper to thatch and cover up so many wet ends of sheaves as the top of a stack contains. But, before thatching can be carried on,

preparations should be made for it some time before—that is, straw should be drawn in bundles, and ropes twisted ready to be used; and a rainy day in harvest cannot be better appropriated than to such purposes. The straw is drawn in handsful out of one another, till the individual straws become parallel, when the handsful are carefully laid together till as much as a thick bundle is drawn, and the bundle is then tied in the middle with a piece of straw-rope, which is the quickest mode, or with a thumb-rope.

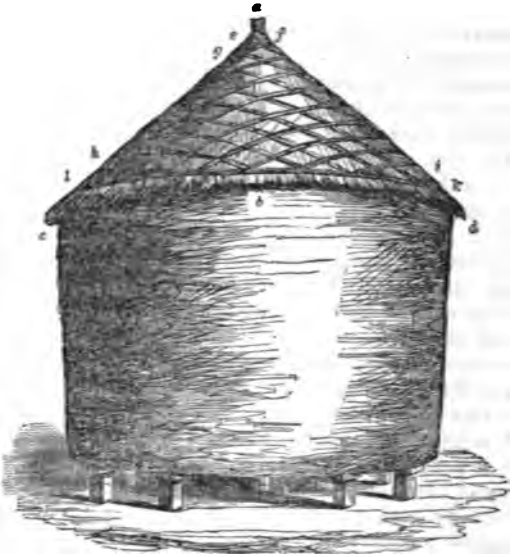
(2256.) Straw is twisted into rope with different instruments and in different styles. The simplest instrument is the old-fashioned *throw-crook*. It is used in this way: The left hand holds by the ring at the end of the shank, and round the point of the head is received a wisp of straw from the person who is to let it out to be spun. The right hand holds the middle of the shank loosely, and causes the head to revolve round an axis, formed by the imaginary line between the head and ring, and the twister walks backward while operating with the instrument. The person who lets out the straw sits still on a stool, or on bundles of straw, and, using the left hand nearly closed, restrains the straw in it till sufficiently twisted, and then lets it out gradually, while the right hand supplies the straw in equal and sufficient quantities to make the rope equal throughout, the twister taking away the rope to the requisite length as fast as the spinner lets it out. The spinner then winds the rope firmly on his left hand in an ovoidal ball, the twister advancing toward him, as fast as the spinner coils the rope, with a hold of the end which secures the ball firm. In the Borders the spinner lets out the straw with both hands, while stooping with his head down and his back turned to the twister; but the rope made in this manner is always thick and rough, compared to the other mode.—A woman is usually employed as the twister, and a man as the spinner. It is great ease to the left hand of the twister to have the crook fastened round her middle with a piece of stout straw-rope. The best sort of straw for rope is that of the common or Angus oat, being soft and pliable, and it makes a firm, smooth, small rope. An ordinary length of a straw-rope may be taken at 30 feet. Counting every interruption, a straw-rope of this length may take 5 minutes in the making—that is, 120 ropes in 10 hours: a man's wages 20d., and a woman's 10d., making together 2s. 6d., will make the cost of twisting a single rope just 1 farthing. Straw-ropes are twisted in quite a different way, with a machine similar to the one used by rope-makers to twist their cords. In using it the twister sits still, while the spinners carry the straw under their arm, and move backward as they let out the straw. The spinners then wind the rope upon the left hand, and advance, during the winding, toward the machine, where they are ready to begin to spin again. Usually 3 spinners let out to 1 twister, and as they can spin as fast with this machine as with the crook, the cost of making each rope will be less than that given above; but an inconvenience attends the use of this twister—when one of the spinners breaks his rope, he is thrown out of work till the others begin a new rope; and all the spinners must let out with the same velocity, otherwise one will make a longer or a harder-twisted rope than the other.

(2258.) It is the duty of field-workers to fetch bundles of straw and straw-ropes to the thatchers as they are wanted.

(2259.) Having the materials ready—drawn straw and straw-ropes—the covering or thatching of a stack is done in this manner: On the thatcher ascending to the top of the stack by means of a ladder, which is immediately taken away, a bundle or two of straw is forked up to him by his assistant, a field-worker, and which he keeps beside him behind a graip, as

noticed in covering the hay-stack (2134). The straw is first laid upon the eaves, beyond which it projects a few inches, and then in an overlapping manner upward to the top. Where a butt-end of a sheaf projects, it should be beaten in, and, where a hollow occurs, it should be filled up with a little additional straw. In this manner the straw is evenly laid all round the top of the stack to the spot where the thatcher began. Suppose he has laid the covering on the top of the stack, fig. 422, all round to the line from *a* to *b*, before closing up which he makes the top *a*, consisting of a small bundle of well-drawn long straw, tied firmly at one end with a piece of cord; the tied end is cut square with a knife, as shown at *a*, and the loose end is spread upon the covering and forms the finishing to it. To secure the top in its place, a straw-rope is thrown down by the thatcher from *a* to *d*, the end of which his assistant on the ground fastens to the side of the stack.—After passing the other end of the same rope round the top, he throws it down in the same direction, where it is also fastened to the stack. In like manner, he throws down both the ends of a rope from *a* to *c*, where they are also fastened by the assistant. These 2 ropes are seen at *e* and *f*. Having thus secured the *top*, the thatcher closes in the covering from *a* to *b*, when the ladder is placed to receive him. Taking the ladder to *c*, he inclines its top over the covering of the stack, and secures its lower end from slipping outward by a graip thrust against it into the ground. He then mounts and stands upon the ladder at the requisite hight above the eaves at *c*, and there receives a number of ropes from his assistant, which he keeps beside him, between the ladder and the stack. Holding on by the end of a coil of rope, he throws the coil from where he stands at *c* down in the direction of *d*, to his assistant, who, taking it in hand, allows the thatcher to coil it up again upon his hand, without ruffling the covering of the stack, till of sufficient length to be fastened to the side of the stack. The thatcher then throws the other newly coiled end in the same direction of *d*, where, on his assistant taking hold of it, the thatcher retains the rope in his hands by the double, and places it in its position at *g*, a little way below *e*, and keeps it in its place till the assistant pulls it tightly down and makes it fast to the stack like the other end. Thus the thatcher puts on every rope below *g*, till the last one on that side has reached *h*. He then takes the ladder to *d*, where he puts on every rope below *f*, till they reach the last one, *i*. Ropes thus placed from opposite sides of a stack cross each other in the diamond or lozenge shape represented in the figure. It will be seen that a windy day will not an-

Fig. 422.



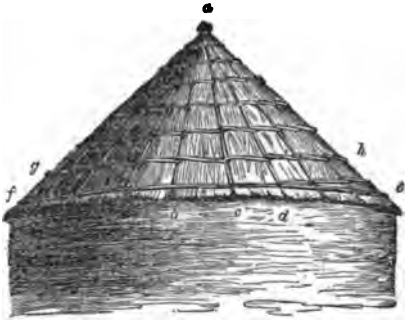
THE LOZENGE MODE OF ROPING THE COVERING OF A STACK.

swer for laying on the covering of stacks. To give the thatch-straw a smoothness, it should be stroked down with a long, supple rod of willow; and to give the ropes a firm hold, they should receive a tap here and there with the fork, while the assistant is pulling the last end tight. The thatcher is obliged to throw down the rope at first *coiled*, and to coil up again the second end before it is thrown down, because the loose ends of straw-ropes would not descend within reach of the assistant. The ends of the ropes are fastened to the stack by pulling a handful of straw from a sheaf a little out of the stack, and winding the rope round it; and the knot thus formed is pushed between the rope and stack, and keeps the rope tight.—On such a stack, which is 15 feet diameter at the base, 17 feet diameter at the eaves, 12 feet high in the leg, and 6½ feet high in the top, 10 ropes on each side are quite sufficient to rope it.

(2260.) It is seldom that the covering of a stack is finished when the straw and ropes are first put on—the stack being placed beyond danger, others are covered to the same state, and the finishing is left till more leisure is found; and, indeed, all the stacks to be early threshed seldom receive the finishing work at all. Many farmers only finish the outside rows of stacks. However, as I am speaking of the subject just now, I shall describe the finishing process at once. An eaves-rope, *k l*, fig. 422, is spun long and strong enough to go round the stack. Wherever 2 ropes from opposite directions cross at the eaves-rope, they are passed round it, and, being cut short with a knife, are fastened to the stack, immediately below the projecting part of the thatch over the eaves. Thus the 2 ends of all the 20 ropes are fastened to the stack, and the thatch is cut with a knife round the eaves, in the form shown from *d* by *b* to *c*.

(2261.) Another mode of roping the covering of a stack is shown in fig. 423, where the covering being put as described above, ropes are put over the crown of the stack all round, from *a* to *b*, *a* to *c*, *a* to *d*, &c.—These ropes, at their crossing over the top, are fastened together by a rope, which is tied above them, and cut off in the form of a rosette, as at *a*. The ropes which cross these are either put on spirally from the top *a*, till they terminate at *d*, or put on separately in bands, parallel to the eaves-rope *e f*. In either case they are twisted round each crown-rope, from the top to the eaves, as *h* is seen twisted round, *a d*, *a c*, and *a b*, by *g*, till it reaches the point *h* again. The crown-ropes, such as *a b*, *a c*, and *a d*, are made to pass round the eaves-rope *e f*, and fastened to the stack under the projecting covering; and the covering is cut short round the eaves, from *e* to *f*, in the manner described above. This mode of roping, though requiring fully more ropes than the last, perfectly secures the thatch against the strongest winds; though the crown-ropes may be fewer in number than shown in the figure.

Fig. 423.

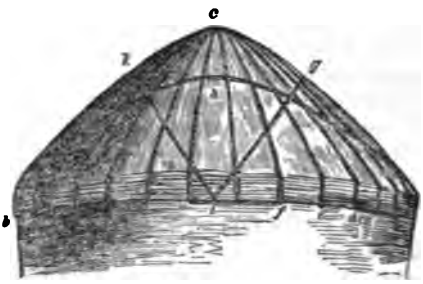


THE NET WORK MODE OF COVERING AND ROPING A STACK.

(2262.) There is still another mode of roping the covering of a stack, and it is applicable to the heads of all stacks whose eaves are formed of a row of sheaves projecting beyond the body of the stack. It is shown in fig. 424, and is in common use in Berwickshire. The first thing done is

to put a strong eaves-rope round the stack, below the projecting row of sheaves from *a* to *b*. The straw is then put on much the same way as before described, but rather thicker, and it projects farther beyond the eaves. The tops of the finishing sheaves of the stack are pressed down, and a rather large, hard bundle of short straw is placed upon them, to serve as a cushion for the ropes to rest upon, and which is put on after most of the covering has been laid on. The thatcher then perches himself upon the top of the hard bundle, where he receives the ropes as they are wanted, and, on being thrown to him, he catches them readily on the point of a long fork. Some dexterity is required to throw a coil of straw-rope to the top of a stack. The best position to do it is to stand as far from the stack as to see the thatcher fully in the face, and clear of the head of the stack; then, to take the coil by the small end, pitch it upward with a full swing of the arm toward the thatcher's feet, and he will catch it firmly on the prongs of the fork; if aimed to a higher level, the fork will be almost certain of missing it—the critical position of the thatcher not allowing him to turn his body, but only to move his arms. Uncoiling the half of a rope, the thatcher throws it past the eaves to his assistant, who fastens that end, and while this is doing he throws the other half of the coil down in the opposite direction, across the top of the stack, to another assistant, who fastens it to the stack at the opposite side: 1 assistant may suffice, by tying first one end of the rope, and then the other; but, with 2 assistants, this mode of roping is conducted with great celerity. Thus, rope after rope is thrown, to the number of 30, before the top of stack is sufficiently roped, as seen in the figure, from *c* to *d*, *e*, *f*, &c. The ropes, where they cross at the top, are tied together with a piece of straw-rope, to prevent their slipping off. The difficult part of this mode of roping is in finishing the eaves—which, if well done, looks remarkably neat, but, if otherwise, is apt to have a slovenly appearance. In finishing, the ends of the ropes are loosened from the stack, and passed between the eaves-rope and stack, and, on being brought upward, are passed behind the ropes themselves, about 8 or 9 inches above the eaves-rope. The end of the first rope, suppose *c d* thus fastened, with the part of the covering which projects beyond the eaves, are brought along the face of the eaves, and the second rope *c e* is placed over them before it is passed below the eaves-rope and turned upward, and passed behind itself. The end of the first rope, that of the second, and the projecting covering, are then all brought along the face of the eaves, and the third rope *c f* is placed over them, and treated like the 2 preceding, and thus all the way round the stack with both ends of the 30 ropes. The last finish is made by bringing the ends of the 2 or 3 last ropes along the face of the eaves, behind the 2 or 3 first ropes. It will be observed that, while the end of one rope fails to go beyond its length, the end of another rope is gained, so that the band of ropes along the face of the eaves remains about the same breadth round the stack. The ropes between the eaves and top are held down by 4 or 8 ropes, *a h b*, *g i*, *k i*, which are so

Fig. 434.



THE BORDER METHOD OF COVERING AND ROPING A CORN-STACK.

thrown across as to quarter the top of the stack, and their ends are fastened to the eaves-rope.

(2264.) There are still other modes of thatching stacks, such as sticking in handsful of straw into the butt-end of the sheaves, and keeping them down with stobs of willow, or with tarred twine, both in imitation of the thatching of cottages; and they are modes in which the use of straw-ropes are dispensed with altogether. Whichever may be the plan adopted, the chief object should be to secure the corn in the stack in a dry state, with the least trouble and expense. Of all the modes in practice, I see none more efficient and better-looking than the lozenge-shaped roping of fig. 421.

(2264.) Where rough grass is found on a farm, such as on a bog which is partially dry in summer, I would suggest its being mown and sheafed, for covering stacks. A day or two spent in mowing such grass, after the harvest is over, are well spent, even at the rate of wages and food of ordinary harvest-work. Not only does this stuff save the drawing of good straw where it is scarce, but of itself forms good covering for stacks which are soon to be threshed; and, by the time it has served the purpose of thatch, it will be dry enough to litter courts, and thereby add to the manure-heap. Reeds might be used in the same way, where they do not find a profitable market as thatch for cottages.

(2265.) These are the usual modes of stacking and covering stacks of wheat, barley and oats, in good weather; but in wet weather many expedients in stacking are tried to preserve the corn from heating, and it is necessary you should be made acquainted with them to put them in practice when required. The most common expedient is to erect a pyramid of 3 small trees or weedings of larch or Scots fir, tied together at the top, and fastened together by the sides with thin fillets of wood. Around this pyramid is the stack built, and its use is to form a hollow space in the center of the stack, into which the air may have access. These structures are commonly called *bosses*. When placed on a stathel, the air enters them directly from below, but, when on the ground, it is requisite to form an opening from the outside of the stack to the boss, by means of a low tressle; and if a tressle is placed on each side of a stack, and the position of both chosen with regard to the direction from which the wind most prevails, a complete circulation of air may be maintained through the stack. The greatest inconvenience felt in the use of this form of boss is that, on the stack subsiding, its sharp point is apt to pass to one side of the center of the top, and thereby to give a high shoulder to the stack; and it is well known that rain is almost certain of entering a stack by such a shoulder.

(2265.) In wet weather corn is built in small stacks even in the stack-yard; and should the weather prove settled wet, a dry moment should be seized to put 2 or 3 stooks into what are called *hand-huts* in the field, that is, small stacks built by hand, by a person standing on the ground. Sometimes corn is built on a head-ridge of the field, instead of being carried to the stack-yard, as the same strength of men and horses will stack more corn in this way in a single fine day, than carry it to the stack-yard; and the stacks derive more benefit from the air in the field than in the yard. These stacks are also thatched in the field, and carried to the threshing-machine some time during the winter. It is not an uncommon practice of some farmers to build a portion of their crop in the field every year; but the practice is not commendable, for, besides the trouble and dirt created in carrying straw for thatch to the field, as much confusion and dirt are created in carrying the corn to the steading in winter, when some of it cannot fail to be shaken out of the sheaves, and when the stacks

wanted cannot, perhaps, be brought in for a track of bad weather or through deep snow. A scheme may be justifiable under peculiar circumstances, which would be wrong in ordinary practice; and this is one of them.

(2266.) Of the 3 species of cereal grains, barley is most liable to heat in the stack, partly owing to the soft and moist quality of its straw, and partly because clover is always mixed with it; and, on these accounts, it is advisable, in most seasons, to make barley-stacks smaller than others, both in diameter and hight, and always to support them with prismatic bosses. Much care should be bestowed, not only by the use of these expedients, but on building barley-stacks safely with proper hearting, to prevent heating; for the least touch of heat spoils it for malting purposes, and malting barley always carries the highest price in the market. Besides injuring the grain, heating compresses barley-straw very firmly together, and, in fact, soon rots it. When a single stack only is seen to heat, it may be instantly carried into the barn and threshed, the air attending which will cool both grain and straw; but when a number show symptoms of leaning on one side, about 24 hours after being built, or exhibit a depression in the top, a little above the eaves, you may suspect heating not only to have commenced, but to have proceeded to a serious degree. An incipient symptom of heating is when moisture is observed on any part of the top of a stack early in the morning, delicately indicated by cobwebs, before the sun has evaporated it; and, when heated air is felt, or steam seen to rise from the top of a stack, the symptom is unequivocal. Heated barley lubricates the parts of the threshing-machine with a gummy matter. Oats are less apt to heat than barley, though their heat is stronger. If there is the least sap remaining in the joints of the straw, oats will be sure to heat in the stalk. Heating gives to oat straw and grain a reddish tinge, and renders the straw quite unfit for fodder, and the grain bitter and unpalatable, both to horses, in the shape of corn, and the people in that of meal. Wheat seldom heats, but, when it does, the heat is most violent. I never saw stacks of wheat heated but once, when it was foolishly led into the stack-yard the day after it was reaped. Partial heating will be induced in stacks by leaning over after being finished in building, when the compressed part may be expected to heat; and to avoid the tendency of a stack leaning to one side or another, a safe practice is to set props loosely round a stack, to guide it in its subsidence, especially if it has been rapidly built; but it should be borne in mind that if one prop is pushed harder in than the others, it will cause the stack to swerve from it. Some stacks begin to sway the moment the top is put on, and such should be supported with props to keep them right.

(2267.) In filling a stack-yard, respect should be had to the convenience of taking in the stacks to be threshed as they are wanted. As barley is the sort of grain first disposed of in the market, the barley-stacks should be built nearest the barn, except those intended for seed. Wheat, except in very fine seasons, is seldom firm enough to be presented to market till the spring, and on that account may be built on the outside of the stack-yard, and wheat-stacks grace a stack-yard well. Oats are wanted at all times, for horses and fodder, and should, therefore, be always at hand, as the stack-yard becomes cleared. Consideration in these particulars saves a great deal of trouble and confusion in bringing in stacks to be threshed.

(2268.) With regard to the carrying of beans and pease, they are usually the last of being brought into the stack-yard, and particularly beans. The bundles of pease are turned in the field till they are won, when they are rolled up in smaller bundles, and tied by a wisp of their own straw.

Pease-straw is very apt to compress in the stack, and, of course, to heat, and should therefore be built with bosses, either in round stacks or oblong ones, like a hay-stack. The largest stack of corn I ever saw was one of pease, which was 150 yards in length; but there was an opening in it, in which any person could have walked upright through the entire length of the stack. When pease become very dry in the field before they are led, the pods are apt to open and spill the corn, particularly in sunny weather; and to avoid this loss, the crop is usually brought quickly into the stack-yard, and built in ventilated stacks. Beans are a long time of winning in the field in calm weather. As it is desirable to have the land they grow on plowed up for wheat, they are not unfrequently carried to a lea field and stooked upon it, till ready to be stacked. Being hard and open in the straw, they keep pretty well in small stacks, though not quite won, and the risk of keeping is worth running in dry weather after much rain, when the pods are very apt o burst and spill the corn on the ground. In building pease and beans, the sheaves are not laid with nicety, nor do the stacks receive much trimming, the pease none at all, the beans with the back of a shovel. Thatching pease and bean stacks is conducted in the same manner as described above; but less pains are bestowed in finishing them off. As, however, a good deal of corn is exposed on the outside of those stacks, the thatching is not unfrequently brought down their legs, and kept on by ropes.

(2269.) In connection with this latter subject, I may mention that when corn is mown in a slovenly manner, a good deal of heads of grain may be observed exposed to the air on the outside of the stacks; and to save these, the stacks are shaved down with the blade of a scythe, fastened lengthwise on a shaft, upon the barn-sheet laid upon the ground to receive the shaved-off corn. This process not only saves the grain, but gives a smoothness to the appearance of the stack, and prevents the mixing of sprouted grain among good samples from the body of the stack, and which mixture would inevitably occur were the grain on the outside allowed to be exposed to the weather. The shaving, it is obvious, should be done immediately after the stack has subsided, and even before, if there is appearance of rain; and it is easily done, and does not occupy much time.

(2270.) These are all the particulars which occur to me to say on bringing in the crop. In conclusion, I may advise you not to imitate those farmers who, because they are gratified on having their crop safe in the stack-yard, seem regardless of the state of the stack-yard itself, and leave it for a long time littered with the refuse of the thatching straw, which, when it becomes wetted with rain, is not only useless as litter elsewhere, but soon heats, and causes an unpleasant odor around the stacks. The spare straw should be removed immediately after it is of no use in the stack-yard, either to the straw-barn, if it is drawn and bundled, or, if loose, into the sheds of the hammels, where it will be ready for littering the cattle that may soon be expected to occupy the hammels for their winter quarters. The ground should be raked clean; the air will then become sweet, the stacks have free circulation of it among them, and the poultry will have the opportunity to pick up every particle of grain that had fallen upon the ground. This act of cleanliness being done, the stack-yard gates may be shut, and the labors of the farm, in so far as they concern the crop, may be said to have been brought to a termination.

(2271.) [The *throw-crook*, fig. 425, is an instrument that has been long in use for the purpose of spinning or twisting straw-ropes, and is one of those primitive inventions that required only the cutting of the first crooked sapling that might come to hand; for though our figure represents an artificially formed implement, any piece of bent material will answer equally well, all that is required being such a form as will give it the character of what we now denominate a *crank*, and

to have a swivel-joint at the end, to allow it to turn freely and independent of that appendage by which it is attached to the body, or to the left hand of the person who turns it. The implement represented in fig. 425 is made of a piece of tough ash, about 3½ feet long; the bent part is thinned off until it is capable of being bent to the curve, and is there retained by the iron stay *a*, the part *b* being left projecting beyond the stay, for the attachment of the first end of the rope that is to be made. The end *c* is furnished with ferule and swivel-ring, by which it is attached to the person, by a cord passed round the waist. In using the implement, the rope-maker is stationary, usually sitting beside the straw, and the spinner moves backward as the rope extends.

Fig. 425.

THE THROW-CROOK.

Fig. 426.

THE STRAW-ROPE SPINNER.

(2272.) The *straw-rope spinner*, fig. 426, is a machine of recent introduction to the operations of the harvest season, and is of considerable importance in facilitating the process of straw-rope making. Comparing it with the old instrument, the *throw-crook*, the advantage is considerable; for with that two people must be occupied in the making of one rope, whereas with the spinner four people only are required to make three ropes, being a saving of one-third of the time occupied by the old practice. The spinner has been constructed in various forms, though exhibiting but two distinct varieties of the machine—the first distinguished by the spinner being stationary, and the rope-maker moving away from it; the second by the rope-maker being stationary, and the spinner moving away from him. The first kind is found to be the best in practice, and I have therefore chosen an example of it for illustration. Fig. 426 is a view of the machine, consisting of a sole-frame, *a*, *a*, measuring about 2 feet each way, with an upright post *b* tenoned into the sole, and carrying the cross-head *c d*. The cross-head is a hollow box or case, adapted to contain the machinery of the spinner, consisting of 5 light spur-wheels, about 6 inches diameter, placed as seen in the case *c d*. Of these, the central and the two extreme wheels are mounted upon axles, which terminate in the hooks *e*, *e*, *e*; the other two wheels being merely placed intermediate, to produce revolution in the three principals in one direction. A winch-handle, *f*, is fixed upon the axle of the central wheel, on the side opposite to the hooks; and, to prevent the machine from moving with the strain of the ropes, a few stones, or other weighty substances, are laid upon the sole-frame. The machine is then put in operation by the driver turning the handle, and the three rope-makers, each with a quantity of straw under his arm, commences his rope by binding a few straws round the hook appropriated to himself. He then proceeds backward, letting out the straw as he advances, and the rope takes the twist, until the length required is completed, when each man coils up his rope into an oval ball.

(2273.) Some machines of this form are mounted on wheels, thereby coming under the character of the second kind, when the rope-maker is stationary; but great inconvenience must attend any attempt at working in this manner. Another form of the machine adapted to work, as one of the second kind, is that which is strapped to the body of the driver, he moving away from the stationary rope-makers. This method also is attended with inconvenience, especially to the driver, who, having the machine strapped in front of his body, the handle being at the end, and the machinery consisting of bevel-gear, having the external form of the cross-head alone of fig. 426, the handle is brought so near to his body that much of the muscular force of the arm is lost by this misapplication. By using a well-constructed machine for straw-rope spinning, not only is there a saving of expense effected, but the ropes are much better twisted, and, of course, stronger than those made by the old implement. The price is from £2 5s. to £2 10s.—J. S.]

(2274.) *Cart-ropes* last according to the care bestowed on them. When used with the corn-cart, they should never be allowed to touch the ground, as earthy matter, of whatever kind, soon causes them to rot. On being loosened when the load of corn is to be delivered to the stacker, they should be coiled up before the load is disposed of, and the coil suspended from the back part of the cart quite clear of the ground. A soft rope holds much more firmly, and is less apt to cut, than a hard one.

36. DRAFTING EWES AND GIMMERS, TUPPING EWES, AND BATHING AND SMEARING SHEEP.

"But rather those, the feeble of thy flock,
Banish before the autumnal months: even age
Forbear too much to favor; oft renew,
And through thy fold let joyous youth appear."
DYER.

"The ewes, being rank,
In the end of autumn turned to the rams."
MERCHANT OF VENICE.

(2275.) When last speaking of sheep, the lambs were weaned and buisted. One of the processes among sheep in early autumn, in the beginning of August, is *drafting ewes and gimmers*—that is, separating those to be disposed of from those to be kept. Drafting, however, applies only to a standing flock of ewes, By a *standing* flock is meant a fixed number of ewes, which are made to rear their lamb year after year. Instead of having a standing flock, some farmers are in the custom of buying every year a flock of ewes big with lamb, receiving the lambs from them, and disposing of both ewe and lamb at such a season as best suits the market for those respective sorts of stock. The ewes are sold in autumn to be fed on turnips, and the lambs are disposed of, after being weaned, to rearers of sheep who breed none. Such a one is called a *flying-flock*. Of course, flying-stock require no drafting; where all are disposed of, none obtain the preference of being kept.

(2276.) There are various marks of deterioration which determine the drafting of *ewes*. *Bareness of hair on the crown of the head*, which makes them obnoxious to the attacks of fly in summer—*deficiency in eyesight*, which prevents them keeping with the flock, and choosing out the best parts of pasture and best points of shelter—*ill-shaped teeth and jaws*, which disable them from masticating their food so well as they should—*want of teeth* from old age, when, of course, they cannot rope sufficient food to support their lambs—*hollow neck*, which indicates breeding too near akin—*hollow back*, which implies weakness in the vertebral column, thereby rendering them unfit to bear lambs to advantage—*flat ribs*, which confine the space for the fœtus within the abdominal region—*a drooping tail-head*, which affects the length of the hind-quarter, a space occupied by superior flesh—*bad feet*, which prevent traveling with ease along with their companions—*round and coarse bone*, which indicates coarseness of flesh—*thin or short coat of wool*, which lessens the clip and the profit of wool—*diseased teat or udder*, which diminishes the supply of milk for the future progeny—*scarcity of milk*, by which lambs, not obtaining sufficient nourishment in the early period of their existence, are stinted in growth, and weakened in constitution—*carelessness of disposition*, which induces neglect of the lamb, particularly one of twins, which is in consequence ill-nursed—*producing worthless lamb*, by which profits are much diminished—*missing being in lamb*, a failing which is apt to recur in any future year—*casting lamb*, a propensity likely to recur every year—*rottenness*, which is, of course, objectionable in every animal that produces young—*shortness of breath*, which prevents them seeking their food, and eating so much of it as they should—*tendency to scouring*, or *the opposite*, the former imposing weakness, the latter inducing inflammation—*delicacy of constitution*, which disables them from withstanding the ordinary changes of the weather—*diminutive stature*, or *inordinate size*, which destroys the uniformity of the

flock. This is a long list of faults incidental to ewes, and yet every one may be observed, and which every breeder of sheep is desirous to get rid of.

(2277.) It is not at all probable that any flock of ewes presents *all* these objectionable qualities in one season; but, notwithstanding this favorable circumstance, it is not in the power of the breeder to draft *every* ewe having an objectionable property every year, because, the farm supporting a stated number of ewes, the extent of their draft depends on the number of *good* substitutes which may be obtained from the gimmers; for it is obvious no good object is attained by drafting a bad ewe, and taking in its stead a bad gimmer. The number of gimmers fit to be transferred to the ewe flock should therefore be, in the first instance, ascertained, and a corresponding number of the worst ewes drafted.*

(2278.) In *drafting gimmers*, many of the above faults may be observed in them also, though every fault arising from lamb-bearing cannot possibly affect young sheep. The faults incidental to gimmers are, bareness of hair on the crown of the head—ill-shaped teeth and jaws—hollow neck—hollow back—flat rib—low tail-head—bad feet—round, coarse bone—thin and short fleece—rottenness—shortness of breath—tendency to scouring, or otherwise—delicacy of constitution—and diminutiveness of stature and inordinate size. These faults are numerous enough, but not likely to be all observed in the same year, and less likely in the same individual.—Most of them may be got rid of by rejecting females which have more than one of them, and by employing tups free of them all. When the external form is improved, the constitution is also strengthened. Gimmers, when they become ewes, are moreover likely to be deficient in milk, careless of their young, and produce small lamb; but these faults disappear in the succeeding year—and should this not be the case, the ewe, though young, healthy, and fresh, should be drafted. Thus, ample drafting can alone insure a sound, healthy, well-formed, young, and strong-constitutioned flock of ewes.

(2279.) After being drafted, the ewes and gimmers are buisted [marked] with tar (2027), those to be retained, on the near rib, and those drafted, on the far.

(2280.) *Tups* require but little preparation on being put among ewes. If their skin is red in the flanks when the sheep are turned up, they are ready for the ewes, for the natural desire is then upon them. Their breast, between the fore legs, is rubbed with *keil* or ruddle, on being placed among ewes, that they may mark their rump on serving them. It is the duty of the shepherd to mark every ewe so served, that he may observe whether or not the season returns upon her, and to be prepared for the day of her lambing when it arrives. The period of gestation of the ewe is 5 months, and as the tup is usually put among the ewes from the 8th to the 11th October, the first lambs may be expected to appear on the 8th or 11th of March following. A young, active tup, a shearling, will serve 60

[* In our Eastern States, where more care and exactness prevail in all branches of husbandry, it is probable that flocks of sheep are periodically overhauled, and all that are defective from age, or disorder of any kind, drafted and in some way disposed of; but, in the Middle and Southern States, very gross neglect is observable, almost universally on this point. Now, every farmer of true spirit will endeavor to attain all practicable excellence in whatever he undertakes—in the quality of his flocks as well as of his implements—in the purity of his butter as in the plumpness of his grain; and nothing requires more searching vigilance than the health and condition of his sheep. It is with them, especially, that a single rotten or diseased individual may infect the whole flock; and no inducement, no false calculation of economy, should induce him to retain such an animal, even for a day, after it is discovered. His character, as well as his interest, forbids it.

Ed. Farm. Lib.]

ewes, an old one 40 ewes. Tup-hoggs are not used, not having attained maturity in any particular, though one is sometimes put among ewes to make an old tup more active. When tups are too fat, they are apt to become lazy, and will only willingly serve a very few ewes; and when this is the case, it is better to put him in a field by himself with a few ewes, selected to suit his particular qualities, than to urge him to over-exertion by means of a tup-hogg, because several of the ewes served by him in such case may miss being in lamb. A tup-hogg so employed is seldom allowed by the tup to serve a single ewe, being driven off wherever he is seen to go with one; but as a sure prevention of his serving, a piece of cloth is sewed to the wool on the under part of his belly. Tups, when too heavy, are apt to contract spavin in the hock joints, in consequence of the great weight of the carcass upon the hind legs, in the act of serving ewes. Most of the ewes will be tupped during the second week the tup is among them; and, in the third, they will all be served. It is likely that some of the first served ewes will return in season, and these should be specially noticed by the shepherd, as it is not improbable they will become tup-eild. The ruddle requires to be renewed almost daily, and even oftener, when the tupping is active.

(2281.) Tups are not selected for ewes by mere chance, but according as their qualities may improve those of the ewes. When ewes are nearly perfect, they may be selected for breeding-tups. A good ewe flock should exhibit these characteristics: *strong bone*, supporting a roomy frame, affords space for a large development of flesh—*abundance of wool of good quality*, keeping the ewes warm in inclement weather, and insuring profit to the breeder—a *disposition to fatten early*, which enables the breeder to get quit of his draft-sheep readily—and *being prolific*, which increases the flock rapidly, and is also a source of profit. Every one of these properties is advantageous in itself, but when all are combined in the same individuals of a flock, that flock is in a high state of perfection. Now, in selecting tups, it should be observed whether or not they possess one or more of those qualities in which the ewes may be deficient, in which case their union with the ewes will produce in the progeny a higher degree of perfection than is to be found in the ewes themselves, and such a result will improve the state of the future ewe flock; but, on the contrary, if the ewes are superior in all points to the tups, then, of course, the use of such tups will only serve to deteriorate the future ewe flock.

(2282.) After 3 weeks have elapsed from putting the tup among the ewes, he should be withdrawn; because lambs begotten so long after the rest, will never coincide with the flock. Tups should, after serving, be put on good pasture, as they will have lost a good deal of condition, being indisposed to settle during the tupping season. The ewes and gimmers may now be classed together, and get such ordinary pasture as the farm affords. During the autumnal months, they will find plenty of food in the pasture fields, but in winter, rather than be fed on turnips, a rough pasture field should be reserved for them. When they have no such pasture, they will require to be put on a break of turnips for 2 or 3 hours every day; but it should be borne in mind that a *fat* ewe always bears a small lamb, and is very subject to inflammatory fever after lambing, from the recovery of which, if she ever recover, the probable result will be scantiness of milk. Swedish turnips will produce this effect on ewes more readily than other kinds, therefore a few white turnips should be reserved for them as long as practicable, should they receive turnips at all.*

* See paper by me on Drafting Sheep, in the Quarterly Journal of Agriculture, vol. iii.

(2283.) Immediately after the arrangements for tupping the ewes are made, part of the sheep-stock undergo a preparation for being put on turnip, and the preparation consists of bathing them with a certain sort of liquid. Sheep are affected by a troublesome insect, the keb or ked, or sheep-tick, which increase so much in numbers as the wool grows, toward autumn, as to become troublesome to sheep; and were means not taken to remove them, the annoyance they occasion the sheep would cause them to rub themselves upon every object they can find, and in thus breaking their fleece deteriorate its value to a considerable extent. Another reason for bathing sheep is, that on experiencing so great a change of food as from grass to turnips, cutaneous eruptions are apt to appear on the skin, even to the extent of the scab, which would deteriorate the fleece even more than the rubbing occasioned by the ked. The liquid, then, which would be of service, should combine the properties of killing the ked with certainty, and of preventing eruptions on the skin, without injury to the staple of the wool; and these effects are attained by the use of tobacco-liquor and spirit of tar, the former instantly destroying the ked, and the latter acting as a preservative to the skin. The former precaution is necessary to be exercised on all classes of sheep, but the latter is the more necessary on sheep bought to fatten on turnips, as traveled sheep are almost always affected with cutaneous eruptions, and especially Black-faced sheep direct from the hills, after they have been on turnips for some time. As a matter of safety, then, for your own flock, however clean it may be, every sheep that you buy from another flock, whether intended for feeding on turnip or for augmenting your own flock, should be bathed immediately on its arrival on your farm, and before it can possibly have had time to contaminate your own sheep.

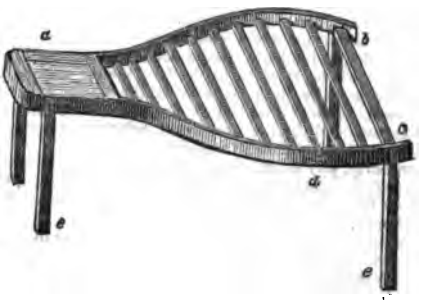
(2284.) The materials used in the *bath* are tobacco, spirit of tar, soft soap, and sulphur vivum. The tobacco is best used in the state of leaf, but I understand it is illegal for tobacconists to sell tobacco in the leaf. Being used in the proportion of 1 lb. of tobacco to every 20 sheep, it is put into a boiler with 1 quart of water for every 1 lb. of tobacco, and boiled gently for several hours. The tobacco is then wrung out, and returned again into an empty boiler with ½ quart of fresh water for every 1 lb., and boiled as long as any coloring matter can be obtained from it, when it is wrung out and thrown away. The entire water will have boiled in to 1 quart to 1 lb. of tobacco. This forms a decoction of tobacco which is much better than an infusion. The soft soap is used in the proportion of 1 lb. to every 20 sheep, and is dissolved thoroughly in a sufficient quantity of warm water. The sulphur vivum is pounded fine and mixed with the soap in proportion of ¼ lb. to 20 sheep, and it combines with the soap in some degree, but when both are mixed with the tobacco-liquor, the sulphur is apt to be thrown down in the original state of powder. I don't know of what particular use the sulphur vivum is, for the greater proportion of it is certainly precipitated to the bottom before it is used, unless its sulphureous property may serve to prevent the ked breeding again for a time; but if this is its only use, the flour of sulphur should be more efficacious. The tobacco-liquor is put into a tub, and the solution of soft soap and sulphur vivum are intimately mixed with it. The bath thus made is administered by means of a tin flask capable of easily holding 1 quart, and provided with a long spout, by which to pour it along the shedded wool of the sheep. The spirit of tar is poured into the flask of liquor when about to be used, in the proportion of ½ a wine-glass to 1 quart, and stirred. Some people use stale urine over and above these materials, for the professed purpose of making the bath stronger, but I cannot see how

it can strengthen any of these ingredients; for, as to any caustic effect upon the skin, a small addition of the spirit of tar will have a much greater effect than the urine. If the urine is employed with a view to its ammoniacal vapor destroying the insects, that may be a good plea for its employment in summer to prevent the extension of insect vermin; but in autumn, when the keds are entirely destroyed by the spirit of tar, and will not again appear till spring in a new progeny, the urine seems useless in winter.

(2285.) This is an effectual bath, and is not expensive; the tobacco being 3s. 6d. per lb., a bottle of spirit of tar 1s. 6d., soft soap 6d., and sulphur vivum 1s. per lb., give a cost of 5s. 6d. for 20, or 3¼d. per sheep. But it should be mentioned, in regard to this bath, that, though in very common use, it tinges the color of the wool, and is more expensive than some other baths to be adverted to hereafter.

(2286.) An useful implement in bathing sheep is the *bathing-stool*, fig. 427, which is made of the best ash. It consists of a seat *a*, for the shepherd to sit on while bathing the sheep, 1 foot square; the sparred part is 3 feet long, and 30 inches wide in front from *b* to *c*, its greatest width being across at *d*. The legs *e*, *e*, &c., are 18 inches high, attached by means of iron rods passed through their upper part and the frame of the stool, and secured with nut and screw.

Fig. 427.



THE BATHING-STOOL FOR SHEEP.

(2287.) The *bathing* is conducted in this way: A sheep is caught and placed on the stool on its belly, with its 4 legs through the spars, and its head toward the seat *a*, on which the shepherd sits astride. The wool is shed by the shepherd, with the thumbs of both hands, from one end of the sheep to the other; and, when he has reached the farthest end of the shed, an assistant, a field-worker, pours the liquor from the flask equally along the shed, while kept open by the shepherd with both hands. The sheds made are 1 along each side of the back-bone, 1 along the ribs on each side, 1 along each side of the belly, 1 along the nape of the neck, 1 along each side of the neck, and 1 along the counter. From these sheds the bath will cover the whole body. The sheep is turned on the sides and back to obtain easy access to all these several parts. Additional liquor is put on the tail, head, scrotum, inside of the thighs, brisket, root of the neck, and top of the shoulder, because these are parts most likely to be affected by scab, and are chiefly the seats of the nidi of insects. The shepherd and his assistant will bathe 40 sheep in a day. Dry weather should be chosen for bathing, else the rain will wash away the newly applied bath; and coarse clothes should be worn by those who administer the bath, as it is a very dirty process. When the sheep are lying on their back on the stool, their legs are not tied, so the assistant should be aware of receiving a kick from the hind feet on the face or on the flask.

(2288.) Shortly after bathing, the keds may be seen adhering to the points of the wool dead; and, when sheep are much infested by this vermin, the fleece may be seen speckled thick with their bodies. Sheep are differently affected with keds; and those which recover from a lean or stinted state to one in better condition, on a change of food, are most liable

to be overrun with them, as cattle are with lice when improving in condition on turnips. This being the case, the ked may be expected to increase rapidly on sheep that have been some time on turnips, and hence the necessity of bathing sheep before being put on turnips. Hoggs are most liable to their attack, because, perhaps, they get most rapidly into condition after being some time weaned.

(2289.) The *diseases* incident to sheep in autumn are yellows and rot, both arising from a disordered state of the same organ—the liver, and pining. The *yellows* is jaundice, exhibiting yellowness of the eye, the mucous membranes, and the urine. Bleeding, and purging with aloes and calomel, are the appropriate remedies. Fat draft ewes which have fed some time upon aftermath are most liable to the disease. Inflammation of the liver is the cause, in which the pain of the affected part is very obscure, and the natural language of the sufferer not very expressive, nor is the symptomatic fever marked. Here a striking analogy is noted between the lower animals and man, inasmuch as there is generally a sympathetic pain in the right shoulder, so strongly marked as often to be mistaken for the principal disorder, and treated accordingly. Whenever you observe, therefore, a lameness of the right leg of any fat sheep on foggage, you may suspect the existence of yellows, and examine the inside of the eyelid, and observe whether any yellowness exists there.

(2290.) The *rot* is a far more serious disease, causing the death of numbers of a flock in a very short period. Deficient food in summer, and a flush of rank wet grass in autumn, occasion ruin to the health and constitution of sheep. In the wet and cold season of 1817, when sheep could not obtain a mouthful of good food in summer, and when the autumn arrived, accompanied with a flush of wet herbage, I knew a farmer in Cheviot who lost 300 Cheviot ewes in the course of 2 or 3 weeks. The early symptoms of rot are very obscure a circumstance much to be lamented, as in the first stage alone does it often admit of cure. "The animal is dull," observes Mr. Youatt; "lagging behind his companions, he does not feed so well as usual. If suspicion has been a little excited by this, the truth of the matter may easily be put to the test; for if the wool is parted, and especially about the brisket, the skin will have a pale yellow hue. The eye of the sheep beginning to sicken with the rot, can never be mistaken; it is injected, but pale, the small veins at the corner of the eye are turgid, but they are filled with yellow serous fluid, and not with blood. The caruncle, or small glandular body at the corner of the eye, is also yellow. Farmers, very properly, pay great attention to this in their examination or purchase of sheep. If the caruncle is *red*, they have a proof, which never fails them, that the animal is healthy. If that body is *white* they have no great objection or fear—it is generally so at grass; but if it is of a yellow color, they immediately reject the sheep, although he may otherwise appear to be in the very best possible condition; for it is a proof that the liver is diseased, and the bile beginning to mingle with the blood. There is no loss of condition, but quite the contrary; for the sheep, in the early stage of rot, has a great propensity to fatten. Mr. Bakewell was aware of this, for he used to overflow certain of his pastures, and when the water was run off, turn those of his sheep upon them which he wanted to prepare for the market. They speedily became rotted, and in the early stage of the rot they accumulated flesh and fat with wonderful rapidity. By this maneuver he used to gain 5 or 6 weeks on his neighbors."

(2291.) It is alleged, that when sheep have access to salt, they are never known to be affected with rot; and I have as little doubt that, were oil-cake put freely within their power in such a season as I have alluded as having occured in 1817, they would escape the malady. Change of pasture from a wet to a dry situation may be the means of even curing the rot, when the change has been effected at an early stage of the disease. All land that has been irrigated in summer, and produces a rank growth of grass in autumn, should be avoided by sheep, as being the very pest-house of rot. Some land, in its natural state, will affect sheep with rot when grazed upon it, such as soft, spongy soil, having a clayey tendency, and never free of moisture. In so far as this last cause of rot is concerned, draining has had the effect of rendering land sound which was known to have rotted sheep in a short time. In the prospect of such an evil, when inevitable, sheep cannot be long kept on the same farm, but must be sold in the course of a few months; in short, tenants, in their fear, are obliged to keep a flying-stock, especially of ewes, for these are the most easily affected portion of the flock. The application of lime has rendered land sound which was subject to rot, even after it had been drained. Sudden frost and thaw, alternately, in spring, produce rot, according to the old proverb—

"Many a frost, and many a thaw,
Beaken many a rotten yow."

(2292.) The liver of rotten sheep always contains the well-known animal the *fluke*, so named from its striking resemblance to a flounder. Its nature has not yet been satisfactorily examined. It was named *Fasciola* by Linnæus, and *Distoma hepaticum* by Rodolphi. Its intestinal ducts contain great numbers of grains of a pale red color like sand, which are supposed to be its eggs; and as no difference of sex has been observed, it is believed to be a hermaphrodite. It is supposed that its eggs find their way to the grass, from which sheep receive them into their stomach, and thus are supposed to find their way into the liver. The eggs are found in the biliary ducts, in the intestinal canals, and even in the dung of healthy sheep, and they swarm in the dung of rotten ones. Much more could be said on the subject of rot, but I must refer you to authorities.*

(2293.) "*Pining*," says the Ettrick Shepherd, "is a very descriptive Scotticism, from the verb; for no creature can have a more languishing and miserable look than a sheep affected by this malignant distemper. Well may I describe it, for in the last 9 years I have lost upward of 900 sheep by its ravages. It is quite a new disease on the Border; for I was 20 years a shepherd and never

* Youatt on Sheep, Quarterly Journal of Agriculture, vol. v. and vol. vi. Parkinson on Live Stock, vol. i.

saw an instance that I can remember of with certainty, nor did I ever hear its name save from Galloway, where it was called the *vinquish*, and where it has been prevalent for ages. It was likewise known long ago in some of the districts of the middle Highlands. It is a strange distemper. On the genuine pining farms, the sheep do not take it by ones or twos, but a whole flock at once. It is easily distinguished by a practiced eye, the first symptoms being lassitude of motion, and a heaviness about the pupil of the eye, indicating a species of fever. I wish I had science to describe it in a pathological manner, which I have not, and therefore shall not attempt it: but at the very first the blood is thick and dark of color, and cannot by any exertion be made to spring: and when the animal dies of this distemper, there is apparently scarcely one drop of blood in the carcass. It lives till there does not seem to be a drop remaining: and even the ventricles of the heart become as dry and pale as the skin. This simple fact may, I hope, enable men of science to comprehend its nature. It is most fatal in a season of drouth; and June and September are the most deadly months. If ever a farmer perceive a flock on such a farm having a more than ordinary flushed appearance by rapid thriving, he is gone. By that day 8 days, when he goes out to look at them again, he will find them all lying, hanging their ears, running at the eyes, and looking at him like so many condemned criminals. As the disease proceeds, the hair on the animal's face becomes dry, the wool assumes a bluish cast, and if the shepherd have not the means of changing pasture, all those affected will fall in the course of a month."

(2294.) The rationale and cure of this fatal disease are thus attempted to be given by a writer. "The disease called *pining*, seems to arise from an enervated and costive habit of the animal, which may be produced by a want of proper exercise, in conjunction with feeding in pastures of an astringent nature. The principal districts in which this disease is found to prevail, are the green pastures of the Cheviot mountains, the chain of hills running through the S. W. parts of Roxburghshire, the pastoral districts of Selkirk and Peebles shires, and some other districts of Scotland, as Galloway. Under the old practice of keeping the sheep in flocks, as they are termed, *hirsels*, of weaning the lambs in the months of July or August, and afterward of milking the ewes for 8 or 10 weeks, the pining was unknown in most of these districts; but under this mode of treatment, the sheep were frequently subject to diarrhea—a disease diametrically opposed to pining. The farmers of those pastoral districts have generally improved upon the older methods of keeping their sheep. They find it to be more profitable to allow the whole flocks to pasture together indiscriminately and undisturbed. The lambs remain unweaned, until they wean themselves, which generally does not take place till the month of December. By this mode of management, the ewes and lambs are found to be of a higher comparative value than all the sum realized by the sale of cheese made from the milk of the ewes; besides, the ewes are not subject to various accidents arising from so frequently collecting them together for the purpose of milking. But under this undisturbed state of management, in all cases where dry astringent pastures are produced, such as on the sienitic porphyry of the Cheviot range, the pining made its appearance. That such pasture promotes this disease, is farther strengthened by the fact that it is more common in dry than in wet seasons; and most so at that season of the year when, by the influence of the sun, the plants are less juicy; or early in autumn, when the grasses which have pushed to seed become less succulent. The disease is not known on the whole of the clay-slate range of the Lammermoor Hills, where heath prevails, occasionally interspersed with green pastures, and where the *hirseling* practice is pursued. Nor is it known to exist in general on green succulent pastures, or even heaths, growing on calcareous or sandstone grounds, where the nature of the food and the exertion of the animal in procuring it appear to counteract the progress of the disease, arising from the inactivity of the digestive function. If we suppose these to be the predisposing causes of this disease, the prevention or remedy will suggest itself either under the head of food or treatment. Should it be deemed inexpedient to adopt the mode of keeping the flocks in hirsels, a change of place, and, consequently, of food, is necessary to accomplish this purpose. The salutary effects of a variety of food on the animal system are well known. When sheep affected with this disease are put upon a heath, it has frequently the desired effect; but when the animal is much overcome with the disease, its state of languidness may prevent it from taking such a quantity of food as will produce a reaction upon the animal functions. The most effectual cure, therefore, in all cases, is a change to a more rich and succulent pasture."*

37. LIFTING AND PITTING POTATOES.

"If planted in fair rows
They marshaled grew, the plow will best perform
The reaping task: amid the tumbling soil
The vegetable mine, exposed to view,
The gatherer's basket fills."

GRAHAM.

(2295.) The harvest-work of a farm cannot be said to be completed until the potato crop is taken out of the ground and secured against the winter's frost. By October the potatoes may be expected to be ready for lift-

* Quarterly Journal of Agriculture, vol. ii.

ing. The fitness of potatoes for lifting is indicated by the decay of the haulms: for as long as these appear at all green, you may conclude the tubers have not yet arrived at maturity. In an early season potatoes will ripen before October; and though the weather should continue fine, the best plan is to let them remain in the ground till the corn crops are entirely harvested. Immediately after the fields are cleared of corn, the potatoes should be taken up and secured, to allow the land to be plowed up for wheat; indeed it will happen, under all circumstances of weather, that the corn will be ready to be cut down and carried in before the potatoes are fit to be taken up.

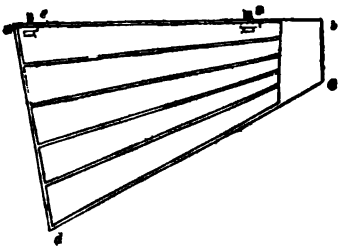
(2296.) There are two modes of lifting potatoes, namely, with the plow and with the potato-graip. The plow is the most expeditious, though I believe the ground is best cleared of tubers with the graip. With either instrument a large number of people to gather the potatoes are required, each of whom should be provided with a small semi-spheroidal shaped basket, with a bow-handle, to gather the potatoes into, and then to put them into sacks or close-bodied carts. When a farmer lifts potatoes on his own account, they are usually put into a cart and carried direct to the pits. When he lifts them on account of a purchaser, or a number of purchasers, they are measured on the spot from the basket, and put into sacks, in which they are easily delivered. When lifted for shipment to the London market, they are first riddled into sizes, then measured or weighed on the spot and put into carts, and taken to the ship's side. The potato-riddle is made of wire, with meshes from $1\frac{3}{4}$ inches to $1\frac{1}{2}$ inches square, and, if rimmed with oak, costs 2s. 6d. each. The riddlings, or small potatoes, are used on the farm. Potatoes are usually sold by weight, and a given weight represents the measure of a boll; which boll, again, differs in weight in different parts of the country, thereby rendering the imperial weights and measures act, in this instance, nugatory. A boll is 20 stones of 14 lbs. to the stone, in some parts of Scotland, and it is 40 stones in others; and, to contradistinguish them, the small boll is called a *single*, and the large a *double* boll. The produce of a crop of potatoes varies amazingly—from 30 to 100 single bolls per imperial acre. It is singular that the price does not vary nearly so much—from 4s. 6s. the single boll, being the limits between dear and cheap prices. Taking 60 bolls [16,800 lbs.] as the medium produce, and 5s. as a medium price, the gross return from an imperial acre of potatoes will be £15 [$75]. If the expense of lifting the crop is taken at 30s. per acre, the return will be £13 10s.; a large sum, certainly, but then it should be remembered that potatoes leave no straw for manure, and require, on the contrary, a large quantity of manure to raise even a tolerable crop. They incur considerable trouble in their delivery; and, being a perishable commodity, cannot be kept beyond a given time.

(2297.) In employing the *plow* to take up potatoes, the common one, with 2 horses, answers well; but as the potatoes run the hazard of being split by the coulter when it comes in contact with them, it should be taken out, the sock being sufficient to enter the plow below the drill, and the mould-board to turn them out of it. The plow in going up splits one drill, and in returning splits the next, but no faster than a band of gatherers, or field-workers, if numerous enough, but if not, assisted by hired laborers, can clear the ground of them into the baskets. In free soil, potatoes are easily seen and picked up; heavier soil is apt to adhere to them, in which case it is a good plan to make a stout field-worker shake those portions of the earth turned up by the plow, which still adhere in lumps, with a potato-graip, and expose the tubers. Potato-gathering should not be con-

tinued so late in the evening as that the tubers cannot be easily seen; nor should it be prosecuted in wet weather, which causes the earth to adhere to them, and renders them undistinguishable from the earth itself. Of course every one, the smallest tuber, should be taken off the ground, not only on the score of economy, to realize the whole crop, but to remove them as a weed from among the succeeding crop. After the field has been gone over in this manner, the harrows are passed a double tine to bring concealed tubers to the surface, when they are gathered by the people, and to shake the haulms free of soil. These after-gathered potatoes are usually reserved for pigs and poultry. Whenever the field is cleared of the crop, the haulms are gathered by the field-workers and carried to the compost stance, to be converted into manure, and these are the only return which the potato crop makes to the soil.

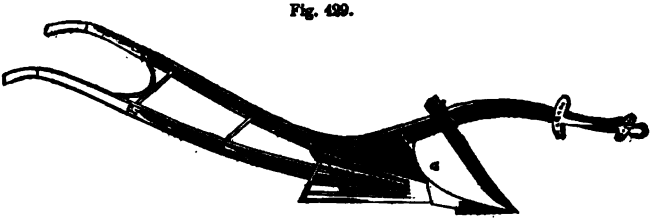
(2298.) A simple instrument, fig. 428, which may be substituted in the plow for the mould-board for turning potatoes out of the drill was contrived by Mr. John Lawson, of Elgin. It consists of 6 malleable iron bars, the outer ones $\frac{5}{8}$ of an inch square, the inner $\frac{1}{2}$ an inch in diameter, joined together in the form of a brander, 26 inches long from *a* to *b*; 5 inches in breadth from *b* to *c*, at the fore part, where is a plate of iron; 27 inches in length from *c* to *d*; and 18 inches in breadth from *d* to *a*. This brander is attached to the right side of the head and stilt of a plow, in lieu of the mould-board, by the screws *c*, *e*, and the fore-end, *b c*, being placed close behind the sock, as seen at *a*, fig. 429, which shows the plow mounted with the brander, having its upper angle at *a*, fig. 428, 8 inches, and the plane of its face so bent down as to have the lower angle *d* only 4 inches above the sole of the plow. The openings between the rods will thus be rather more than $2\frac{1}{2}$ inches at the widest end of the brander, between *a* and *d*. The mode of operation of the brander is, that while the earth partly passes through it, and is partly placed aside by it, the potatoes are wholly laid aside, so there are few of them but are left exposed on the surface of the ground.

Fig. 428.



THE POTATO-RAISER OR BRANDER.

Fig. 429.



THE POTATO-RAISER ATTACHED TO THE PLOW.

(2299.) "This plow," says Mr. Lawson, "is drawn by one pair of horses, in the same manner as the common plow. In working it, the plowman inserts it into the potato-drill so as to have the whole of the potatoes on his *right-hand side*. He then proceeds along the drill, splitting it up in the common way. The earth is then thrown to the right-hand side, and the potatoes lie scattered on the surface of the ground behind the plow. Women follow, provided with baskets, into which they gather the potatoes, and throw the stems upon the drill which lies to the right hand of the one

from which they are gathering the potatoes. The reason why the potato-stems are thus removed is that as soon as the potatoes which lie on the surface are gathered, the plow returns, and again proceeds as before, through the part of the drill in which the potatoes lay, still turning the earth to the right-hand side. This second operation raises to the surface any stray potatoes which the first may not have turned up, and the potatoes thus raised are gathered by the women who attend for that purpose. The second operation may be delayed till about 12 drills are turned over by the first operation, and the potatoes gathered. The plow may then be put through these 12 drills the second time. By this there will be a saving of labor, as a smaller number of women will gather the potatoes by the second operation, while the greater number of them may remain with another plow in its first movement. If the stems of the potatoes be very *strong and luxuriant*, a few of the women might be directed to go along the drill and pull them out of the ground, at the same time plucking off any potatoes that may adhere to and come along with the stems. If this is done, the plow will turn up the greater part of the potatoes by going only *once* through the drill; but, in going twice, it will do it in the most satisfactory manner. A man with 1 pair of horses will thus pass over the ground as quickly as with the common plow. In light soils this plow performs its work in a very efficient manner. It pulverizes the soil in an extraordinary degree, and scarcely leaves a single potato in the soil. I have never before been able to clear my fields of potatoes so effectually as by this implement, or at nearly so small an expense."*

(2300.) When potatoes are taken up by manual work, it is done with the *potato-graip*, fig. 430, the prongs of which are flattened. Being rather severe work to use this graip, men are employed for the purpose, 1 man taking 1 drill, close beside that of his fellow-workmen, while 2 gatherers to every man are ready to pick up the potatoes he turns out into the baskets. In using the graip, it is inserted into the side of the drill, and below the potatoes, with a push of the foot, and the graipful of earth thus obtained is turned on its back into the hollow of the drill, exposing the potatoes to view on the top of the inverted earth, whence they are gathered. The men then pass the prongs of the graip here and there through the inverted graipful and the soil on the drill, to detect and expose to view every tuber lurking beneath the soil. In this manner, 1 man and 2 women will take up, of a good crop of 80 bolls of 20 stones per acre, 20 bolls a day, which will cost 3d. per boll at the following wages: 1 man 2s., and 2 women at 1s. 6d. each per day, without food=5s. per day, or 20s. per acre. Such graips cost 2s. 3d., and when handled 3s. each.

Fig. 430.

THE POTATO GRAIP.

(2301.) In regard to the *storing* of potatoes, there is no difficulty in the early part of winter, when a low temperature prevails, and vegetation is lulled into a state of repose. Potatoes may therefore be kept in almost any situation in the early part of winter; but then, if damp is allowed to surround them for a time, it will inevitably rot them, and if air finds easy access to them at all times, the germ of vegetation will be awakened in them at the first call of spring. To place potatoes beyond the influence of those elements as long as convenience suits, they should be stored in a dry situation, and be covered up from the air; and no mode of storing affords more ready means for both those requisites than the ordinary forms of pits in dry soil.

* Quarterly Journal of Agriculture, vol. viii.

(2302.) Fig. 431 shows the two different forms of the ordinary potato-pits, the one being conical, the other prismatic in shape. The conical form is usually employed for pitting small quantities of potatoes, and is well suited for small farmers and cotters; the prismatic is the form commonly adapted for storing large quantities. For both sorts, a situation sheltered from the north wind should be selected, and the ground should either be so dry of itself as to absorb the rain as it falls, or so inclined as to allow surface water to pass quickly from the site of the pits. The site should be conveniently situated for opening the pits and admitting the carts to them, and so near the corner or side of a field as not to interfere with its being wrought in winter.

(2303.) A *conical* pit of potatoes is formed in this manner: If the soil is of ordinary texture, and not very dry, let a small spot of its surface be smoothened with the spade. Upon this spot let the potatoes, as they are taken out of the cart, be built by hand in a conical heap, not exceeding 2 feet in hight; and the breadth which a cone of that hight will occupy, so as not to impose much trouble in piling up the potatoes, will not be less than 4 feet, and is more likely to be 5 feet. The potatoes are then covered with a thick thatching of dry, clean straw. Earth is then dug with a spade from the ground in the form of a trench around the pit, the inner edge *a*, fig. 431, of the trench being as far from the pile of potatoes as the thickness of the covering of earth to be put upon it, which is to be considered sufficient at 1 foot. The first spadeful is laid around the potatoes on the ground, and the earth chopped fine and beaten down with the spade, in order to render the earth as impervious to cold as possible, and the drier the earth is, the less effect will frost have upon it, and the less distance will it penetrate through it. Thus spadeful after spadeful of the earth is taken from the trench and heaped on the straw above the potatoes, until

Fig. 431.

THE CONICAL AND PRISMATIC FORMS OF POTATO-PITS.

the entire cone *a b c* is formed, which is then beaten smooth and round with the back of the spade. The top of the cone at *b* will then be about 3 feet 3 inches in hight, and the width of the cone from *c* to *a* about 7½ feet. The trench round by *a c* should be cleared of earth, that no surface water may lie near the pit, and an open cut should be formed from the lowest side of the trench to allow the water to go away most freely.

(2304.) When the soil is naturally thoroughly dry, the site of the pit may be dug out of the solid ground a spade depth, for storing the potatoes into what would then really be a pit, and then the apparent hight of the pit above the surface of the soil will be small; but unless the soil is as thoroughly dry as sand or gravel can make it, the potatoes should be piled upon the natural surface of the ground.

(2305.) The *prismatic*, or *long* pit, *d e f g*, fig. 431, is formed exactly in the same manner, with the exception that the potatoes in it are piled in a straight line along its sides *d h*, instead of round, as in the case of the conical pit *a b c*. The hight of the pile of potatoes should not exceed 2½ feet, and its breadth will spread out to about 7 feet, and allowing 15 inches for thickness of straw and earth, the hight of the finished pit will be 3 feet 9 inches, and breadth 9 feet 6 inches. The direction of a long pit should always be N. and S., in order to place both its *sides* within reach of the sun's rays.

(2306.) It is considered that when fresh potatoes are heaped together in large quantities, a certain degree of fermentation ensues, which increases the temperature of the mass so much as to awaken vegetation in the tubers, and the existence of long sprouts so frequently found covering the top of the heap of potatoes when a pit is opened in spring, is adduced as a proof of the effects of such an increase of temperature; and the thick covering of dry straw usually placed above potatoes in pits is also considered a great means of retaining within the bounds of the pit the heat evolved from the potatoes, and hence a plan has been suggested, of having openings left along the upper parts of pits through which such heated air may escape. The openings are left by drawing small bundles of long straw, tied at one end with a piece of cord, and cut square like a rosette on the top of a corn-stack *a*, fig. 422, and which are placed upright, and project upward at short intervals along the top of the pit, before the earth is thrown upon the straw near its ridging, and the earth is put round, and beaten down, and finished smoothly, beside the projecting part of each bundle. These vents may be seen at *i* and *k*, in fig. 431

(2307.) It is truly remarked by Sinclair, that "the varieties of the potato are very numerous, and the confusion of their names inextricable." Without attempting to particularize any one variety, I would say generally, that as an article of food, the potato is now universally cultivated, and this, no doubt, chiefly from the facility with which it may be raised, the pleasantness of its taste, the simplicity of its cookery, and the nourishment which it affords. According to a statement of Sinclair, it appears that in several varieties of potato fit for human food, the nutritive matter varies from two hundred to two hundred and sixty grains in 64 drachms; that those quantities of nutritive matter contained from 169 to 204 grains of starch, and from 31 to 61 grains of albumen, mucilage, and sugar.*

(2308.) As compared with grain, "Cobbett's assertion, that wheat produces more nutritious matter per acre than potatoes, is now completely disproved. Later experiments have shown that it is very near the truth to estimate the proportion of the nutritive power of wheat to that of potatoes as about 7 to 2; or, in other words, 2 lbs. of wheat afford as much sustenance as 7 lbs. of potatoes, though it may be doubtful whether they afford so much nourishment; for, by calculating the produce of the two crops, it has been determined that 1 acre of wheat will produce sustenance for 3 persons as long as 1 acre of potatoes affords it to 6 5-6 persons. This is on the supposition that the power of nutrition of a plant is only in proportion to the quantity of farinaceous and glutinous matter contained in it. But this is by no means certain. We have not been able to discover what it is that renders one substance more proper for food than another. . . . In estimating the amount of aliment afforded by potatoes and grain, we should rather calculate according to the mass of vegetable matter capable of satisfying a full-grown person. . . . . I may add that potatoes, from some peculiarity in the mixture or degree of condensation in their nutritive matter, seem to possess an advantage over all grains as constant food. It is well known that potatoes and water alone, with common salt, can nourish men completely; we have hundreds of instances, in many parts of Ireland, where the people have lived constantly on this diet from necessity, and yet have been robust, healthy, and long-lived as persons fed plentifully on animal food. Now, I know of no meal derived from grain used as the general food of any nation, without being mixed with other kinds of alimentary matter, as oil, fruits, whey, or milk."†

* Sinclair's Hortus Gramineus Woburnensis.

† Quarterly Journal of Agriculture, vol. v., a paper enumerating the various uses to which the Potato may be applied.

(2309.) The potato has been subjected to careful analysis by different chemists, and these are a few of the results:

KINDS.	Starchy Fibrin.	Starch.	Vegetable Albumen.	Gum.	Acids and Salts.	Water.	Analyst.
Red Potato	7·00	15·00	1·40	4·1	5·1	75·0	Einhoff.
.. germinated	6·80	15·20	1·30	3·7		73·0	
.. sprouts	2·80	0·40	0·40	3·3		93·0	
Kidney	8·80	9·10	0·80			81·3	
Large Red	6·00	12·90	0·70			78·0	
Sweet	8·20	15·10	0·80			74·3	
Peruvian	5·25	15·00	1·88	1·87		76·0	Lampadius.
English	6·83	12·91	1·04	1·70		77·5	
Onion	8·38	18·75	0·90	1·66		70·3	
Voigtland	7·13	15·41	1·25	1·95		74·3	
Paris	6·79	13·30	0·92	3·3	1·4	73·12	Henry, Jr.

Of these constituents of the potato, it will be observed how large a proportion the water bears, and the remainder is chiefly composed of fibrin and starch. Hence, potato differs essentially from wheat and barley, by containing no gluten, and approaches in some measure to the nature of rye.* Of the dry constituents, starch is frequently used in the manufacture of wheaten bread, the potato-flour giving to the loaf, when stale, a tendency to excessive crumbiness. Potato-flour does not injure bread as an article of food; but still it is an adulteration, and its use constitutes a fraud on the public, when the same price is demanded for the loaf partly made of this cheap material as for one of wheat alone.

(2310.) Potato starch may be converted into *tapioca*. The tapioca of commerce is derived from cassava, a preparation made in the West Indies, the tropical regions of America, and on the African coast, from the root of the manioc *(Jatropha manihot)*, an euphrobaceous plant. "The cassava cakes sent to Europe, which I have eaten with pleasure," says Dr. Ure, "are composed almost entirely of starch, along with a few fibres of the ligneous matter. It may be purified by diffusion through warm water, passing the milky mixture through linen cloth, evaporating the strained liquid over the fire with constant agitation. The starch dissolved by the heat thickens as the water evaporates; but, on being stirred, it becomes granulated, and must be finally dried in a proper stove. Its specific gravity is 1·530—that of the other species of starch. The product obtained by this treatment is known in commerce under the name of *tapioca*; and being starch very nearly pure, is often prescribed by physicians as an aliment of easy digestion. A tolerably good imitation of it is made by beating, stirring, and drying potato-starch in a similar way."† An acquaintance of mine, a farmer in Forfarshire, Mr. James Scott, Beauchamp, instead of disposing of his potatoes, of which he used to raise large quantities every year, converted them into tapioca; thereby saving a great deal of carriage which the delivery of potatoes occasions, and retaining the refuse of the manufactured potato, upon which he fed a large number of pigs, and which, moreover, afforded a good mash to the horses.

(2311.) "When potatoes are boiled, they lose from 1 to 1¼ per cent. of their weight. The juice which may be separated from them is sweet tasted. The meal is insoluble even in boiling water, though potato-starch forms a transparent solution with hot water. Thus it appears that by boiling, the albumen, fibrous matter, and starch combine together, and form an insoluble compound." Simple as the matter appears, it is not every cook who *can* boil a potato *well*.

(2312.) "When potatoes are exposed to the action of frost, it is well known that they become soft, and acquire a sweet taste. This taste is succeeded by a sour taste, owing to the rapid evolution of acetic acid, and the root soon passes to putrefaction. From the experiments of Einhoff, we learn that the sugar is formed at the expense of the mucilage; for the other ingredients were found in potatoes sweetened by frost, in the usual proportion. He considers this sweetening process as connected with the vegetative powers of the root." "Dr. Peschiez of Geneva has described the presence of mucous sugar and of gum in the potato. This explains why it is capable of undergoing the vinous fermentation." The acids contained in potatoes in the natural state were ascertained by Einhoff to be a mixture of the tartaric and phosphoric acids. He also obtained from 1.820 parts of dried potatoes, 96 parts of a grayish-white ash. Of these, 64 parts were *soluble* in water, and 35 *insoluble*‡. A minute analysis of the ash of potatoes is given by Professor Johnston, including that of the haulms. In 10,000 lbs. there were found of—

	In the roots.	In the tops.		In the roots.	In the tops
Potash	40·28 lbs.	81·9 lbs.	Silica	0·84 lbs	89·4 lbs.
Soda	23·34 ..	0·9 ..	Sulphuric acid	5·40 ..	4·2 ..
Lime	3·31 ..	129·7 ..	Phosphoric acid	4·01 ..	19·7 ..
Magnesia	3·24 ..	17·0 ..	Chlorine	1·60 ..	5·0 ..
Alumina	0·50 ..	0·4 ..			
Oxide of iron	0·32 ..	0·2 ..	Total	82·83 lbs.	308·4 lbs.

It will be observed what a large proportion of potash, lime and silica the tops of the potato plant yield. "These roots," as observed by Professor Johnston, and the observation applies to turnips, carrots and parsnips, as well as to the potato, "contain very much water, so that, in a dry state, the *proportion* of inorganic matter present in them is very much greater than is represented by

* Thomson's Organic Chemistry of Vegetables

† Ure's Dictionary of the Arts and Manufactures, art. *Cassada*.

‡ Thomson's Organic Chemistry of Vegetables.

the above numbers. I have, however, given the quantities contained in the crop as it is carried from the field, as alone likely to be of practical utility. The crops of these various sorts vary very much in different localities, being in some places twice, and even thrice as much as in others—every 10 tons, however, which are carried off the ground, contain about 9 times the weight of saline and earthy matters, indicated by the numbers in the Table."*

(2313.) *Solanina* was discovered by M. Desfosses in the fruit of the common potato, and M. Otto discovered it also in the potato itself, after it had been allowed to germinate, and this substance is an acrid narcotic poison. "Its existence in the potato after germination," says Dr. Thomson, "is an interesting fact, and should lead to the cautious use of that important vegetable after germination has commenced."

(2314.) "It is well known that a spirit can be extracted from potatoes. From this spirit Messrs. Bertillon and Guietand extracted a volatile oil, being a colorless, limpid liquid, having a strong smell, hot, acrid taste, and being very soluble in alcohol."†

(2315.) The particles of potato-starch are irregular ellipsoids, varying in size from 1-300 to 1-3000 of an inch; those of wheat being separate spheres of 1-1000 of an inch; so that it would be an easy matter to detect potato-flour among wheaten flour with the microscope.

---

38. SOWING AUTUMN WHEAT, AND THE CONSTRUCTION AND PRINCIPLES OF AGRICULTURAL WHEEL-CARRIAGES.

"How ceaseless is the round
Of rural labor! Soon as on the field
The withered haulms and suckers crackling blaze,
And with their far-extending volumes load
The wings of Autumn's latest lingering breeze,
The WHEATEN SEED-TIME all your care demands."
GRAHAM.

(2316.) How ceaseless, indeed, is the round of rural labor! No sooner does the farmer secure his crop, the progress of which toward maturity has excited his most lively solicitude during the course of a whole year, than he begins to sow the succeeding one, and strives to prepare as much land for it before winter sets in as he possibly can secure. The crop usually sown in autumn is *wheat*, that plant being able to bear the vicissitudes of winter in our latitude, though barley and tares are also sown at the same time in some parts of England, where they stand the winter well, but neither can withstand a Scottish winter.

(2317.) You have just seen (2312) that the constituent parts of the haulm of potatoes consist of large proportions of potash, lime, and silica—ingredients useful to many of the crops which follow in rotation after a summer-fallow; and though incineration is the means by which the chemist discovered those substances in potato-haulms, yet I would advise you to make a compost of them, as I did before (1613), rather than convert them into a "crackling blaze," as described in the motto, inasmuch as their inorganic constituents can be secured equally well by fermentation as by incineration, while their organic constituents are not dissipated, but thereby preserved for use.

(2318.) You will recollect that we left off the working of summer-fallow after the land was dunged (2155), and when the land was to receive no lime. It is now our business to finish the summer-fallow, by the sowing of *autumn wheat*, the crop for which the land was specially prepared by fallow. The first process is the leveling of the drills which cover the dung, by harrowing them across a double tine; and, unless the land is of very strong clay, 1 double tine will be sufficient for the purpose. After the land has been harrowed level, any root-weeds that have been brought

* Johnston's Lectures on Agricultural Chemistry and Geology.
† Thomson's Organic Chemistry of Vegetables.

to the surface should be removed, but the surface-weeds will soon wither in the sun and air. The land should now be feered, to be gathered up (650), fig. 133, into ridges, and if it has been thorough-drained, or is otherwise sufficiently dry, 1 gathering-up will make a good seed-bed; but should it be too wet for once gathered-up ridges to lie safe all winter, the ridges should be twice gathered-up (665), fig. 139. The second gathering-up, however, should not be done immediately after the first, but after such an interval of time has elapsed between them as to allow the land to subside, and the subsidence will be much hastened by a fall of rain. Should the fallow-land have been dunged in the usual way, that is, the dung spread upon the surface, and plowed in, with feered ridges, the feerings should have been so made as to leave a ½ ridge at the side of the field, that now, when the land is about to be plowed for the seed-furrow, the ½ ridge is converted into a whole one, and the field thereby made fit to be continued in that form.

(2319.) But a practice has come into use since the introduction of the grubber, Plates XXIX. and XXX., which possesses some advantages, on strong land, in certain circumstances, which is to cover in the sown wheat with the grubber, instead of first plowing the land for a seed-furrow, and to finish the work with a slight harrowing. When the grubber is contemplated to be thus used, the land, in summer-fallowing, should be feered in ridges, as if for the seed-furrow, when covering in the dung, as the subsequent grubbing will not alter the form of the ridges farther than to reduce their crowns, and fill the open-furrows a little. When a tough, waxy clod is expected to arise on plowing strong land, rather wet below, for a seed-furrow, or when there is appearance of unsettled weather, the grubber will be found useful in keeping dry the meliorated soil on the surface, and also in getting quickly through with the wheat-seed.

(2320.) Land that has grown *beans* is usually gathered-up for the seed-furrow at once, and sown immediately, as the season is far advanced by the time the bean-crop is carried in and stacked; but the seed-bed would certainly be in a better state for wheat were the land allowed to subside for a few days before the seed is sown. Where the land is strong, and the ridges are sufficiently rounded, the grubber may be used on bean-stubble, as on fallow-land, for covering in the wheat sown broadcast on it, but for this purpose a 4-inch grubber is required, the surface being finished with a slight harrowing. The grubber will succeed in this very well, in as far as the wheat is concerned, and it has a great advantage in a late autumn in getting through the work expeditiously; but on strong land, not thorough-drained, and in a comparatively flat state, grubbing will not succeed on bean-stubble; at least, the wheat-seed would incur considerable risk of being rotted in that state of the soil all winter, and the land itself of becoming soured; and the land would not escape the effects of such an injury, even though it should be fallowed the succeeding year.

(2321.) The land which has grown *potatoes* should be plowed for a seed-furrow, because, having been laid flat for the culture of this summer crop, the grubber cannot be employed with advantage in the case, as that implement leaves the land as flat as it found it. The land only receives 1 furrow after potatoes; and it should have time to subside a little, though the usual practice is to sow the wheat upon it as soon as plowed. The reason why I have frequently recommended the subsidence of the land before being sown with seed is, that wheat thrives better in soil having a little firmness in it than in the loose state the plow leaves it.

(2322.) When the land is naturally strong enough to grow wheat, but is

somewhat soft, and so wet below as to make it apt to throw out the wheat plant in spring, the best plan is to make a seed-bed by *ribbing* with the small plow, fig. 320, and (1748). The wheat is sown broadcast over the ribs, and harrowed in with a double-tine along (1769). The ribbing gives the wheat a deeper bed in the soil than mere harrowing, and a deeper hold of the soil in spring, and it has also the advantage of stirring only the dry surface-soil for the seed-bed. It can only be practiced, however, on land that has been ridged up for a seed-bed for a considerable time, as the small plow does not make good work on new-plowed land, it, small as it is, going too deep, and making the drills too wide; and it is never employed on land that has not been ridged, being unfit to turn up land in a hardened state.

(2323.) Another mode of preventing the throwing out of the wheat plant in spring on soft land, otherwise well adapted for wheat, is, first, to feer the land into ridges, sow the wheat broadcast between the feerings, and cover it in with a light seed-furrow, leaving the land unharrowed and rough all winter.

(2324.) Whether harrowed or not, it is of great importance to leave wheat land *rough* all winter, that is, with a round large clod upon the surface. These clods afford shelter from wind and frost to the young plants, and when gradually mouldered by frost, serve to increase the depth of the loose soil, and protect the roots of the plants from frost. Indeed, whenever the land is harrowed as fine as meal with autumn wheat, the rain never fails to batter its surface into a crust, and the frost heaves it up in spring like fermented dough; and this action raising the plants along with the soil, they are exposed on the surface after the frozen earth has subsided, on being thawed by sunshine (1772). Such an effect, however, can only occur where a considerable quantity of moisture exists under the surface of the soil, ready to be acted on by frost. Draining, then, is the only safeguard against the young wheat plant being thrown out of the earth in spring. As the ground is desired to be left in a rough state in autumn, no use is, of course, then made of the roller.

(2325.) Autumn wheat is almost always sown broadcast in Scotland, except, perhaps, in the neighborhood of large towns, where it is sown with the drill, Plate XXVII., figs. 325 and 326; and the reason why the drill is used in that particular locality is the facility afforded by the drilled rows to hoe the land free of surface weeds, which invariably make their appearance where the street manure is used. In England wheat is very generally drilled, for the reason just given, and surface weeds seem more generally numerous and troublesome throughout England than Scotland. Sowing broadcast is represented by fig. 322, and is fully described from (1756) to (1766). The machines for sowing grain in drills will be found fully described by Mr. Slight from (1824) to (1829).

(2326.) Wheat is *pickled* at this season, as well as in spring, before it is sown, and the reasons for treating it thus, as far as they are known, as well as the best method of doing so, will be found described in (1754) and (1755).

(2327.) Almost every year some new variety of wheat, of great reputation, is offered to public notice, and no doubt a good variety may thus occasionally be obtained. But the safe plan for you to follow is to adhere to that variety, or those varieties, which have succeeded in the district in which you farm; because one variety may succeed well in that locality, and not another. It is right to try experiments in growing new varieties which are well recommended, and you should give such experiments every justice; but until the fact is proved by yourself or your neighbors, that

the recommended wheat is a good one for your locality, it should not be extensively cultivated. The good properties of wheat are: heavy weight, fine sample, prolific per acre, and plenty of clean straw. A good weight is from 62 lbs. to 66 lbs. per bushel; it is now, however, as easy to obtain 65 lbs. as it was a few years ago to get 63 lbs. a bushel. Years ago, 24 bushels per acre were considered a fair crop on ordinary wheat land; it is now as easy on the same soil to raise 32 bushels. The greatest difference in these results has been realized in the course of years, from the inferior, not the superior classes of soil.

(2328.) There are other modes than those I have mentioned of sowing wheat on fallow ground. One of these is *dibbling*, and there are various ways of dibbling wheat. One is to make a hole not exceeding 2½ inches deep, with a dibble not so thick as that used for planting potatoes in gardens, to drop 1 seed or 2 into it, and to cover them with earth with the foot; the holes being made 4 inches apart, and 7 inches wide between the rows. But this is a very slow process. A more expeditious plan is to use an implement of a cylinder of wood 6 feet long, 4 inches in diameter, and divided lengthways by the middle, to make into 2 dibbles. Pins of wood of a conical form, 3 inches long, are driven perpendicularly at 4 inches apart into the apex of the curved side of the split cylinder. This implement forms a number of dibbles, by being laid along the ground with the pins downward, which are pushed into the ground with the pressure of the foot, to make as many holes as there are pins. The implement being removed by means of a handle attached to its flat side, boys or girls drop 2 seeds into each hole, and cover them with earth. Another and more certain plan of dibbling is this: a flat, thin board of wood is provided with holes 4 inches apart in the row, and the rows 7 inches asunder. This is laid flat on the ground, when small dibbles are pushed through the holes to the requisite depth of 2½ inches into the soil, the depth being determined by a shoulder on the dibble; 2 seeds are then dropped into the hole as each dibble is withdrawn; and when the board is lifted up from the space it occupies to another space in advance, the earth is brought over the holes and seed by the foot. It is asserted by those who have sown wheat by dibbling, that about one bushel is sufficient seed for one acre, and that the produce will be 5½ quarters per acre; that is, the produce bears a proportion of 44 to 1 of the seed sown.*

(2329.) Another mode of sowing wheat has a similar effect in the appearance of the growing crop as ribbing with a small plow, and this is accomplished by using the *common plow with a single horse*, and depositing the seed, and along with it, if necessary, any species of manure dust, such as rape-dust, in the furrow. The seed is dropped out of a hopper placed in the bosom of the plow, and the quantity is regulated by a grooved axle, made to revolve by a small wheel, which receives its motion by being carried along the ground with the plow. The immediate effect of this operation is to cover the seed-wheat with the plow-furrow, to prevent its being thrown out by the frost in spring in soft and spongy land, and to cause the crop to grow in rows 9 inches asunder. The pulverized manure is sown at the same time and in the same manner as the seed, out of the same hopper in which a division is formed to separate the seed from the manure, and both fall through spouts, one placed behind the other. Such a drill has already been described by Mr. Slight in (1770) and (1771). The advantages resulting from this mode of sowing wheat on spongy clay soil are, that the horse does not tread on the seed, and the seed requires no covering in by the harrow. It is necessary, however, to caution you in the use of rape-dust and guano in contact with seed, as both are apt to affect the vitality of seeds, without the intervention of a little soil, or the previous mixture of a little earth.†

(2330.) Another mode recommended for cultivating wheat is *transplanting*. It is proposed to sow a small portion of ground with seed early in the season, and take up the plants as they grow, divide them into single plants, and transplant them. By thus dividing the plants as they tiller into single plants at 4 periods of the season, a very small quantity of seed will supply as many plants as would cover a large extent of ground. Though wheat no doubt bears transplanting very well, yet as the scheme implies the use of much manual labor, it is questionable if it will repay the expense. The proposed method has been tested by experiment, and the question of comparative expense stands thus: Suppose 440 grains of wheat are sown on the 1st of July, by the beginning of August each seed will afford 4 plants, or in all..... 1,760 plants.

At the end of August these will produce.....	5,280 ..
In September these again.....	14,080 ..
And in November these last will produce	21,120 ..

The *time* occupied in sowing the 440 grains, and dividing and transplanting the produce of them, stands thus:

			Hours.	Minutes.
" July, sowing	440 grains		0	20
August (beginning), taking up	440 plants		0	20
.. dividing into.....	1,760	..	1	10
.. planting	1,760	..	3	30
August (end) .....taking up	1,760	..	1	28
.. dividing into.....	5,280	..	3	30
.. planting.....	5,280	..	10	33
September.....taking up	5.280	..	4	24
.. dividing into.....14,080		..	9	22
.. planting.....14,080		..	28	9

* See Mark Lane Express for February, 1843. † See Mark-Lane Express for November 24, 1862.

			Hours.	Minutes.
November	taking up	14,080 plants	11	44
..	dividing into	21,120 ..	14	4
..	planting	21,120 ..	42	14
			120	49."

Nearly 13 days.

Of these 13¼ days, 4½ days may be reckoned for women and boys occupied in taking up and dividing the plants, which, at 10d. per day, will cost 3s. 9d. The remaining 9 days are for men transplanting at 10s. per week, 1s. 8d. a day, which will cost 15s. more; in all 18s. 9d. per acre. As the saving of seed was estimated at 16s. 6d. per acre, the expense of transplanting would thus be greater than the saving effected. It appears, besides, from Mr. Palmer's small but well-conducted experiments, that 10 plants out of 48 died, which is a large proportion, leaving more than 1-5 of the ground blank, while the return of the produce does not warrant the supposition that the remainder would make up the deficiency; the 2½ lbs. of grain from the space of ground experimented on is not more than 20 bushels per acre, and still, after adding ¼ to this for the destruction of seeds occasioned by birds, the whole amount, only 25 bushels, would not be a full crop. Taking 2d. an hour as the fair cost of a man's labor, the cost of transplanting would be £1 12s. 9d., to set against the 16s. 6d. of seed saved; and supposing the plants to be set as far apart as 1½ feet, the cost would still be £1 4s. 8d. per acre. "In my opinion," says the experimenter, "the only way of executing this plan is to dibble in the seed, 2 grains in a hole, about 4 inches from each other, the plants to be taken up when they are in a proper state, and divided into 5, which would be as many on an average at that time as could skillfully be made, and then planted out at once, where they are to remain, thus getting rid of all the intermediate dividings. The number of grains of wheat required for 1 rood would be 42,240, which would not exceed 1 pint at farthest, as I have ascertained by actually counting that quantity; and, consequently, 1 pint of wheat will plant 21,120 holes. If each hole gives 5 plants on an average, which may be reasonably expected, there would be at the disposal of the farmer 105,600 plants, a quantity sufficient to plant 5 acres, at 17½ inches apart. If farmers were to adopt a system of this kind, there is little doubt but it would soon gain ground in the country. Seed for 5 acres, sown in the usual way, would cost about £4 12s. 6d., whereas 1 pint of wheat would only cost about 1 penny. The plants may be taken up, separated, and planted again by 50 people in one day; 25 taking up, dividing, and supplying 25 planters, allowing each to plant 4,224 per day, and this might be wholly done by boys and girls at 6d. per day; consequently, the farmer's saving, exclusive of the original cost of dibbling 1 rood, would be £3 7s. 5d. per every 5 acres, as thus:

"Cost of seed-wheat for 5 acres			£4 12 6
Cost of 1 pint of seed-wheat	£0 0 1		
Dibbling it in ¼ of an acre	0 0 0		
Taking up and planting	1 5 0		
		1 5 1	
			£3 7 5"*

(2331.) The object of these various modes of sowing wheat is the *saving of seed*—a great object certainly, when it is borne in mind that 1-14 of the whole grain grown in the country is consigned to the earth in seed. From the statement just given in regard to the transplanting of wheat, it appears that 4 English pints of wheat are capable of supplying a sufficient number of plants for 1 acre. By ordinary drilling, 3 pecks are enough seed for 1 acre, according to a statement of Mr. Hewitt Davis, whose wheat crops average 4½ quarters per acre on poor soil, which is manured when the green crops are sown, and by sheep eating green crops off the land. His profits from farming seem to arise solely from the economical system of management he pursues. "The soils I cultivate," he says, "are naturally very poor. Two of my farms are principally gravel, and most of one is a moorish, boggy gravel, extremely spongy in winter, and very apt to burn in summer, and formerly in the state of, and similar to, the heaths at Bagshot and Blackheath. The other is a very hilly farm, with but few inches of soil, on chalk. These farms have been greatly improved by the use of the subsoil and trenching plows; but they are *only kept in profitable tillage by the general economy of the system.*"†

(2332.) But practice has always tended against the use of a small quantity of seed; and the practice is sanctioned by the fact that, though large quantities of seed are usually sown, in many seasons the young plants come up rather scanty. There is a circumstance attending the germination of seed which may account for much of the seed being destroyed by the insect tribe, especially if the weather be such as to cause its germination to be tardy. The circumstance I allude to is the nutritive matter of the seed, which constitutes its largest proportion, speedily becoming fluid after being sown, by absorption of moisture, then milky in its aspect and sweetish in its taste. In fact, a good deal of saccharine matter is always evolved in the process of germination. Now, as all creatures are known to be fond of sugar, the germinating seeds become a ready prey to hosts of insects constantly existing in the soil; and should the progress of germination be retarded, by any cause external to the seed, we can easily conceive that injury derived from insects may soon render the seed useless for the purposes of vegetation; for, if the nutritive matter be extracted, there is nothing to nourish the rudimentary plant, as it is not then sufficiently developed to draw nourishment from the soil.

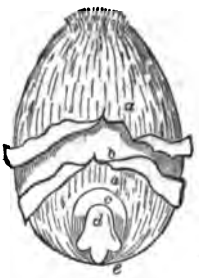
(2333.) Fig. 432 represents a grain of wheat magnified, and so dissected as to show its component parts. It consists of 2 skins, an outer and an inner—*a a* the outer, and *b* the inner, skin; *b* is where the nutritive matter, called the *albumen*, is situate, and it constitutes the whole seed, and

* The Gardener's Chronicle for October, 1843.

† Bell's Weekly Messenger for Sept. 1843; and see also Mr. Davis's pamphlet on the same subject.

is mostly hid beneath the skins; *c* is the little scale or cotyledon through which the nutritive matter passes in the sweetish state, when the grain is germinating, and by which it is rendered most fit for the nourishment of the little plant; *d* is the rudimentary plant, at the base of which 3 tubers may be seen, from which as many roots or stems, or both, will afterward proceed; and *e* is the point where all the 3—the nutritive matter, the little scale, and the rudimentary plant—are united. All these parts are essential to the growth of the seed; for, when any one of them is absent by accident or design, the seed fails to spring.

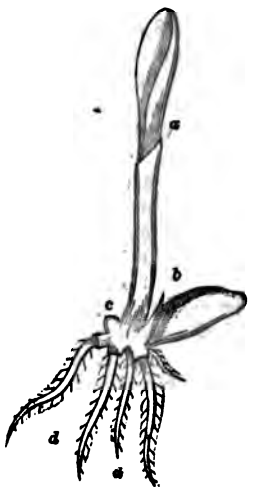
Fig. 432.



THE COMPONENT PARTS OF A GRAIN OF WHEAT.

(2334.) The seeds of almost every species of plant naturally possess such a structure that only 1 stem can proceed from them; but in the grasses, and more particularly in the cereal grasses—that is, those which yield corn—there is observed a remarkable departure from this form of parts. In them the embryo plant is usually thickened toward its base, and so organized that, instead of 1 stem, 3 or 4 usually spring from 1 grain; and, in other cases, a number of stems so great has issued as almost to exceed belief. The peculiarity mentioned may be observed at *d*, fig. 432, which is the rudimentary plant, having 3 projections in the lower part, while in another seed there would have only been 1; and from each of these a rootlet or a stem, or both, will proceed when the grain is placed in the soil. Fig. 433 represents the grain in a state of germination, 1 shoot *a* having left the sheath, another *b* is just evolved, and a third *c* remains unevolved; and *d d* are the rootlets. It is this peculiarity of structure which compensates, in some degree, for the loss arising from the destruction of seed. The germination of autumn wheat takes place in about 17 or 19 days. The force of the vegetation of a single seed is so great as to be able to raise a weight of 200 lbs., as has been proved by the process being made to split hollow balls, in the same manner as the Florentine academicians measured the expansive force of freezing water.

Fig. 433.



A PLANT OF WHEAT IN THE STATE OF GERMINATION.

(2335.) There is a valuable property in the growth of wheat which I must not omit to mention, which is, that the wheat plant pushes out 2 sets of roots, the one from the seed, and the other from the crown of the plant, from which the leaves originate.—The *seminal* roots as *d*, fig. 433, push out from the seed wherever it may have been sown, provided the depth does not exceed 7 inches; but the *coronal* roots always push out as at *a*, fig. 433, very near the surface of the soil, not much exceeding 1 inch below it. The existence of those 2 sorts of roots clearly indicates the nature of the plant to bear sowing both in winter and spring; and the relative position of the roots indicates the differences of culture which should be given to the plant in winter and spring. In winter, wheat-seed should be pretty well covered with soil, say 4 inches, in order to be placed beyond the influence of frost, but in spring it should be sown nearer the surface. "The first or *seminal* root," says a writer in the Georgical Essays, quoted by Colonel Le Couteur, "is pushed out at the same time with the germ—which, together with the farina, nourishes the plant until it has formed its crown." "In the spring, when the crown has become sufficiently large, it detaches a number of strong fibres, which push themselves obliquely downward. These are the *coronal* roots. A small pipe preserves the communication between them and the seminal roots, and it makes an essential part of the plant; and is observed to be longer or shorter, according to the depth that the seed has been buried. It is remarkable, however, that the crown is always formed just within the surface; its place is the same, whether the grain has been sown deep or superficial. I believe I do not err when I call this *vegetable instinct*. As the increase and fructification of the plant depend upon the vigorous absorption of the coronal roots, it is no wonder that they should fix themselves so near the surface, where the soil is always the richest. From an attention to this circumstance, we are led to explain the operation of *top-dressings*." . . . . "Wheat sown superficially," continues the same writer, "must be exposed to the severity of the frost, from the shortness of the pipe of communication. The plant in that situation has no benefit from its double root. On the contrary, when the grain has been perfectly covered, the seminal and coronal roots are kept at a reasonable distance. The crown, being well nourished during the winter, sends up numerous stalks in the spring. On the *tillering* of the corn, the goodness of the crop *principally depends*." Spring-sown wheat, having no time to tiller, may therefore be sown nearer the surface, and also thicker than autumn-sown. Viewed in this light, drilled wheat in spring should grow more equally than seed covered in with the harrow; for, as this writer justly observes, "a field of wheat, dibbled, or sown in equidistant rows by the drill-plow, always makes a better appearance than one sown with the harrow. In the one, the pipe of communication is *regularly of the same length*, but in the other *it is irregular, being either too long or too short*." I would say, with Colonel Le Couteur, that the exact depth at which wheat should be sown is a question of local experience, bearing relation to the nature of the soil and climate.

(2336.) As to the natural tillering of wheat, some varieties evince extraordinary powers in that respect. Colonel Le Couteur mentions that "one plant from a single grain of a downy variety, in 1833, threw out 32 tillers; all produced ears, with an average of 50 grains to each, or 1 600 grains

from 1—an enormous produce," as the Colonel regards it, but judiciously adds, "which no field cultivation could be fairly expected to attain, as it is not the extraordinary quantities which art may produce, either by *extreme care, subdivision, and transplantation*, that should be brought under the consideration of farmers; but the *fair and legitimate mode of husbandry*, attainable to all who will devote to its pursuit that industry and inquiry without which their art is a mere mechanical operation, throwing in a little seed into the ground, and leaving Nature to do the rest."*

(2337.) Early sown wheat, when growing luxuriantly in autumn, is sometimes affected by slugs in damp weather. Mr. Wentworth, of Harlow, gives this recipe for destroying them: "Provide, fresh from the kiln, as much lime as will allow 5 bushels to the acre. Slake it 2 days before sowing; choose a calm and mild morning; commence sowing early enough to finish before daylight; and 1 man can sow 1 acre per hour, sowing 2 yards at a cast." Turnip-leaves have been recommended to be laid upon wheat, and, as slugs readily take shelter under them, they can thus be collected and destroyed. Of the 2 modes of destruction, I should conceive the quicklime to be the more efficacious, especially in moist weather.

39. EGGS.

"Mine honest friend,
Will you take eggs for money?"
WINTER'S TALE.

(2338.) The treatment which every kind of poultry should receive in autumn is that recommended in spring (1939), to be followed in summer. Geese, ducks and turkeys should only hatch in spring and the early part of summer; for late hatchings of these never produce birds worth rearing, as they cannot attain in the same season a tolerable size and degree of fatness. But common fowls may be hatched throughout the summer, and even to a late period in autumn, and the chicks be reared to a useful state. What can constitute a more delicate dish than a chicken, boiled, roasted or broiled, at any season, but especially when the productions of the garden are in the highest state of perfection, in summer and autumn?

(2339.) Hens are fond of making their own nests and bringing out broods in corn-fields, and at the roots of hedges and shrubs; and *when hens have their liberty during the day*, it is impossible to prevent their following this inclination, which is common to all, under the best regulated system; and so high a value do I set upon liberty to these creatures, on the score of health and strength of body, and flavor in flesh, that I would rather run the risk of losing a few broods in the year, by the fox and polecat making free with a self-set hen or two upon nests of their own seeking in corn-fields, than see them cribbed in summer within a court of the largest dimensions.

(2340.) One of the daily cares of the hen-wife in summer and autumn is the *gathering of eggs*. Whenever a hen is observed to show a desire to lay, a nest should be provided for her in a quiet and convenient place, and if she is directed to it at the commencement of her laying, she will continue to frequent it ever after, if undisturbed; but a nest is not required for every laying hen, as several will lay in succession in the same nest, some hens laying earlier in the day than others; and so tenacious are they of their right to particular nests, that two hens will not unfrequently occupy the same nest at the same time.

(2341.) Every place is not equally suitable for a hen's nest. In other places than the hen-house, hens are not fond of laying their eggs on a level with the ground, though a quiet corner in a shed under some shelter is not unfrequently selected by themselves for the purpose; but they

* Le Couteur on Wheat; and it is but justice to Mr. Lawson, of Elgin, to state that he detected this peculiarity in the germination of wheat, when too deep sown, so long ago as 1837—as may be seen by referring to No. VI. of the Old Series of the British Farmers' Magazine.

usually prefer to be elevated above the ground, such as in the mangers of stables, or in a trough of a shed or hammel, or upon the top of the wall of a stable, byre, or outhouse, immediately below the roof. When nests are made in such places as hens would themselves prefer, they are much more likely to be frequented than when an opposite determination is taken. One reason, perhaps, for their preference to the manger of the work-horse stable is that in daily picking up morsels of food dropped there by the horses, while the latter are at work in the field, the manger presents a convenient place on the spot when the pressure for laying overcomes them.

(2342.) Ducks are very careless layers, dropping their eggs wherever they seek for food, and these, when discovered by the pigs, are champed up as the most delicate morsels that fall in their way. Common rooks watch for such stray eggs, and carry them off even out of the courts of the steading. To secure the eggs of ducks, the birds should be examined before being let out in the morning, and those indicating hard with egg should be confined in the hen-house till they have laid, and afterward let at large.

(2343.) It should be the hen-wife's duty to visit every nest and collect the eggs from them every day, and the period of creating the least disturbance to the poultry in this duty is the afternoon, say between 2 and 3 o'clock, before the birds begin to retire to roost. A nest-egg should be left in every nest; because it is an old established fact, that all domestic birds, at least, prefer to lay in nests containing eggs to those which are empty. Eggs are most conveniently collected in small hand-baskets; and a short, light ladder will give easy access to all nests elevated above reach from the ground.

(2344.) Whether eggs are retained for use at home, or disposed of to the egg-merchant, it is of importance to keep them in a fresh state for some time. This end may be attained by preventing the air penetrating the pores of the shell, and the yolk coming in contact with its inside. A simple and effectual way of preventing the air penetrating the shell is to rub the egg over with butter when taken warm from the nest; and as simple a way of preventing the yolk adhering to the inside of the shell is to roll the egg from one side to the other every day. This treatment eggs should daily receive, whether kept for your own use or sold to the dealer, and it will preserve them in quite a fresh state for several weeks. But I need hardly inform you that this is not the general mode of treating eggs in farm-houses, whether intended for use at home or for sale, they being commonly kept in promiscuous heaps, and used in the state when taken from the nest; and if they are habitually used on the day they are laid, no unnecessary trouble is required to be taken with them. When trouble is desired to be avoided with eggs, they are sold to the dealers every week in spring and early summer, when most abundant; but the price is then very low, not above perhaps 4d. per dozen—a price unremunerative for the least degree of care bestowed on fowls. If it is desired to render eggs a remunerative item of farm economy, they should be preserved in a fresh state until the season of scarcity arrives, when, of course, they would realize a fairer price. It is easy to preserve eggs to that season by simply smearing them with butter immediately from the nest, and setting them on their small ends among salt in barrels in a dry room. They may be kept in this manner for 7 months, at least I have found them *quite fresh* at the end of that period, so much so, that they contained the very *milk* which constitutes the criterion of an egg being fresh when boiled; and how much longer they would have remained in that state I cannot say, as I never tried the experiment farther. I have heard of an instance

of eggs packed in salt becoming so salted as to be useless; but in this case the salt might have been damp, and the eggs might not have been greased at all. Both circumstances are material, for without grease air cannot be excluded, and I know that new-laid eggs will soon become salt when floated in *brine*. Eggs will also keep fresh in a barrel of lime-water; but the dry salt, in a dry chamber, is a much more agreeable material to put the hand among every day. In short, they may be kept in any way that will exclude the air entering the shell; but whatever other additional expedient is adopted, that of greasing them with butter immediately from the nest should never be neglected.

(2345.) Hens begin to lay about the beginning of March, and continue to the beginning of October. They do not lay every day, that is, every 24 hours, some laying every other day, and some missing one day in three. They lay about 2 dozen of eggs at one period, then cease for 2 or 3 weeks, and again lay other 2 dozen, and so on for the number of months mentioned. Of all these months, however, they lay most constantly in March and April. After each period of laying they are inclined to sit on the eggs, and when it is not desirable for them to incubate, it is difficult, in most cases, to drive them from their propensity to *clucking*, as it is commonly called.

(2346.) Many cruel expedients are practiced by country people to prevent hens clucking, such as ducking them in water, dipping them in water for a few seconds, pulling feathers in a particular manner out of particular parts of their body, and such like barbarities—all of which I believe to be ineffectual, at least I never saw a single instance of their success. The only effectual plan I know, without giving bodily pain to the animal—for if it is desired to have hens to lay eggs in preference to hatching chickens, it is requisite to remove from them the desire to sit—is to place them in darkness, and there deprive them of food and water for 2 days and 2 nights, and, in difficult cases, for the third day. The simplest means of accomplishing this is to procure a number of light-made tubs, each just large enough to hold one hen within it when standing on her feet, and to have its top and sides pierced with holes to afford air, but so small as to exclude light, and to give them such an inclination as the hen may not see through them. Such a tub is placed mouth downward over a hen, in a quiet place, such as an out-house, and not in the hen-house. In this position, the desire to sit will be removed from her in 2 days, and in obstinate cases in 3 days. It is not an uncommon practice to whelm an ordinary tub over a number of hens, with one side of its mouth raised a little from ths ground, the effects of which contrivance are to allow as much light to enter the tub as to let the hens see to fight each other, and in many such cases they are removed with their scalps bared to the bone, and even pecked and trampled to death.

(2347.) Neither dogs nor children should be allowed to run after laying hens, as such treatment obliges them to lay their eggs before they are provided with the shell. Guinea fowls are incessant chasers of hens.

(2348.) Ducks are great layers, laying an egg almost every day. They commence at the beginning of April, and cease at the season the bean usually comes in bloom—in July.

(2349.) Autumn is the time to select hens for laying the eggs in the ensuing winter. They should all be young, but of different ages, that a succession of layers may be maintained during the season, as I have mentioned before in (1473), and the food they should receive I have also mentioned in (1939). Like the eggs collected in summer, those dropped in winter should also be smeared with butter when taken from the nest.

Hens readily taken to the nests made for them at this season, evincing little desire to make them in the fields for themselves. Autumn is the season of moulting with fowls. The only care requisite under this periodic visitation, is to keep the creatures warm at night, for chillness of air may be looked for at nights in October.

(2350.) *Pigeons* will produce a young brood in every month in autumn, and in this season of heat and abundance of food, both old and young become full-sized and in fine condition. They should be fed in common with other poultry; but though this be regularly practiced, they are fond of going to the fields in search of variety of food. Fields of new-sown peas, oats, barley, and wheat, are eagerly visited by them in quest of grain that has escaped burial by the harrow. Even the turnip-seed is eagerly sought for in a new-sown field; and where the wheat crop is laid by the weather, there they will congregate in flocks, and pick out every kernel within their reach. For wheat and pease they will fly miles to obtain. It is, no doubt, provoking to see corn nearly ready for the sickle destroyed in the field by any kind of animal; but a farmer regards the depredations *of his own pigeons* in a pardoning mood.

(2351.) Turkeys and geese commit sad havoc in corn-fields situate near the steading, for a week or two before harvest—a sight intolerable to the farmer, not so much on account of the quantity of grain actually consumed, as for that scattered about and trampled down. When corn happens to be growing near the steading, all the poultry should be confined within court-yards for a time, and supported entirely by hand. A few sheep-nets stretched over the court-walls of hammels, afford an easy means of confining a large assortment of poultry, and of subdividing them into classes.

(2352.) The egg, being a remarkable object, and produced in such abundance, and so universally esteemed as an article of food, a few particulars obtained by men of science of its nature and constitution may prove interesting to you.

(2353.) "The *eggs* of all birds," says Dr. Thomson, "so far as they have been examined, bear a striking resemblance to each other. They consist of 4 parts, *first*, the *shell*, which is white in the eggs of the common fowl, and of many other kinds; but it is often colored or spotted of various colors, so as to give it a beautiful appearance; *second*, the *membrana putaminis*, a thin, transparent pellicle, immediately within the shell; at the great end of the egg this membrane is detached from the shell, leaving a certain distance between them, which is filled with air; *third*, the *white* or *albumen*, a glairy liquid, consisting of albumen dissolved in water, and contained, like the vitreous humor of the eye, in an extremely thin membrane, divided into cells: *fourth*, the *yolk*, a thick and almost solid yellow matter, inclosed in a peculiar membrane; this membrane, by 2 ligaments, called *chalazæ*, is tied to the membrane of the albumen, and thus the yolk is kept in the center of the egg."

(2354.) In regard to the constitution of these various parts, it appears from an analysis of Dr. Prout, which was later than that of Vauquelin, that the *shell* of the common fowl consists of

Carbonate of lime, with a little carbonate of magnesia	97 parts.
Phosphate of lime and magnesia	1 ..
Animal matter	2 ..
Total	100 parts.

The *membrana*, according to Hatchett, consists of coagulated albumen. The *white*, or *albumen*, coagulates into a firm white solid, when heated to 159° Fahr.; and when evaporated to dryness, leaves about 14 per cent. of albumen. Dr. Bostock has shown that it contains also a little mucus. The constitution of the white, according to him, is

Water	80
Albumen	15·5
Mucus	4·5
Total	100·

Dr. Prout obtained, by combustion, the following fixed constituents in 1,000 grains of the white of egg, from 3 different eggs:

Sulphuric acid	0·29	0·15	0·18	grains.
Phosphoric acid	0·45	0·46	0·48	..
Chlorine	0·94	0·93	0·87	..
Potash, soda, and carbonates of potash and soda	2·92	2·93	2·72	..
Lime, magnesia, and the carbonates of lime and magnesia	0·30	0·25	0·32	..
Total	4·90	4·72	4·57	grains.

M. Mulder has proved that the sulphur and phosphorus are in the state of sulphur and phosphorus, and not in that of acid; and this was to have been expected, from the well known alkaline reaction of the white of an egg. Dr. Prout's analysis of the *yolk* of an egg which was hard boiled in distilled water, and weighed 316·5 grains, gave these results:

Water	170·2 grains	or	53·78	in 100 parts.
Albumen	55·3	..	17·47	..
Yellow oil	91·0	..	28·75	..
Total	316·5	..	100·00	..

According to Planche, 1,000 parts of yolk of egg furnish, at an average, 180 parts of oil. This oil consists of stearin 10, and of elain 90 parts; the stearin is white and solid, and does not stain paper like oil. He found this stearin and the fat of fowls to agree very nearly. The elain possesses the character of a fixed oil. Chevreul found 2 coloring matters in the yolk, the one *red*, and the other *yellow*. Lecanu, besides the stearin and elain, extracted from the yolk a crystaline matter, which melted at 293° Fahr., and which he considered as of the same nature with cholesterin from the brain. Dr. Prout determined the quantity of fixed constituents in 100 grains of the yolk, by incineration, in 3 different eggs, thus:

Sulphuric acid	0·21	0·06	0.19	grains.
Phosphoric acid	3·56	3·50	4·00	..
Chlorine	0·39	0·28	0·44	..
Potash, soda, and the carbonates of potash and soda	0·50	0·27	0 51	..
Lime, magnesia, and the carbonates of lime and magnesia,	0·68	0·61	0·67	..
Total	5·34	4·72	5·81	grains.

Whether the sulphur and phosphorus exist in the yolk in the state of acids, or as sulphur and phosphorus, is unknown. When we compare the fixed constituents of the white and yolk, we cannot avoid being struck with the difference. The *white* contains a much greater quantity of fixed alkalies than of any other fixed constituent; while in the *yolk* the most abundant constituent is phosphoric acid, which amounts to from 3·5 to 4 grains; or if we suppose it to exist as phosphorus, it varies in different yolks from 1·55 to 1·77 grains.

(2355.) The specific gravity of a new-laid egg varies from 1·080 to 1·090; an egg, therefore, is heavier than sea-water, the specific gravity of which is 1·030. When kept, eggs rapidly lose weight, and become specifically lighter than water. This is owing to the diminution of bulk in the contents of the egg; the consequence of which is, that a portion of the inside of the egg comes to be filled with air. Dr. Prout kept an egg 2 years, and found that it lost weight daily, at an average rate of 0·744 grains. The original weight was 907·5 grains, and after 2 years' exposure to the atmosphere, it weighed only 363·2 grains. The total loss amounted to 544·3 grains, or considerably more than half the original weight. The loss in summer was somewhat greater than in winter, owing, no doubt, to the difference of temperature. When an egg is, therefore, employed as a test of the strength of brine, the newer it is, the stronger is the brine that floats it. The relative weights of shell and membrane, albumen and yolk, are very different. Supposing the original weight of the egg to be 1,000 grains, Dr. Prout found the relative proportions, in 10 different eggs, to be as follows: Shell and membrane 106·9, albumen 604·2, and yolk 288·9 grains. When an egg is boiled in water, it loses weight, particularly if it be removed from the water when boiling, and be permitted to cool in the open air. The water will be found to contain a portion of the saline constituents of the egg. The loss of weight from boiling is not constant, varying from 20 to 30 grains, supposing the original weight to have been 1,000 grains. The quantity of saline matter obtained by evaporating the distilled water in which an egg was boiled, amounts, at an average, to 0.32 grains. It is strongly alkaline, and yields traces of all the fixed principles found to exist in the egg; but the carbonate of lime is most abundant, and is obtained by evaporation in the form of white powder.

(2356.) The source whence are derived the bones of the chick while in the egg, is still an object of research. At the full term of incubation, important changes in the constitution of the egg are completed. "The albumen," as Dr. Thomson observes, "has disappeared, or is reduced to a few dry membranes, together with earthy matter. The yolk is considerably reduced in size, and is taken into the abdomen of the chick, while the animal has attained a weight nearly equal to the original weight of the albumen, together with that lost by the yolk, minus the loss of weight sustained by the egg during incubation. The alkaline matters and chlorine have diminished in quantity, while the earthy matters have considerably increased. . . . . During the last week of incubation, the yolk has lost most of its phosphorus, which is found in the animal converted into phosphoric acid, and, combined with lime, constituting its bony skeleton. This lime does not exist in the recent egg, but is derived from some unknown source during the process of incubation. Mr. Hatchett made the curious remark, that in the ova of those tribes of animals the embryos of which have bones, there is a portion of oily matter, and in those ova whose embryos consist entirely of soft parts, there is none. In what way the oily matter contributes to the formation of bone it is impossible, in the present state of our knowledge, to conjecture. Nor can any source of the lime of the bones be pointed out, except the shell; and it would be difficult to determine whether the shell loses lime during the process of incubation."*

(2357.) M. Raspail, in investigating the nature of animal albumen by the microscope, as exemplified in the white of the egg, observes that "the albumen of the pullet's egg is composed of an insoluble and regularly organized texture, which contains in its cells a soluble substance much more susceptible of alteration than the texture is. Chemists had previously acknowledged the existence of an albumen soluble in water, and of another which was insoluble; but they had not remarked that these 2 sorts of albumen existed together in the white of eggs, and they had consider-

* Thomson's Chemistry of Animal Bodies.

ed this substance as a variety of the insoluble albumen. . . . . But the insoluble substance of the white of an egg is rendered apparent only by degrees, and accordingly there is a period when it can scarcely be distinguished in this respect from the soluble substance, and this is when the egg is fresh, that is, recently laid. Hence, as I have already pointed out regarding the vegetable textures, the textures are formed by the aggregation of the particles of the soluble substance, or, in other words, the soluble substance is converted by solidification into the parietes of cells. All these circumstances establish a complete analogy between *gluten* in vegetables and *albumen* in animals."*

(2358.) Of the nature of egg and seed, the origin of animal and vegetable individuality, and of the natural analogy between them, M Raspail thus expresses himself: "The egg and the seed are cells detached from the texture of the mother, in consequence of an influence of an opposite kind. This influence may proceed from an external body which we call the male, or from an internal cause which we altogether neglect to notice. The egg and the seed may more particularly attract our attention, in consequence of their forms and dimensions; but the slice of a polypus, which becomes an entire animal, and the fragment of a potato, which produces a complete plant, are sufficient to teach us that the generative faculty is preserved by the whole organic system, and that the whole organized being is complete in any one of its cells."†

(2359.) The duty on the importation of foreign eggs is fixed by the new Tariff at 10d. per 120, and 2½d. from British Possessions. The trade in eggs is carried on to a very great extent in this country. The importation from France is large, and the supply obtained in the west coast of England and Scotland from Ireland is also great. About 20 years ago and upward, £30,000 worth of eggs used to be sent from Berwick-on-Tweed to the London market in the course of the year, but since the interference of large importations from France and Ireland, that trade, I believe, has almost dwindled away. The price of eggs is never high in the country, but in towns it is almost always so. In the most abundant season, eggs, that can be relied on as fresh, are never below 7d. per dozen in Edinburgh, and in winter, especially at Christmas, when the confectioners use large quantities, they are as high as from 14d. to 18d. per dozen.

---

40. THE POINTS POSSESSED BY THE DOMESTICATED ANIMALS MOST DESIRABLE FOR THE FARMER TO CULTIVATE.

"From fairest creatures we desire increase,
That thereby Beauty's rose may never die;
But as the riper should by time decrease,
His tender heir might bear his memory."
SONNETS, BY SHAKSPEARE.

The most difficult branch and the highest aim of farming is the breeding and rearing of live-stock, so as to produce the most perfect animal that shall yield the highest profit. It is very easy to maintain a flock or a herd that will propagate its kind; as the actual condition of many flocks and herds in the country abundantly testifies. It is even easier to do this than to cultivate arable land for the purpose of raising corn; for the latter demands and must receive more trouble, at all events, if not attention, than a flock or herd of neglected animals, who will keep themselves alive if food be within their reach, and who will propagate their kind even in due season, if the sexes are not kept asunder.

I am not aware that the principles upon which the proper breeding of animals should be based are understood by our farmers; for I hold that our stock have been brought to their present state of perfection, merely from each farmer exercising his individual taste and judgment—by gratifying his eye and satisfying his mind—and not in pursuance of any fixed principle he is acquainted with on the subject. There can be no doubt, however, that the symmetry, disposition to grow and fatten, and the relative proportions of the different parts of animals, are entirely dependent on laws which govern animal life; and could these be understood, so as to render their application easy, the breeder of stock would no longer intrust his success to uncertainty. The botanical physiologist and the chem-

* Raspail's Organic Chemistry. † Ibid.

ist have been very dilatory in proposing suggestions to the farmer, but the animal physiologist has hitherto almost entirely neglected him. The physician and surgeon, on the other hand, have not; for the veterinarian, now a man of science, administers his prescriptions and performs his operations with the confidence and ease of a proficient. Pity the physiologist should have almost neglected so extensive and fine a field as a breeding and rearing farm presents for his peculiar pursuits, and where the functions of the living and growing structure might so easily be observed, and their effects afterward as easily demonstrated by *post-mortem* examinations. The results obtained from such investigations would afford invaluable data with which to compare the functions of the human structure; and, fortified by the investigations of the comparative physiologist, the human physician would treat diseases with increased skill. The anatomist acknowledges the great importance of Comparative Anatomy to his profession; and the surgeon owns to have received many useful hints from the veterinarian, in the treatment of wounds and the conducting of operations of magnitude and difficulty; and so, in like manner, no doubt, would the physiologist also acknowledge the importance of the observations he might make on a breeding-farm, were he disposed to turn his attention to the subject. Meantime the breeder of stock must go on, as he has hitherto done, by the light of his own genius.*

From what I have said of what is known of the principles of breeding stock, you will not expect from me so concise an explanation of them as I have given of the methods of conducting the operations of the field; and were it even possible, I could not find space here for the discussion of so extensive a subject. Suffice it to give you a few of the rules which guide the breeder in the treatment of his stock with a view to its improvement; and for your better ability to follow me in a subject which is yet confessedly in a state of confusion, I have selected a numerous group of illustrations, in whose good points you should have confidence, because they were all faithfully taken from the life, from individuals considered excellent by competent judges.

The great aim of breeders is that their stock shall possess fine symmetry—*shape*, as it is commonly called—robust constitution—and a disposition to attain early maturity, which insures good quality of flesh, as well as of wool in the case of sheep. Let us consider what each of those properties means, and also the *points* by which the existence of each is indicated in the animal.

Symmetry or Shape.—The shape is the first object to be attained; for without fine symmetry no animal looks well, however passable it may be in other respects; but, in fact, when symmetry is wanting, so are the other good particulars. In fine symmetry, the outline of the figure viewed, whether on the side or at either end, or from above, should be *rectangular*. Fig. 273 represents the side view of a fat Short-Horn ox; and it will be observed that the body nearly fills up the rectangle *a b d c* inscribed about it. A fat ox will fill up the rectangle more fully than a lean one; but still a lean ox should have the rectangular outline. But it is not enough for an ox to present the rectangular outline in the side profile only; it should have it in other positions, such as when viewed from behind, as in fig. 274, where the same sort of outline may be observed within the rectangle *a b d c*. True, this is a different rectangle from the other,

* The only physiologists I am aware of who have made observations on breeding stock, were the late Mr. Knight, and his valuable suggestions will be found in the Philosophical Transactions; and Mr. Walker, whose original views on Physiology have been made public in several works; for as to the value of the experiments of Sir John Sebright, his scientific acquirements were not of so high an order as to inspire practical men, at least, in the accuracy of his observations, and correctness of his conclusions.

approaching near the square, while the other is oblong. I do not know whether the rectangles of the side and the ends should bear a given proportion to each other, as the outlines of the ox have never, I believe, been subjected to proportional measurement, though these could easily be ascertained by employing an adjusting-frame; but, judging from measurements taken with the view of ascertaining the weight of beef in oxen (1988), it is probable that a fine symmetry gives, on the side profile, a rectangle of double the length of that of the end profile. The end profile, viewed from behind, gives a rectangle equal, of course, to the depth of that of the side profile. Another point of a well-proportioned ox is that the breadth across the hooks from *a* to *b*, fig. 274, should be equal to the depth from the hook *a* to the hook *c*; that is, the hind profile should be inscribed in a square. Now, an ox may be rectangular in its side, and across its rump, and yet be of different shape across its shoulders, when viewed from the front of the animal—it may, for example, be narrow at the top of the shoulder, and wide below at the brisket. In such a case the ribs will be flat, that is, fall quickly downward, and not project square from the back-bone, as they always do in fine symmetry. Fig. 275 shows the front end of a fat round-ribbed ox filling up the rectangle; but though the top of the shoulder fills up the rectangle as well as the lower part of the body across the shoulder-points *e f*, yet the rectangle may not be a square; that is, the ox may be narrower in front than behind; and this is no uncommon case in many breeds of cattle in this country, and many breeders maintain that this form constitutes perfect symmetry, at least for certain purposes, as for milk. This mode of reasoning, however, is not satisfactory; for the idea conveyed by perfect symmetry is an equilibrium of parts. Now, we cannot conceive an equilibrium of parts to exist in an ox whose fore-end is narrower than its hind; and where this disparity is found there is evidently something wrong in the symmetry. For observe fig. 276, which gives the top view of the body of an ox—a view which is never seen unless sought for on purpose. Here, again, is the long rectangle as of the side; but when an ox is narrower before than behind, this figure would not be a rectangle, but a trapezium—a figure no way associated with symmetry—so that, for fine symmetry, it is not enough to have the front outline filling up a rectangle, for that rectangle should be equal to that of the hooks, as may be seen in comparing figs. 274 and 275; and as we have seen, in fig. 274, that the breadth of the hooks is equal to the depth of the hock, and *its* rectangle is therefore a square, so we see, by fig. 276, that the breadth and length of an ox, when seen from above, forms a rectangle equal to that of its side, as seen in fig. 273. Perfect symmetry in the ox, therefore, implies that all the horizontal, as well as vertical lines inscribing its outlines, are respectively parallel to each other; and that these two sets of parallel lines are at right angles to one another. On dividing the entire area of the side view of an ox into 5 parallel and horizontal parts, $\frac{3}{5}$ will be found to be occupied by the body, and $\frac{2}{5}$ below the body.

This is the abstract view of symmetry, as applied to the ox; but it is not to be supposed that every ox fulfills these conditions; for, even in the figures referred to above, it will be observed that in the side view of fig. 273 the brisket falls below *b*, and the flank rises a little at *e*. The brisket *h* may be observed to drop below the horizontal line *c d* in the front view of fig. 275; and in the hind-view of fig. 274, it frequently happens that the hocks, *c* and *d*, do not descend so far as to constitute a square figure with the hook *a b*. Still the aim of the breeder should be to attain all the points of the abstract model, and he should never rest satisfied until he attain them.

Nevertheless, it must not be imagined that the configuration of any ox in any view should fill up the *angles* of the rectangles, inasmuch as the invariable roundness assumed by the animal frame forbids such a form, which would, in fact, destroy the beautiful blending of curved lines abounding in the body, and deprive us of the highest enjoyment in looking at a symmetrical animal.

Of the states of *cattle* on a farm, that of the full-grown ox approaches nearer than any other to perfect symmetry of form. If you compare the picture of the ox in Plate VI., though that animal was then only 1 year 11 months old, with that of the bull or the cow, by imagining a rectangle inscribed around each figure, you will find his symmetry more correct than that of the others. The bull in Plate XXXII. has the brisket drooping even lower down than the ox, while his neck rises in a crest behind the head. In Plate XV., though the side view of the cow is pretty similar to that of the ox, the hind view is proportionally broader across the hooks, while the front view is somewhat narrower across the shoulders. If the broad hook-bones, with the narrow chest, are not entirely occasioned in cows by calf-bearing, the disproportion between them is, at all events, greatly increased by it.

So far in regard to the symmetry of the outline of the ox; and as to the filling up of the outlines, the remarks offered in (1309) will apply to cattle in all states, though there especially referring to the points of a fat ox. There should be a straight back, round ribs, and full muscles in every state of cattle, and the objectionable deviations from these points, mentioned in (1311), are as much to be deprecated in the bull, the cow, the heifer, and the calf, as in the ox.

Apply the rectangle to the figure of the *sheep*, and it will fit the more closely the nearer the animal approaches to perfection. In fig. 462, the rectangle *g h i k* is applied to the new-clipped body of a Leicester tup, and though an old tup, and deviations from correct form may be expected in old age, still the figure fills up the rectangle very well. Apply it over the wool to the picture of the Leicester tup in Plate XXXIII., and it will fit still better; and carry it to the picture of the South Down in Plate XIV., and it will still apply; though in this particular animal the wool grew more than usually rank upon the top of the rump. Even the figure of the lamb in the fig. 444, will bear the application of the rectangle. In regard to the end and top views of the figure of the sheep, the ribs of the Leicester breed are so very much rounded that they form curved lines down the sides of the rectangle, inscribing the hind and fore profiles; and along the sides of the rectangle, inscribing the view of the back from above; still the flatness across the back, and the straightness across below the chest, fill up the lines of the rectangle. In other breeds, such as the Black-faced and Cheviot, the rectangle may still be applied.

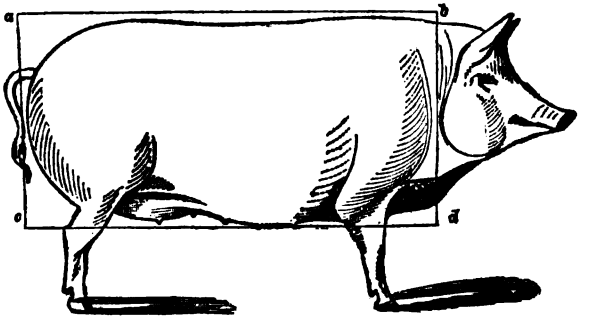
To the figure of the *horse* the rectangle may also be applied, as the picture of the draught-gelding in Plate VII. may be imagined to be inscribed, and of this class of stock the gelding is the best state for comparison, as the ox is that of cattle. The picture of the draught-stallion in Plate VII., will bear the same application; though in this, as in all cases of stallions, the neck rises to a high crest. * * * But the end views, in the case of the horse, bear different proportions to those of cattle, the hind view being always broader, and broadest in the mare, approaching more to the square, or like that of the ox, than the front view, which is always narrow. The square-like hind view is very well seen in the left-hand dark figure of a

mare, in Plate XVII., and the narrow front view is as well observed in the right-hand dark figure of a draught-horse, Plate VII. The comparative breadths of the hind and front views approach nearer each other in the draught-horse than in any other breed; his drawing powers lying in the shoulders, the muscles there become developed to a great degree, while, in the saddle-horse, the propelling power is in the hind-quarter, where the muscles become developed; as the fore-quarter is only required to support the fore-hand of the animal in action, the muscles there are all light. For these reasons, it is obvious that the view of a horse from above will not form a rectangle but a trapezium. In perfect symmetry the void below the body is of the same depth as the body to the top of the rump; the length of the body from the shoulder-point through the center of gravity of the horse to the hams is two times the depth of the body; the length of the neck to the withers is equal to the depth of the body from the withers; and the distance from the fore-fetlock to the elbow-joint is the same as from the latter point to the withers.

There are peculiarities in some of the points of the horse which deserve to be mentioned. A horse with ears set high on the crown of the head is of lively temperament, but is hasty of temper, and easily made afraid; while a horse with ears set wide apart is dull in action, but sagacious, and easily taught.

Following the same rule, the rectangle will be found to apply to the shape of the *pig* as to the other domesticated quadrupeds, as may be seen by *a b d c*, in fig. 434. The end views of the best formed pigs are quite

Fig. 434.



THE RECTANGLE TO ILLUSTRATE THE SYMMETRY OF THE PIG.

rectangular, though the generality of those met with in the country have a tendency to a larger rectangle in the fore than in the hind view. The view from above is also rectangular, except in the case of the pigs having thick shoulders.

Robustness of Constitution.—Having obtained a good shape, the next object of the farmer with his stock, is to impart to them a strong constitution, that is, to impart to them physical powers to do their work with ease, to eat their food with good appetite, to digest it within a reasonable time, to feel no fatigue with necessary daily exercise, and to withstand the weather, whether hot or cold; in short, always to enjoy good health, and be in a growing condition. The following are indications of robust health which cannot be mistaken: The skin loose upon the body, feeling soft and mellow, and covered thickly with long soft hair. The eyes full and clear, and in the case of cattle, sheep, and pigs, the skin of the nose always bedewed with moisture. The bones of the leg strong, broad, and flat, with the

sinews thick, strong, and distinctly developod; the whole being closely covered with the skin. This condition constitutes what is termed *clean* limbs. The horn of the feet and horns smooth and shining, and indicating healthy growth at its junction with the hair. The hair of the tail in cattle, and of the mane and tail in horses, long, shining, and with a tendency to crisp; the wool of sheep waved, greasy, interlaced, and of fine quality.—Along with these physical properties, the animal spirits are alive to every passing event, the senses acute, and the instinct sagacious.

All these indications of a sound constitution are obtainable by selecting parents which possess them; and they are sustained by kind treatment, comfortable lodging, and abundance of good food. Neglect of a proper selection of parents will produce, perhaps, the very opposite results. The skin will become thin and covered with scanty hair and open wool. With such a covering, the animal will easily be affected by the least change of weather, be overcome with the heat of summer, feel uneasy in the cold of winter, and be chilled by every shower that falls. A very small bone, however clean, is always accompanied with reduced size of carcass, though indicative of great disposition to fatten. Should the bone become thick and round, it gives a clumsy form to the limbs and head, and is invariably accompanied with dullness of spirit, and in the horse, in particular, with want of action. Those conditions of the skin and bone are not so much objectionable in themselves, as hurtful in their consequences. A thin-skinned and a thick-boned animal is ill to maintain in condition. Thin-skinned animals are easily affected by the weather; a fit of indigestion in consequence frequently overtakes them, and their condition alternates between worse and better; they are, in fact, tender in constitution. Thick-boned animals never seem to relish their food, and show carelessness about everything that concerns them.

Disposition to attain early maturity.—But the farmer's aim is not confined to a good shape and robust constitution; there must be a fineness given to every point—every part must be finished off, as it were, with a polish. This fineness can only be superimposed by parents derived from a race which have long possessed all the fine properties—individuals whose pedigrees can be traced—whose breeding is accounted pure. No matter whether the breeding be of the plebeian caste of the draught-horse, or of the aristocratic family of the racer,—nor whether the animals be horses, cattle, or sheep; the breeding of all should be pure of its kind.

The immediate effect in employing parents of pure breeding, is not so obvious upon the carcass as upon the extremities. The head and limbs first become finer; the fat disappears from them; the muscles expand into a thin, broad form; the tendons increase in strength; the bone becomes harder and of finer quality; the blood-vessels large and full of blood; the skin thinner, and drawn more tightly over the bone, so as to exhibit its irregularities, and the tracings of the blood-vessels distinctly; the hair is smoother and closer; the nostrils more expanded; the eyes more prominent and clear; the ears thinner, more capacious, set higher upon the head, and more quickly moved about; the action of the limbs quickened; and the animal spirits raised. All these changes may take place without materially affecting the shape of the body or the strength of the constitution; but the improvement of the extremities is rapidly followed by that of the body; the skin, though not thinner of itself, floats upon a thicker mass of cellular tissue, which imparts to it the agreeable sensation of the *touch*. The hair multiplies in numbers, becomes finer in quality, more fixed in color, longer, and softer. The proportion of flesh to bone increases.

The fat is more generally and equally diffused over the body. The texture of the muscles is finer and firmer in the fibre, and the tissue between them becomes loaded with fat. In a word, such a total change is effected upon the entire animal, that from being coarse, dull, clumsy, and sluggish, it becomes fine-spirited, handsome, and active; and as it improves in personal appearance, so it increases in its tendency to grow, and to come sooner to maturity in stature and condition.

Selection of Parents.—You must not imagine, from this uninterrupted description of the improvement of parts in animals, that all those changes are, or can possibly be, effected during the lifetime of one individual parent. The entire of those changes can only be effected in the course of generations; but as all domesticated animals produce rapidly, that is, within the course of every year, it is possible to effect great improvement in the offspring during the lifetime of a female parent, by employing a better male every year. To hasten the improvement more rapidly, better parents of both sexes may be chosen as soon as the points of the progeny show themselves, and which are appreciable in 2 years.

Of the two sexes, the properties of the male are more obviously imprinted on the offspring than those of the female; and it is on this account that males are in most request among breeders for the improvement of their stocks. High prices have been given, and high premiums are annually offered, for superior males, whether stallions, bulls, or tups; and it is fortunate for the more rapid extension of the improvement of stock, that the influence of the male thus bears sway in the propagation of his kind, as by permission of polygamy one male may serve many females, and of course extend his influence in the exact proportion to the number of the latter; whereas a female produces usually 1 in the course of a year. A stallion serves from 60 to 80 mares, a bull 60 cows, and a tup 60 ewes in a season, not once or twice only, but as often until the female prove with young. Generally the female conceives at the first service of the male, and at all events at the second; but should her desire continue beyond that time, it is better to withdraw her from breeding altogether, than run the risk of having a late progeny, or none at all; for a late calf, lamb, or foal, loses 1 year of its progress, compared with its earlier born companions. But the part which the male and female respectively undertake, in the improvement of the progeny, differs widely, and is entirely dependent on their state of breeding—the head and extremities being improved by the highest, and the carcass and procreating powers by the lowest bred. The highest bred imparts the small head, prominent eyes, thin ears, wide nostrils, clean limbs, full blood-vessels, action, spirit, and intelligence; in short, all the parts which go to develop the mental qualities; while the lowest bred improves the shape of the carcass, by straightening the back and rounding the ribs, extending the muscles, laying on the fat, enlarging the capacity of the pulmonary organs, and decreasing the size of the abdominal. On distinguishing the parts more immediately imprinted by each parent, it is obvious that the effects of the highest bred are more striking than those of the other. Hence, a fine head, well set upon the neck, a lustrous eye, a gay look, an engaging manner, and free action, are more readily appreciated than a fine mould, sound constitution, touch, and disposition to grow.

Few farmers commit a mistake in the choice of the male for improving their stock. Breeders themselves pay particular attention to the production of the male, and farmers who purchase or hire males never grudge paying a high price for them; and hence the male-breeding market is always at a premium. But many mistakes are made by breeders in the

choice of the females to breed from. In the case of horses particularly, any sort of mare is considered good enough to produce a foal, and if she happen to be unfit for work, or has met with an accident, such as having swung her back, or has a bad leg, she is the one selected for breeding the future labor-stock of the farm. The best stallion, it is true, will be put to her, most probably the prize-stallion of the local agricultural show; but as to the mare herself, it is considered a great sacrifice of physical power to breed from young fresh mares. Now, in acting thus, the farmer commits a fatal blunder; he is depriving himself of the use of superior farm-horses, which would not only work with ease to themselves and satisfaction to him, and at the same cost of keep, but would do him credit wherever they went. Instead of pursuing this system, he should select 1 or 2 of the best mares in his possession to breed from, and if he has none possessing youth and beauty of mould, let him buy 1 or 2 at any price, if such are to be purchased. Let them not be under 5 years of age when the horse is first put to them; for they will not have acquired their full stature until that age. From that period let them bear a foal every year till they attain 12 or 13 years, when they should cease to breed; for *old* mares, any more than old females of other classes of animals, cannot produce a vigorous progeny. For those 7 years the fresh young mares, stinted to the best stallion that can be secured, will each produce, and bring up, a foal every year, and perform, at the same time, their part of the work with ease. Such foals will be strong in bone and constitution, and be always in high condition, because they are the offspring of young mares themselves, high in condition, and overflowing with milk; and having been brought up together will work better together. I speak not in this tone for the purpose merely of condemning the practice usually followed by farmers in breeding farm-horses, but having myself tried the system I recommend, I can do it with confidence. I purchased from a dealer a very excellent Clydesdale mare in St. John's Market at Perth, for £42, a large price for the time. She was 5 years old off, and was altogether such a mare, for mould and strength, as is seldom to be found in a market. Next year she was put to a prize stallion, also of the Clydesdale breed, and bore a foal every year till she reached 10 years of age, when, much to my disappointment, she ceased to breed. Her first 2 foals were fillies, and, when 4 and 5 years old, were sold at the sale, when I declined farming, for £108, to convert into brood-mares. Her other 2 foals, colts, at 4 years old, realized £38 and £44. I had other 2 mares which began to bear foal at 7 years of age, 1 of which bred draught-horses, which realized from £35 to £40, and the other was put to a coaching-stallion, and produced excellent harness-horses; 1 of them, a mare, was purchased by a friend in Ireland, and proved one of the fastest goers in harness I ever saw. I am perfectly certain the same results will be realized everywhere by breeding from excellent young mares; and though 3 mares out of 10 horses, which wrought my farm, bore foals every year, the work never fell behind its season; and they had as rough and heavy work to do for several years, while improvements were in hand, as could be encountered on any farm. The system pursued in regard to the breeding of cattle and sheep is generally much better than that for horses, though I think that cows are not generally so well selected as they should be; and one reason is this: whenever a cow happens to be a good milker, she is kept to breed as long as she is worth keeping for that purpose, without regard to any other point of excellence; and her calves may be good or bad, in proportion as the points of the bull which begot them are so. Those who keep a stock of cows for breeding bulls, of course, do not follow this haz-

erdous plan of producing valuable calves; but I believe by far the greatest number of cattle bred in this country are produced in this careless manner; and the simple recital of the system is quite sufficient to account for the great number of inferior cattle to be met with in all our public markets.

The system of breeding I have recommended is applicable to every kind of stock; but modifications are allowable in it, and in fact expedient, according to the particular object the breeder has in view. If his object is simply to breed cattle and sheep for ordinary markets of fat and lean stock, a useful lot of cows or ewes, with a good tup or bull, are all that are requisite; and once having obtained a desirable stock of either, and not wishing them of finer quality, his solicitude will be confined to sustaining their character by preventing the least tendency to deterioration. In such a case the females are commonly bred by the farmer himself, and the male is purchased from a breed of superior class to his own. So far the practice is good; but when a good cow, or a lot of good ewes, of the same or superior character as the stock itself can be picked up now and then, the opportunity should not be lost of infusing a *fresh* strain of blood into the stock. A frequent change of the male is advisable in such a system, as the stock will soon become too near akin to him. On the other hand, those whose professed object is to breed animals to propagate their kind, must bestow great care and skill to sustain their breeding-stock in the highest state of perfection. The least defect in the female, whether arising from accident or inherent weakness, should be the instant signal for her removal from the stock, and as to the male, the very best that can be found should be purchased at any price. The best male in reference to the particular case may not be the best animal of the stock from which it is desired to purchase, because it should preëminently possess points which will either improve or sustain those of the females which he is destined to serve. The properties, therefore, which a male should possess are entirely relative and not absolute; for absolutely good points ought to be possessed by the females before the breeder should attempt to produce breeding-stock from them. To manage this part of his business well is a very difficult task for the breeder; and a single mistake committed in this respect, for a single season, may cause him more trouble to rectify, and incur greater loss than if he had been content with his own stock in the state it was. It must be owned, however, that whenever a breeder discovers a defect in any point in his stock, his desire to remedy it is natural; and whenever he finds an animal superior to his own, it is as natural he should endeavor to possess it. If, for example, he thinks his own stock somewhat slacker behind the shoulder than they should be, the remedy, he conceives, is to use a male which is free of that deficiency. The usual practice is to select a male for this purpose which is *rather full* behind the shoulder; because, what more natural than to fill up a deficiency with a redundancy? Such an expectation, though natural enough, may lead to unexpected results; for the use of the *redundant* point may give such an impetus in the stock to rectify their deficiency, that its tendency to fill up may proceed too far, even in one generation, and cause redundancy where there was deficiency before; but this is just the result which ought to have been anticipated, if there is any truth in the breeders' maxim that "like begets like." The employment, therefore, of a symmetrical shoulder to rectify a deficient one is the practice most consonant to reason and principle; for what *more* is wanted than to *fill up* the deficiency behind the shoulder; and how should that be *best* attained but by using a model which is exactly in the state which you wish the deficiency to assume? The

want of forethought to consequences of this sort has been the cause of deterioration to many a good stock. Too many farmers attempt to produce breeding-stock, and they are tempted to proceed with the system as long as they observe the progeny improve upon their parents; and as long as they are observed to improve, purchasers will be found to pay good prices—for they like to purchase from a thriving stock—till a point is reached beyond which improvement does not succeed; and this is considered the point of perfection, though it may be very far short of it. The breeder's skill may be unable to carry him farther; and, on account of his want of skill, will be induced to present his breeding-stock to the attention of other breeders with the greater earnestness. Herein is concealed another source of error; for it is clear, that as long as a stock is itself far short of perfection, its offshoots cannot afford a certain means of improving other stock. Trial may be made of it; but the result may be disappointment to the purchasers, and disgust to the self-sufficient breeder himself. One circumstance alone, I conceive, would justify a breeder in offering imperfect stock for breeding, which is, being situate in a country where crossing with other breeds might be carried on with advantage. The conclusion of the whole matter, then, is that a stock producing offshoots fit to breed from should have arrived at perfection, at least to such a degree of perfection as the best stocks known; and the object of the owner of such a stock should not be so much to *improve* its best animals—for that seems impossible—as to improve the inferior, and *sustain* the quality of the best; and before a stock can be brought to that state of perfection, the pedigree of its best animals—for no stock contains all its animals equally good—might be traced back for many generations. Doubtless this is a severe criterion by which to judge the character of a breeding-stock; but when it is considered that its members are preferred with a view to improve, or at least sustain, the breeding of members of another stock equally well bred as itself, it is necessary to fix a high standard of comparison, and nothing short of this will afford satisfaction. There are many stocks of Short-Horn cattle and Leicester sheep whose character will bear the strictest scrutiny by such a criterion.

Breeding in-and-in.—No wonder high-breeding produces such an improvement in stock as to render the head small, fine and beautiful, the extremities elegant, the form handsome, and the disposition so accommodating as that the animals grow and fatten without feeling disturbed at what passes around; in short, become so prepossessing as to make their owners mistrust the stocks of others, and employ only their own to increase its own numbers. It was this feeling which actuated Bakewell to breed only from his own stock, after he had brought the Leicester sheep and Long-Horn cattle to perfection. For a time Mr. Mason, of Chilton, pursued the same course; and there are breeders in England at the present time who maintain that it is the best system, and will follow no other. Perhaps a stock brought to the highest state of perfection, and at the same time possessed of sound constitution, may be supported free of deterioration for many years by the peculiar skill of its owner; and I can conceive a high-bred stock, full of young blood, such as Bakewell's was during his whole lifetime, to be increased and supported by its own members though bred in-and-in, that is, supported by near kindred or consanguinity. There was one valid reason for Mr. Bakewell employing only his own stock, which was, that there was no other so good as his own to select from; and it would have seemed extraordinary in him, of all men, to have employed any animal of acknowledged inferiority to his own; but I suspect no such liberty may be taken, with impunity, with a stock as

highly bred, but not so youthful in blood. At all events, many instances have occurred in which many fine stocks have been ruined in character, and have entailed irreparable loss on their owners simply by being bred in-and-in. The immediate effects of employing parents nearly allied by blood to propagate their kind are remarkable. The bone becomes very small, of condensed texture, and fine quality. The skin is so thin as to receive the appellation of *papery*, and so open of texture as to be sensible to the least change of temperature; and hence animals bred in-and-in are very susceptible of catarrhal affections, and on which account they are liable to consumption and clyers. The carcass is much reduced in size, and the disposition to fatten increases to such a degree that the animal may be said to be always in a condition to be slaughtered; and it is, perhaps, this tendency to fatten, which has proved the great inducement with many breeders to tolerate the in-and-in system. The hair is short, smooth, and thin-set, and the wool short, thin-set, and watery; and both hide and fleece lose a large proportion of weight. The body assumes a change of form, the barrel being beautifully rounded, but seems stuffed, as it were, within the skin. The extremities are very fine, the head and hoofs small, the ears thin and broad, and the head of the sheep is almost bare of hair, of a blue color, very liable to be scalded by the heat of the sun, and attacked by the fly. The necks of both cattle and sheep are thin, and droop with a downward curve from the head to the top of the shoulder. The points just enumerated show the unprofitable state into which a stock may be brought by being bred in-and-in. Mr. Mason's fine Short-Horn stock latterly showed symptoms of the bad effects of this system; and Mr. Robertson's stock at Ladykirk, which contained at one time by far the finest Short-Horns in Scotland, suffered after his demise from the same cause, as was apparent on the animals presented at the sale which dispersed them. Only cattle and sheep have been subjected by farmers to be bred in-and-in, for their draught-mares are usually covered by stallions obtained from a distance; and of cattle and sheep, the injurious effects of the system have only been observed in Short-Horn cattle and Leicester sheep. The injurious effects of the system have been felt, it is true, in the racing-stud, and are evinced by the racers of the present day being unable to carry heavy weights, and run the long distances of the horses of old. At present nothing but speed is regarded.

Now, that high-bred stocks exist in every district of the kingdom, there is no excuse for pursuing the in-and-in system of breeding; and the attempt is the more inexcusable from the remarkable fact, brought to light only since the distribution of high-bred stock, that its progeny, after being distributed for a time, may be brought together to propagate their kind, and their offspring will exhibit no symptoms of in-and-in breeding. Such a result would seem to indicate that change of soil and situation renovates the animal as well as the vegetable constitution.

It may be proper to mention what relations are considered allied in blood, in breeding in-and-in. Connection of the sire with his grand-dam, dam, and sister, is improper. So it is even with his aunt, niece, and cousin-germain. One should imagine that a breeder would feel repugnance at connecting so near a consanguinity as the former; yet the union is too often permitted to take place in the latter cases.

Crossing.—The union of different breeds of the same sort of animal is a favorite scheme with many breeders, and, under certain conditions, produces good results. Those conditions are, that the male employed in the crossing shall have the superior breeding of the 2 parents, and that the situation in which the cross-progeny shall be brought up shall be suitable to

it. The first condition is usually complied with, but the second is as commonly disregarded; and the consequence is, that the crosses attempted to be brought up in situations quite unsuited to their nature have proved a failure.

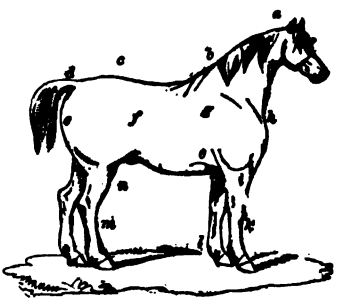
In the crosses commonly attempted in this country, among cattle the Short-Horn bull, and among sheep the Leicester tup, have been employed to serve the ordinary breeds of cattle and sheep. The effects have proved satisfactory; for though the progeny could not but be expected to be inferior to the sire, they are superior to the dam. The effects are: an enlargement of the carcass, a finer skin, longer hair and wool, cleaner bone and finer head, and the disposition to fatten greatly accelerated—all of which are superior to the ordinary points of the breed; but, of course, the better the dam is, the more decidedly improved will those points be. In effecting such a cross, it has been found that the higher bred the male is the finer is the cross; that is, the nearer will it approach his properties; and even an *over-bred* male, that is, one showing symptoms of having been bred in-and-in, may be used with advantage in crossing. Where a superior cross-male happens thus to be produced, a strong desire is evinced by the breeders to keep him entire for service, and to use him as a sire, instead of expending money in the purchase of a high-bred male. A more short-sighted step than this cannot be taken by a breeder, because from such a male he has no assurance that the progeny will be superior to the dam. Indeed, he has no guaranty of what the state of the progeny will be at all, for it may be worse than either sire or dam; and if such a disappointment overtakes him, he has himself to blame, having left the whole matter to chance. The employment of a high-bred sire, on the other hand, will never lead to disappointment, as the progeny will assuredly be superior to the dam. It is this assurance which affords much satisfaction to the breeder of high-bred stock, by which he can anticipate the quality of his forthcoming young stock; and it is with high-bred stock alone that the maxim of "like producing like" is realized. Nevertheless, there are situations in which high-bred stock cannot be maintained *as a breeding stock*, and in which nothing but crossing can be practiced when improvement is desired; but the desire for improvement has been carried by some breeders beyond the bounds of prudence; they have crossed the Black-faced ewe with Leicester tups, in situations where the enlarged lamb has been unable to subsist in winter; and on this account the policy of changing the Black-faced breed of sheep in high localities seems doubtful. In lower situations, the Cheviot ewe, which inhabits the middle range of green pasture, may be crossed with the Leicester tup with advantage. Every crossing, however, should be prosecuted with caution, because the result may overstep the intentions of the breeder. It is clear that if the crossed stock is retained as females, which, in their turn, are served by high-bred males, the time will arrive when the character of the original stock will be entirely changed, and become unsuited to their native climate and pasture, and will, in fact, have become the same breed as their high-bred sires. It is quite possible to originate a race of Short-Horns and Leicester sheep anywhere suited to their nature, by constantly employing a high-bred bull and tup to serve cross-bred heifers and gimmers, generation after generation; and were this practice generally adopted, the time would arrive when the original breeds which were crossed would disappear altogether. Such a result would prove injurious to the breeder himself, inasmuch as the pasture would be unsuited for the stock he had caused to be produced; so that his best plan is to preserve the original breeds in the higher parts of the country, and take the crosses to the low

country to be fed off. The temptation of larger profits has already caused the Cheviot to drive the Black-faced breed from the lower pastures to the highest, while the cross-bred Cheviot, with the Leicester, have descended, on the other hand, to the low country, and there have met the true bred Leicester. This result, upon the whole, has done good, as it has increased the quantity of mutton in the market; and the skillful pasturage which the hills have received since a regular system of breeding has been introduced, has caused them to yield a larger quantity of finer grasses. The crossing of the Black-faced sheep has undergone a change; the Leicester tup is too heavy to serve Black-faced ewes on the hills, and to bring those ewes to the tup in the low country is attended with trouble and expense. Instead, therefore, of the Leicester tup being so employed, the Cheviot tup has been substituted; and though the cross is inferior—for nothing can exceed the beauty of the lamb produced between the Black-faced ewe and Leicester tup—it is a good one, and has enlarged the Black-faced mutton. So long as crossing is conducted with the breeds in their natural state, it will go on without confusion, but the moment cross-bred tups are employed as improvers of stock, their interference will produce confusion in the crosses, and throw discredit upon crossing altogether.

I purpose giving a short description of the animals whose portraits are given in the Plates illustrative of this work, and shall make such remarks on the form of the animals as to give you an idea of their leading points, whether good or bad. In order to render reference to the figures in the Plates more easy, wood-cuts of their points have been provided, that they may be more distinctly indicated.

Horses.—Among horses I shall take the draught-horse, fig. 435, and Plate VII., as the standard of comparison. This gelding is of gray color, was bred by Mr. Curry at Brandon, in the county of Northumberland, and is the property of Messrs. Howey and Co., the great carriers from Edinburgh into England. He is not a thorough-bred Clydesdale, having a dash of the coaching blood in him, a species of farm-horse very much in use on the Borders, and admired for their action and spirit. This gelding exhibits such a form as to constitute, in my estimation, the very perfection of what a farm-horse should be. His head *a* is small, bone clean, eyes prominent, muzzle fine, and ears set on the crown of the head. His neck rises with a fine crest along the mane from the trunk *b h* to *a*, and tapers to the head, which is beautifully set on, and seems to be borne by the neck with ease. His limbs taper gradually from the body, and are broad and flat; the knee *k* is straight, broad, and strong, and the fore-arm *i* broad and flat—all excellent points in the leg of a draught-horse, giving it strength and action. The back of the fore-leg, from the fetlock-joint *l* to the body *o*, is straight, indicating no weakness in the limb—a failing here causing the knees to knuckle, and rendering the horse unsafe in going down hill. The hind legs *m*, as well as the fore ones *k* and *l*, stand directly under the body, forming firm supports to it. The body is beautifully symmetrical. The shoulder slopes backward from *h* to *b*, the withers at *b* being high and thin. The sloped position of the shoulder affords a proper seat for the collar, and provides the muscles of the shoulder-blade *g* so long a lever as

Fig. 435.

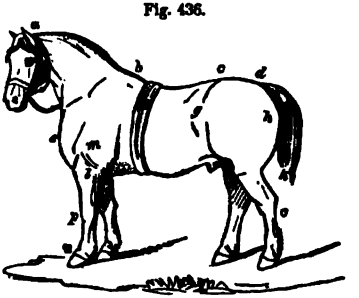


THE DRAUGHT-HORSE.

to cause them to throw the fore-legs forward in a walk or trot; and with such a shoulder a horse cannot stumble. The back, from *b* to *c*, is short, no longer than to give room to the saddle. The chest, from *b* to *o*, is deep, giving it capacity for the lungs to play in, and room for the muscles required in draught. The top of the quarter from *c* to *d* is rounded, the flank, from *c* to *n*, deep, and the hind-quarter, from *f* to *e*, long. On looking on the side profile of the entire animal, the body seems made up of two large quarters, joined together by a short thick middle, suggesting the idea of strength; and the limbs, neck and head, are so attached to the body as to appear light and useful. In a well formed horse, I may remark, the line from the fetlock *l* to the elbow-joint, at *o*, is equal to that from the joint *o* to the top of the withers *b*. In a low-shouldered leggy-horse, the line *l o* is much longer than the line *o b*; but in the case of this horse, the body *b o* is rather deeper than the leg *l o* is long, realizing the desideratum in a farm-horse of a thick middle and short legs. The line across the ribs from *g* to *f* is, like the back, short, and the ribs are round. He is 16 hands high, measures from *a* to *b* 35 inches, from *b* to *c* 33 inches, from *c* to *d* 19 inches, being in extreme length 7 feet 3 inches. Length of the face 25 inches, breadth of face across the eyes 10 inches, length of ears 6½ inches, breadth across the hook-bones 22 inches, girth behind the shoulder 80 inches, girth of fore-arm 23 inches, girth of bone below the fore-knee 9½ inches; the breadth of this bone shows the strength of the fore-leg of every horse; girth of neck at the onset of the head 32 inches, girth of muzzle 21 inches, width of counter 19 inches, and hight of top of quarter from the ground 63 inches. In a draught-horse the collar causes the muscles to enlarge upon the shoulder, and the neck to become thin. This horse's name is Farmer, his walk is stately, and he can draw 3 tons on level ground, including the weight of the wagon. He is a well known animal in Edinburgh, and is generally admired.

Fig. 436 as here shewn is the portrait of the black draught-stallion Champion, bred by Mr. James Steedman, Boghall, in the county of Mid-Lothian. He is of the true Clydesdale breed. He gained the first prize at the Highland and Agricultural Society's Show at Glasgow in October, 1837, and obtained premiums elsewhere. He is a sure foal-getter. He is fully 17 hands high, and though otherwise a large animal, being 8 feet 7 inches in length, his action is high and uncommonly light. On comparing him generally with the gelding just described, though his body is longer, both hind and fore quarters are long and deep, and exhibit a large display of muscle. His middle is somewhat small, as is almost always the case with stallions which have served many mares. Like all stallions, his neck rises beautifully from his body *b e*, in a full crest from *b* to *a*, evincing that castration has the effect of reducing the size of the muscles of the neck of all geldings. The shoulder slopes well back from *e* to *b*, giving freedom of action to the fore-legs, while the muscle at *m* being fully developed, assists in imparting power to that action. The hind-quarter, from *g* to *h*, is long and deep. The fore-leg is straight, and short from knee to fetlock, *p* to *n*, the bone under the knee strong, and the fore-arm *l* flat and broad. The hind-legs *o* are remarkably handsome. The sweep of line from the crown of the head along the back

Fig. 436.

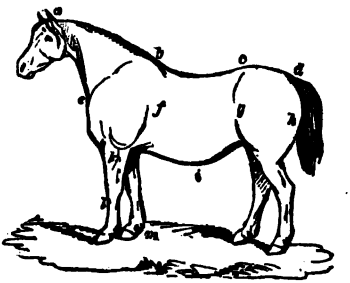


THE DRAUGHT-STALLION.

to the tail-head is truly elegant, giving a very fine top to the quarter, and the plenitude of hair in the tail *d k* indicates great strength of back. His eye is good, though somewhat small, the ratch of white down his face is against his cast of countenance; and having the 2 hind-legs white is also against his general appearance. His disposition is remarkably docile, and his whole demeanor harmless. His constitution is good, and he is an excellent traveler. These are a few of his dimensions: from *a* to *b* 51 inches, from *b* to *c* 30 inches, from *c* to *d* 22 inches; in all 8 feet 7 inches Length of face 26½ inches, breadth of face across the eyes 11 inches, length of ears 6½ inches, breadth across the hook-bones 30 inches, girth behind the shoulder 90 inches, girth of fore-arm 28 inches, girth of bone below the fore-knee 12 inches, hight of top of quarter from the ground 67 inches girth of neck at the onset of the head 39 inches, girth of muzzle 24 inches and width of counter 22 inches.

Fig. 437 as here shewn is the portrait of a brown mare belonging to Mr. George Bagrie, Monkton, near Dalkeith, Mid-Lothian. She gained the first premium at every show of stock she was ever exhibited. The white ratch down her face, and so much white on her legs, detract from her general appearance; but notwithstanding these drawbacks, she is an exceedingly handsome mare. You have only to look at the Plate to observe the beautiful flowing lines of her whole contour, and also the great substance of both fore and hind quarter. The rise and crest of her neck from *b* to *a*, and from *e* to *a*, are remarkably fine. The back from *b* to *c* is somewhat hollow, and there is a corresponding depression of the belly at *i*, both the consequences of foal-bearing, as well as a slackness of the flank in front of *g*, the usual deficiency there of brood-mares. The top of the rump from *c* to *d* is also very fine. The shoulder slopes well from *e* to *b*, indicating good action; the muscles are well developed on the fore-quarter from *e* to *f*, indicating power in draught; and the ribs are round, and long from *f* to *g*, a favorable configuration in the brood-mare for giving room for the growth of the fœtus. The hind-quarter from *g* to *h* is long. The legs are placed directly under the body, the fore-knee *l* being broad and strong, the back of the fore-leg from the fetlock *m* to the body straight, and the fore-arm *k* broad and flat. I have no measurement of the dimensions of this mare, which I regret, as losing a means of comparison with the gelding and stallion. Beside roundness and length of rib, a brood-mare should be wide across the hook-bones and the pelvis, to afford room for the growth and subsequent egress of the foal.

Fig. 437.



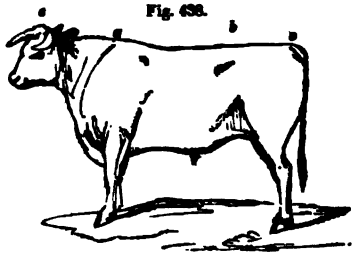
THE DRAUGHT-MARE.

I have chosen a *black* stallion, *brown* mare, and *gray* gelding, as illustrative of the three colors most commonly seen among farm-horses. A black stallion seems the generally favorite color, and a brown mare is not uncommon, but the gray color is less in vogue than it was 20 years ago; but why I cannot say. It is said that the feet of gray horses are more tender than of horses of other colors; and, for the same reason, whatever that may be, it is alleged that white feet are more tender than any other color. I once corresponded on this subject with the veterinary surgeon of one of the regiments of Life Guards, the horses of which are black, and

his statement was that he had not observed any remarkable defect in those horses which happened to have white feet; but that his attention had not before been particularly drawn to the subject. It might be worth while to ascertain whether or not it is found that the horses of the Scots Greys are more liable to tender feet than those of other corps of a different color.

Cattle.—I have already said so much on the points of cattle, that nothing more remains to be advanced on that subject; so I shall merely allude to the particular points exhibited by the animals represented in the Plates. And, first, I shall take, as a standard of comparison, the Short-Horn ox, fig. 438 given below. This was an ox from the herd of Mr. Wilson, of Cumledge, in Berwickshire, who has long been known as a successful breeder of Short-Horn steers. His stock comes to maturity and is fattened off at 2 years of age, when they commonly attain 70 stones imperial. The ox in fig. 438 was 1 year 11 months old when his portrait was taken; and he was afterward shown at the Highland and Agricultural Society's Show at Berwick-upon-Tweed, in October, 1841. He was of a roan color, with a good deal of white. His head was remarkably fine, with a pleasant countenance, full eyes, and small, slouching, sharp-pointed horns. Besides a fine head, he had a straight back, round rib, deep flank, and full neck-vein. His principal measurements were, from *e* to *a* 27 inches, from *a* to *b* 32½, from *b* to *c* 21½ inches, in all 6 feet 9 inches; and the girth of the body behind the shoulder at *f* 7 feet 3 inches. His measurement for beef was 4 feet 6 inches in length by 7 feet 3 inches in girth, equal to 56 stones imperial; so I should say from these figures, that this ox was rather too short for a perfectly symmetrical figure.

Fig. 438.



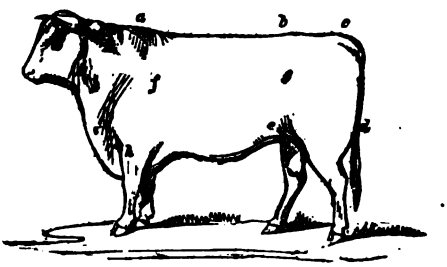
THE SHORT-HORN OX.

Fig. 439 given on page 443, is a portrait of a red and white Short-Horn bull. This animal was bred by the late Mr. George Brown at Whitsome Hill, in Berwickshire. He was got by a red and white bull belonging to Mr. Robertson, of Ladykirk, named Valentine.* At that period, Mr. Robertson's stock of Short-Horns was in its glory. The dam of this bull was got by a red bull, never named, bred by Mr. Thomas Smith, now at Buckden, then at Grindon, in Northumberland, and was a son of his old roan bull Duke; and at that period few farmers had so high a bred stock as Mr. Smith. The grand-dam was one of twin quey-calves produced by a heifer, purchased in calf by Mr. Brown from Mr. Mason, of Chilton. One of the twin calves, when a 2-year-old quey, Mr. Brown sold to the late Duke of Buccleuch for 50 guineas, and the other he retained for himself. I purchased this bull when 1 year old from Mr. Brown for 20 guineas, and kept him at Balmadies, in Forfarshire, for 8 years, during which time he proved himself a sure and excellent calf-getter, and evinced a gentleness of disposition to every person who approached him, in a remarkable degree for a bull. He had many good points—small head, lively eye, small, fine, white horn. He was well filled up behind the shoulder, at *f*, fig. 439, a point in which many bulls are deficient. He had a long quarter from *g*, a difficult point to attain in a bull, carrying the flesh of the hocks *d*; a thick flank *e*; ribs round, forming a *straight line* from the

* For Valentine's pedigree, see Coates's Herd Book, vol. i.

shoulder-point in front of *f*, past *g*, to the margin of the round above *d*. His fore-arm *h* was very strong; neck-vein full; and the crest of his neck *a* fine and not lumpy, as is too often the case in bulls; his hooks and back were remarkably straight and broad, measuring across the hook-bones at *b* 36 inches; the rump between *b* and *c* was full and round, and the tail-head *c* was remarkably level and fine, showing no undue development of muscle, as is often the case here—a deformity too generally admired, and in so far shows a prevalence of bad taste. His neck and shoulders were strewed over with curled locks of long hair, the entire body being thickly covered with long soft hair; the face was garnished with curled hair in a line down in front of each eye; and the roots of the horns were hidden with long hair falling over the forehead. His hide was thick and mellow, and the touch fine. He had a most robust constitution, never having had a day's illness in his life of nine years. Unfortunately I had no measurement taking of him before he was killed fat, when the butcher, Mr. Johnston of Arbroath, informed me he weighed 139 stones imperial, sinking the offals. His flesh was fine, much more like ox than bull beef.

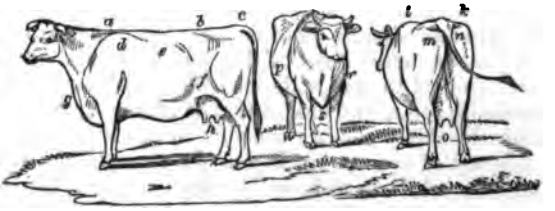
Fig. 439.



THE SHORT-HORN BULL.

Fig. 440, given below, are the portraits of three Short-Horn cows belonging to the Duke of Buccleuch, at Dalkeith Park, in Mid-Lothian. They are all of pure blood, being descended from Mr. Robertson of Ladykirk's stock, when Mr. John Rennie had a part of them in his possession at Phantassie in East-Lothian. The cow, a *roan*, whose side view is

Fig. 440.



THE SHORT-HORN COWS.

given, was in a lean state when the portrait was taken; but the likeness is the more valuable on that account, in giving an idea of the skeleton, which in her case is very fine. She is the beautiful Kilmeny, got by Match 'em. The hook-bone *b* is finely prominent, and at the same time level; the ribs *e* round; the shoulder-blade *d* sloping; the top of the shoulder *a* broad: the neck-vein at *g* fine; the muscle at *f* well developed; the tail-head *c* level with the hooks; and the udder *h* hemispherical, the teats being pendant at equal distances. The uncommon half-slouching, half-projecting form of her horns, and a staring of the eyes, give her countenance, though her head is otherwise fine, a somewhat more austere aspect than cows generally have. The front view of the *red* cow in the middle is intended to show the breadth of the fore-quarter from *p* to *r*, the roundness of the ribs at *p*, the depth of brisket at *s*, and the width of space upon which the fore-legs stand. The hind view of the *white* cow,

on the right, shows the broad space between the hooks from *l* to *k*, and the same across the pelvis from *m* to *n*, 2 points essential in the cow, as a safe breeder of full-grown calves. The form of the udder behind at *o* shows the proper position of the 2 hind teats, and exhibits the loose, soft skin above the udder, which is characteristic of good milkers.

The 3 colors, roan, red, and white, were purposely chosen to show the common colors which the Short-Horns bear. Though thus divided into 3, only 2 colors are, in truth, sported by Short-Horns, namely, red and white, the roan being a mixture of the other 2. The roan is a handsome color, and is, I believe, the general favorite now; the fancy for color having gone from the red to the white, and is now settled on the roan. Dark-red usually indicates hardiness of constitution, richness of milk, and disposition to fatten; light-red indicates great quantity of thin milk, and little disposition to fatten; but the red in either case is seldom entire, being generally relieved with white on the sides, and the belly, as in the case also of the bull described above. White was considered indicative of delicacy of constitution; and to get quit of it, and at the same time avoid the dullness of red, the roan was encouraged, and now prevails. I think I have observed that white animals show the symptoms sooner than any other color of being bred in-and-in.

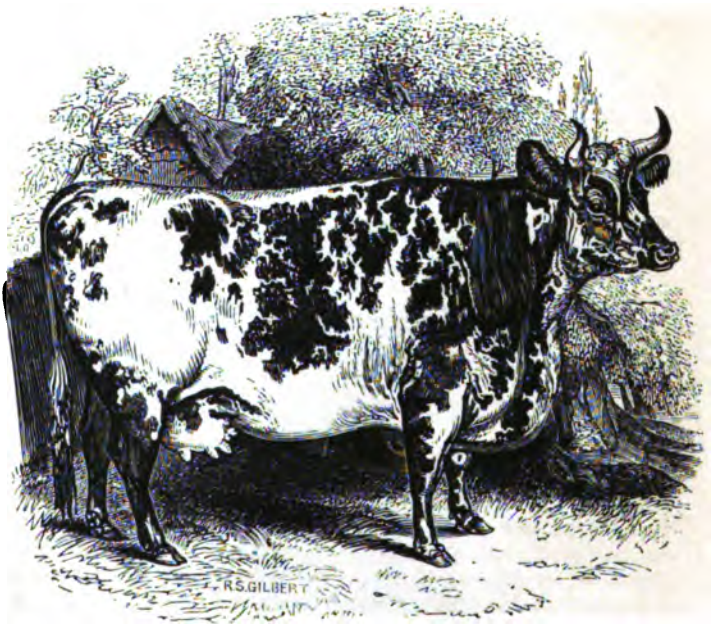
A single *black* hair on the body, and particularly on the nose; or the slightest *dark* spot on the flesh-colored skin upon the nose, or around the eyes, or the horns tipped with *black*, at once proclaim that a Short-Horn sporting either of these is not pure bred—all attestation to the contrary being of no avail.

To show that careful breeding improves the *head* of every breed of cattle, specimens of the heads of 3 celebrated breeds are given, one being the *Long-Horns*, a breed not confined to England, as it extends over Ireland, though it is only in England that fine specimens of the breed are to be seen. This is the breed which the famous Bakewell improved in Leicestershire, a few years before the Collings improved the Short-Horns, by which they established to themselves a fame which eclipsed that of Bakewell as a breeder of cattle; not because they understood the principles of breeding cattle better than he did, but, fortunately for them, they selected a better subject to deal with—the Short-Horns. Their fame, however, was not established at the cost of that of Bakewell, for he had already acquired an imperishable name as a breeder, in the improvement of the old Leicestershire breed of sheep; but it must be owned that when the Collings advanced beyond Bakewell as breeders of cattle, the advancement was the more meritorious in being made in competition with so very formidable a rival. The Long-Horns were originally called Leicesters; but having long horns, they were so named in contradistinction to the Durham breed, whose horns were short; and, besides, Bakewell's improved sheep were as often called Leicesters as the Dishley breed.

Fig. 441.

THE HEAD OF A LONG-HORN BULL.

The Long-Horn bull, a likeness of whose head is here given in fig. 441, belonged to Mr. R. Horton, in Warwickshire, and was shown, and obtained the first prize of his class at the Show of the Royal Agricultural Society of England at Oxford, in July, 1839, when he was 4 years 2 months old. It will be observed that the muzzle is fine, the eye large and ex-



R.S.GILBERT

pressive, the horns fine, tapering, and sharp-pointed, and the entire countenance agreeable. His color was light-brown, brindled with black stripes. The skin of the nose and around the eyes dark-flesh color. The slouching position of the horns is very common in the Long-Horn breed; they are brown, with a few reddish streaks, and tipped with brownish-black.

Another breed to which much attention has been paid, is the *Hereford*, which has long been famed for its excellent steers. Fig. 442 is the portrait of the head of a Hereford ox which belonged to Mr. S. Druce of Ensham, in Oxfordshire, and was shown at Oxford, at the Show of the Royal Agricultural Society of England, in July, 1839, when 4 years 4 months old. It will at once be observed that the muzzle is fine, the eye large and full, and the horns small, tapering, and sharp-pointed. A white face is quite common in the Hereford breed, with white horns, and brownish-red points. The body is either dark or light-red and white, a common color, or a dark rich chestnut-brown, which is becoming fashionable. The skin on the nose and around the eyes is fine flesh-color.

Fig. 442.

THE HEAD OF A HEREFORD OX.

The *West-Highland* has long been famed in Scotland as a superior breed of cattle. They have most of the points of the Short-Horns in the body, which is covered with shaggy hair, that bids defiance to the keenest blasts and the most drenching rains. Fig. 443 gives an idea of the head of an ox belonging to Mr. Campbell of Jura, which was shown with another, as a pair, at the Highland and Agricultural Society's Show at Inverness, in October, 1839. It will be observed that the muzzle is fine, eye large and full, and the horns small, tapering, sharp-pointed, white, and tipped with black. The color of the body is usually black, sometimes red, and not unfrequently dun. The black-colored, in my opinion, makes the most profitable animal to the feeder. The skin on the nose, and around the eyes, is always black.

Fig. 443.

THE HEAD OF A WEST-HIGHLAND OX.

There is a breed of cattle extensively cultivated in Scotland, the importance of which consists in affording milk for the purposes of the dairy. It is a remarkable circumstance in the history of the breeding of this race for the dairy, that the very opposite points have been cultivated by its breeders, which I have described as being essential in the opinion of the best breeders of every other race. The breed I allude to is the *Ayrshire*. The points considered good in an Ayrshire bull, by the

breeders of that species of stock, are a broad, short head, the horns spreading from the side of the head a little in front, and turning upward. The top of the shoulder sharp, back narrow, ribs, of course, flat, hooks confined, hams thin, tail-head somewhat drooping, belly enlarged, and legs very short. These are all points contrary to those of a good Short-Horn; and the points in which they agree are a straight back, loose mellow skin, large eye and small horn. The cows are best liked for a very sharp shoulder and wide hooks and pelvis, in which case the ribs are flat and the belly large. The udder is desired to be hemispherical, well forward, and provided with loose, soft skin behind.

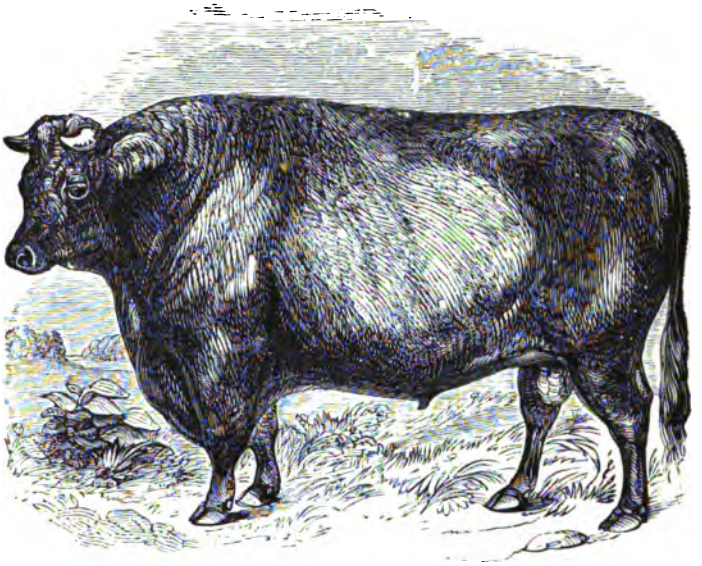
I am satisfied that the points thus desiderated by Ayrshire breeders are not necessarily promotive of the principal object they have in view, namely, a large quantity of milk; for though it cannot be denied that Ayrshire cows are generally good milkers, it is attributable, in my opinion, more to the great length of time they have been devoted to that particular purpose, and which property has now become inherent in the breed, than to the form which the breeders promote; and my reason for thinking so is this: it is well understood, in large dairies in large towns, that the Short-Horns prove the most steady milkers, that is, they continue to yield milk in large quantities for a longer period than any other breed. When they are not allowed to bear calves, they will continue to yield milk until they are fat enough for the butcher; and when allowed to bear calves, they will give milk to within 5 or 6 weeks of the time of calving. Now it is averred by Ayrshire breeders, that the points cultivated in Short-Horns are for the purpose of yielding flesh; and the averment is quite true; but if the points which yield flesh are also favorable to yielding milk, as the experience of dairymen in towns has proved, and their preference of Short-Horns to others testify, it is clear that it is *not* in consequence of cultivating points in the Ayrshire breed of entirely an opposite character to those of the Short-Horns, that the Ayrshire yields so large a quantity of milk; but that it must depend upon some other quality, otherwise the Short-Horns should yield little or no milk, but entirely flesh—which is found not to be the case. I had a light-red Short-Horn cow, which gave 17 Scots pints of milk at the hight of the grass season, and would scarcely go dry before calving; and have seen another roan cow, which gave 30 pints a day for 3 months, and had to be milked for relief 5 times a day.

Horns of Cattle.—There is much to be observed in the set and form of the horns of cattle. Small, short, slouching horns on a 2 or 3 year old steer give a grave and majestic cast to the countenance. Horns rising outward from the side of the head, and looking up, and bending backward, never fail to impress one with the conviction that their bearer is an ill-tempered brute, and ready to use them offensively on all occasions. Horns curving laterally and horizontally forward, give a finished appearance to the top of the head, when viewed in front, as exemplified in the figure of the lesser Short-Horn cow in Plate XV. When horns are long, and rise outward, forward, and elevate their points, they impart a very majestic mien to the ox, as shown in fig. 443 of the West-Highland ox. Some horns are set looking backward behind the head, and give an idea of malformation. A horn thick at the root never looks well, neither does one that is blunted at the point; and both kinds are associated with dull feeders; nor do those which spring outward and then turn downward, look well, as shown in the left-hand Short-Horn cow in Plate XV. A good horn is small where it emerges from the head, and tapers gradually to a fine point. A white horn is better than a dark-colored, and a finishing of

Book of the Farm

SHORT HORN BULL

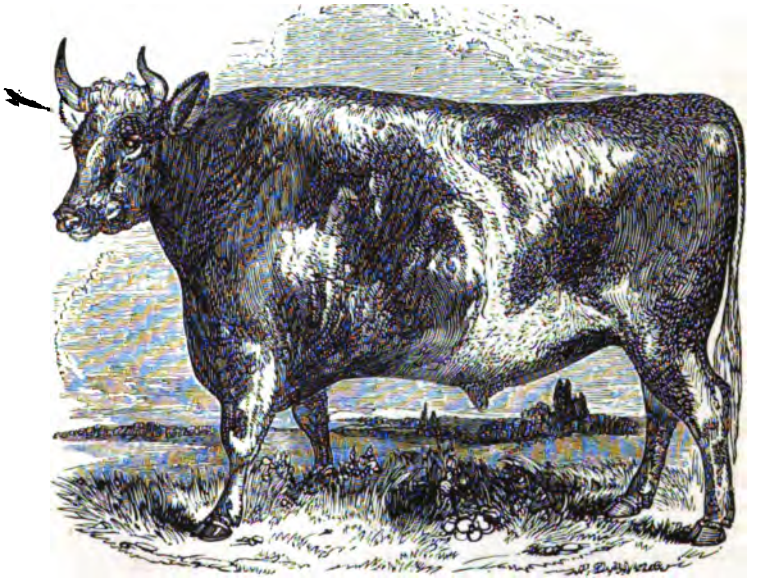
Plate XXXII



Book of the Farm

SHORT HORN OX.

Plate VI



brown or black at the tip, according to the breed, is a good outset, though many Short-Horns, especially of white color, have their horns all white, and being short, do not seem obtrusive—indeed, in most Short-Horns the horns serve more for ornament than purposes of defence. Oxen with spreading horns are better feeders than those which contract toward the front. Horns indicate the age of cattle. At 3 years of age the horn has attained its state of uniform growth; that is to say, it is uniformly smooth from the root to the tip. Every year after the horn is protruded from the head, with a notch on it, so that by counting the number of notches, and adding 3 to the number, the age of the animal may be ascertained. Tricks are practiced by fraudulent dealers, by filing down the notches, to make the animal appear younger than it is; but a slight inspection of the horn will easily detect the fraud; and the period of the year, whether late or early, in which the animal was born, will have some effect on the notches of the horn.*

Sheep.—Of the numerous varieties of sheep cultivated in Great Britain, I have only selected 3 for illustration here, as these include all the breeds brought up in Scotland, though another has been partially introduced. The three varieties alluded to are the Leicester, the Cheviot, and the Black-faced, and the supplementary variety, as it may be called, is the South-Down. The three varieties are well suited, not only for the climate of Scotland, but also for the peculiar zones, as they may be termed, into which the pasturage of that country is subdivided. The Leicesters are adapted to heavy pastures and sheltered fields in low lands. The Cheviot is equally well fitted for the middle range of green pastures to be found in the pastoral districts of the South and North of Scotland. While the Black-faced derive their chief support from the heathy pastures of the mountains; at least that range of country forms the nurseries of this hardy race.

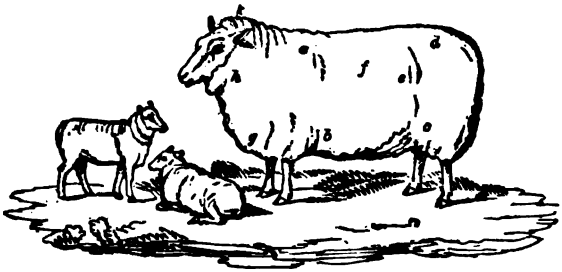
Plate XXXIII. contains the portrait of a *Leicester tup* belonging to Mr. Tow of Riby. * * This animal exhibits the peculiar properties of the breed to which he belongs; the principal of which are, a white face and legs covered with hair, hornless head, and body enveloped in long wool. The individual characteristics of this tup are, rectangular carcass, round rib, small bone, fine head, small muzzle, large, full eye, and expressive countenance; but his ears are much shorter than usual. The head of the tup is broader across the eyes than that of the ewe or wether, and the skin becomes wrinkled upon the nose when he gets aged. The wool is thick-set, long, of good quality, and the fleece covers the entire body above and below—a mark of sound constitution, and a great means of preserving the animal from the bad effects of the weather above, and of the dampness of the ground below. A level broad back from neck to rump, and across the ribs, is characteristic of the Leicester, and on being turned up, a broad chest and fullness on the inside of the hams. The touch should be equally mellow along the back, a hardness in any part indicating a defect. In ordinary condition, the flesh above the tail-head is nicked, which may be easily felt with the points of the fingers; but when in high condition, which they should be at tupping-time in autumn, the nicking should extend all the way from the shoulder-top to the tail. The rib should also be well covered with flesh and fat, and, indeed, a *round* rib is almost always so.

Fig. 444, given on page 448, contain the portraits of a *Leicester ewe* and *lamb* belonging to Mr. Brodie, Abbey Mains, in the county of Haddington. The Leicester ewe's head is generally long, narrow, and clean,

* See a paper on this subject in the Quarterly Journal of Agriculture, vol. iii.

with fine muzle, prominent eyes, and long, broad, thin ears. The bone is small and fine. In this particular instance the body is well-wooled and formed. The counter *g* is full; the shoulder well filled up behind at *a*; the rib at *f* round and full, and the loin at *e* not hollow, as is sometimes the case, particularly after ewes have borne a number of lambs. In regard to the wool it is full behind the ears on the top of the neck at *k*, thus

Fig. 444.



LEICESTER EWE AND LAMBS.

keeping these organs protected; it is also full toward the cheeks at *k*, which keeps the throat warm; the belly is well covered with wool below at *b*; and so is the flank *c*; the rump *d* has rather a redundancy, and it affects even the shape; but gimmers, that is, ewes of their first lamb, often produce a large quantity of wool on this point, which afterward reduces itself to an equality of the rest of the body; but it is a good property in a ewe to have plenty of wool on the rump, to protect the anal and vaginal passages below the tail, and it is also an indication that the tail-head is placed nearly on a level with the back. It is no uncommon occurrence in a Leicester ewe to bear twin-lambs, nor is it uncommon to wean twins to the extent of 50 per cent. of the whole flock, some of the ewes bearing twins every year, while others only occasionally.

The Leicester breed of sheep has been cultivated with very great care in Great Britain, since the days of Bakewell, who brought them in his own lifetime to a very high degree of perfection. Many of the flocks in the kingdom can trace their pedigree to that of Bakewell, with as much truth as the purest stud of the race-horse, or the purest herd of Short-Horns, though no Flock-Book has been kept to record the names of the most renowned sheep; a circumstance which excites in me much surprise. The breed is deserving of the utmost attention that can be bestowed upon it, as it possesses many valuable properties. The individuals are in themselves handsome, displaying a beautiful contour, with a pleasant aspect. Their disposition is so amiable that they have no desire to overleap a fence; and this disposition, no doubt, is fostered by their aptitude to fatten. The result of their condition is a large proportion of flesh to bone, and of useful parts to the offal. Many people affect to dislike the mutton, as being too fat and flavorless. The muscle is certainly larger-grained than that of the other 2 breeds, and the fibres are intermixed with fat; but though the mutton may be disliked, for these reasons, by the higher orders, the breed being generally of robust constitution the meat is always wholesome, and acceptable to work-people. Colliers, who eat a large quantity of meat, will have none other. For these reasons, Leicesters are more profitable to the farmer, where they can be reared, than any other breed. The wool is of the most valuable description, not on account of the *fineness* of its quality,

for many short-wooled sheep have much finer wool; but its great length, as well as its tolerably fine quality, renders it useful in the manufacture of all fabrics which require combing wool, and in which worsted is employed. This wool seems peculiar to the British climate; for in no other country have sheep-breeders succeeded in raising it of the same quality; the pile becoming shorter or coarser in warm countries. So long, therefore, as peculiar fabrics are made from Leicester wool, the breeders of Leicesters need not fear the want of a steady, if not a high market for their wool; and it must always be in demand, since no other country can compete in raising it to the same degree of perfection.

Fig. 445 represents the head of a *Cheviot tup* which gained the first prize of his class at the Highland and Agricultural Society's Show at Aberdeen in 1840, and was shown by Messrs. Craig, Bighouse, Sutherlandshire. It will be observed that its face is longer than that of the Leicester, muzzle not so fine, eye not so full, ears set not so high and handsomely upon the top of the head, and there is a rugosity of the skin across the bridge of the nose. In the white face, and want of horns, the Cheviot resembles the Leicester. The wool is short, thick-set, and of fine quality, fit for the manufacture of inferior qualities of broadcloths. The carcass is usually unequal, the fore-quarter being lighter than the hind—narrow in front, with the fore-legs set near, and a want of depth and breadth in the counter. The flesh is fine-grained, often well intermixed with fat, and is generally esteemed for the table. The disposition of the Cheviot is somewhat suspicious, with an inclination to rove; which disposition renders the breed rather unkindly to feed, at least at an early age.

Fig. 445.

THE HEAD OF A CHEVIOT TUP.

The Cheviots, as their name implies, had their origin in the Cheviot Hills, in Northumberland. They occupy almost all the pastoral hills of the south of Scotland, especially from the center of the country to the eastward. They are localized in some of the best parts of the Grampian mountains, and are to be found as far north as the hills of Caithness and Sutherland. They may, therefore, be regarded as a hardy race, and are well suited, on that account, for the middle green pastures of the mountainous parts of our country.

The *South-Downs* are little known in Scotland; but what is known of them is favorable to their character. Like the Cheviot, they are covered with short, thick-set, fine wool, which is of a dusky brown color, and it also affects the hair which covers the face and legs. They are a hornless breed. In symmetry of body they are much superior to the Cheviot, bringing their quarters, like the Leicester, to an equality. Their flesh is fine-grained, and, as high-flavored mutton, is preferred to that of the Cheviot in the London market. They have also a gentler disposition, and are in consequence better feeders. The only doubt with the South-Downs, on their introduction into Scotland, was their ability to withstand the damp climate of our sub-alpine pastures. The experience of several years has proved that they are capable of enduring any climate with the Cheviot and this being the

case, with their other superior qualities, they bid fair to rival and perhaps ultimately to displace that breed. Hitherto, however, they have only been tried in a few places. Mr. Hugh Watson has had them at Keillor, in Forfarshire, for more than 20 years, and they have thriven with him upon the pastures of the Sidlaw Hills. The Duke of Richmond has them in Morayshire. Our small flocks are scattered through the country.

Figs. 446 and 447 represent the heads of a *Black-faced ram* and *ewe* The ram, fig. 446, was shown by Mr. Robert M'Turk, Hastings's-Hall, in Dumfriesshire, at the Highland and Agricultural Society's Show at Berwick-upon-Tweed in 1841, where it obtained the first prize of its class. As indicative of the long period and care with which the breed has been cultivated, we have only to look at the tapering face, small muzzle, and full eye, exhibited by the specimens in the figures. The Black-faced ram has always an arched nose, expressive of boldness and courage. The face and legs are covered with black or mottled hair, mostly the latter. The head is horned; and the horns are considered as picturesque an object as is exhibited by any animal of this country. The wool is long and coarse, which render it of small value as an article of manufacture, and being thin-set exposes the body to the inclemency of the weather It is to assist the animal for this latter defect in the fleece that the filthy operation of smearing is resorted to. The carcass is well formed, carrying its depth forward to the brisket better than the Cheviot; but still the entire body is narrow, owing to the flatness of the ribs, which gives too much lightness to the whole carcass; or want of *substance*, as it is commonly called. The flesh is fine-grained, high flavored, greatly esteemed, and can be fed sufficiently fat on the turnips and pastures of the low country. The breed is very hardy, frequenting the highest parts of our heath-clad mountains, and in summer require little care from the shepherd.

Fig. 446.

THE HEAD OF A BLACK-FACED RAM.

As with cattle, the *horns of sheep* afford facilities for ascertaining the age of the animal. In fig. 446, the age of the tup is distinctly marked, the 1st year's growth being evidently the space from the point of the horn to the letter *a*; the 2d year is from *a* to *b*, the growth of the dinmont being stronger than that of the hogg; the 3d year's growth is marked from *b* to *c*; the 4th, from *c* to *d*, which great growth shows the vigorous state which the animal had attained at that age; and this is no doubt the most vigorous period of the life of a sheep; and the 5th year's growth is shown from *d* to *e*. The respective ages of the ewe, fig. 447, and of the wether, may be traced in like manner, but the horns not attaining the full development in them as in the ram, the yearly marks cannot be discerned

without minute examination. As to this figure of the ewe it is evidently that of a young one, probably a maiden ewe or gimmer, or at most with the first lamb.

Plate XXVIII. exhibits a group of *fat wethers* of the 3 native breeds we have been considering and illustrating; but all the animals composing the group are by no means alike favorable specimens of their respective breeds. The Black-faced wether is a good specimen, and many such are brought fat to the Edinburgh market every winter. They are fed in Forfar, Fife, and Perth shires, on turnips in winter, but the finest fat are those fed on turnips in East-Lothian—that county affording by far the best feeding land for stock in Scotland. The Cheviot is evidently not a wether, being only a dinmont, and not pure bred; and on both these accounts is not a ripe specimen. The letter P is left on the rump to show the tar-mark of the farm on which, or the name of the farmer by whom it had been bred. The lightness of the fore-quarter, characteristic of this breed is, however, very well shown in the figure. It is rare to meet with Leicester wethers now-a-days, the dinmonts attaining a sufficient degree of fatness for all useful purposes. The figure in the Plate is a dinmont, and not a favorable specimen, not being pure bred, and too small for the breed. The characteristic distinctions of the three breeds are, however, sufficiently marked in the *heads* of the figures given in the Plate.

Fig. 447.

THE HEAD OF A BLACK-FACED EWE.

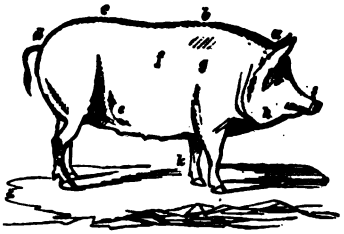
A desire seems to be spreading in this country for the naturalization of the *Alpaca* from South America. It is the opinion of those who have seen the Alpaca in its native country, that it would thrive well on our highest mountains, upon the coarsest fare that can be obtained—upon what, in fact, is refused by even Black-faced sheep—and at the same time yield a coat of fine wool, far finer and longer than any grown in this kingdom. Could this opinion be established by experiment, the cultivation of the animal would be worth attempting on a large scale; and no doubt sufficient supplies would be obtained of it in a few years. As yet, the subject is only under discussion.*

Swine.—There are many breeds of *swine* existing in the country; and whatever denomination they may pass under, if they do not possess the points exhibited in the adjoining fig. 448, and in the Plate, they may be pronounced defective. Here the same rules apply, not only of symmetry, as we have seen in fig. 431, but points of breeding. The head *a* is small, the face tapering to the muzzle or snout *i*, which is short and fine, the ears set on the crown of the head, being broad, thin, long, and so mobile as to indicate quickness of perception. The value of the head, as an article of food, is indicated by the enlargement of the muscle upon the cheek *k*. The neck from *a* to *b* is full; the back from *b* to *c*, broad; the rump from *c* to

*A little work, named The Alpaca, by Mr. William Walton of Liverpool, published by Blackwood in 1844, gives an interesting account of this animal, both historical and natural. The author seems to know the habits of the animal; considers that it would thrive to a profitable extent in this country; and details the particulars of a practicable plan by which a regular and sufficient supply of it, at a remunerative rate, might be obtained.

d full and round, and the roundness descends to the hams; the ribs *f* are round; the space behind the shoulder at *g* filled up, and so is the flank *e*; the shanks *k* are small and short, and finely tapered. A pig with these properties is always in a condition for use from the state of a pig sucking milk, through its progress of porkling and shott till it attain the full size for bacon and hams. Such a breed never requires feeding, and as it is always in condition, it must only have time to grow to the size wanted, when a little firming of the flesh by corn is all that is required to prepare it for slaughter.

Fig. 448.



THE BROOD-SOW.

The slouch-eared breed that prevailed in the country is fast being supplanted by the one I have been describing; because, wherever such a character of ear is seen, it is universally accompanied with length of leg, length of nose, narrowness of back, and dilatoriness in feeding. I believe the prick-ears, short snouts, and full cheeks, may be traced to an improvement derived from the Chinese breed, which possess those points even to a deformity. The cross with our old bony breeds has been the means of disseminating through the country a race of beautiful, profitable, delicate-fleshed pigs.

Fig. 449.

THE HEAD OF A BOAR.

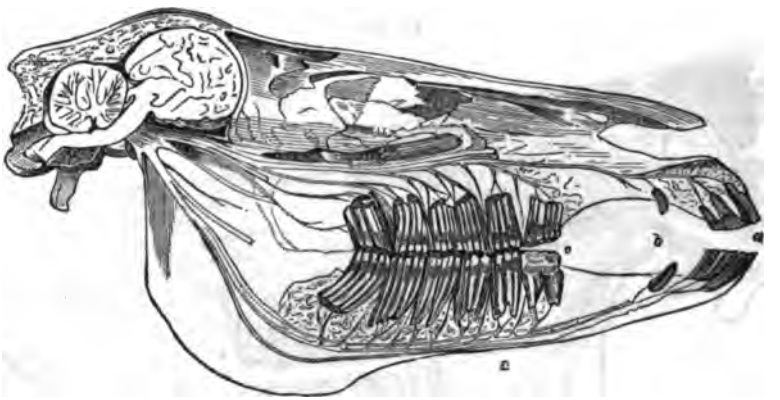
Fig. 449 represents the head of a *boar* belonging to the Duke of Buccleuch, and the *brood-sow* represented in the Plate, is also from His Grace's stock. The boar, though evidently full-grown and large, bears the same character of pricked ear, tapering face, short nose, and full cheeks, and the flesh of the neck is seen to be fully able to support the fullness of the head; these pigs are, moreover, strong-constitutioned, and covered with plenty of white hair and valuable bristle. Their temper is generally docile, and the animals seldom wander far from the steading, or engage in mischievous pursuits.

Teeth.—The teeth are far more imperfect organs to the domesticated animals than the horns. The horns are the instruments of defence and of attack; and, in the situation in which those animals are placed, are seldom put in requisition, and the more seldom the better; but the teeth are the instruments by means of which their food is broken and masticated in winter, and cropped and masticated in summer; and this being the case, the condition of the animal mainly depends upon the state of soundness in which the teeth may be preserved. There is one similar property between the horns and teeth of animals; both furnish data by which the age of the animal may be ascertained. You have already seen how the horns are indicative of the age; we shall now advert to the manner in which the teeth may be examined for the same purpose.

Fig. 450 represents the left half of the head of an *adult horse*, viewed internally, and so figured as to show the origin of the fifth pair of nerves, and the nervous branches which go to the teeth; and for this reason the figure may be consulted with equal advantage for a knowledge of the dis-

tribution of the nervous system and of the teeth. The milk-teeth of the horse consist of 12 incisors, 6 in each side of the head; and of molars 16 in number, 8 on either side of the head—in all 28 teeth. The teeth

Fig. 450.



THE VERTICAL SECTION OF THE HEAD OF THE ADULT HORSE, SHOWING THE TEETH AND THE NERVOUS SYSTEM IN CONNECTION WITH THEM.

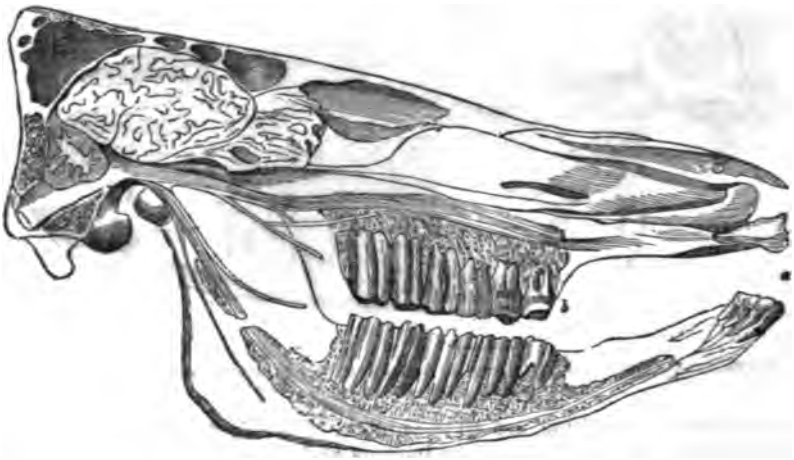
of the second dentition are 40 in number, of which 28 have replaced the milk-teeth. Those between the incisors and molars, called the canine or tusks, do not appear along with the teeth at an early age. Others complête the arch by occupying the room made by the growth of the jaws; these are new molars which come out of both jaws. The full set consists of 12 incisors, 4 canines, and 24 molars—in all 40 in number. In fig. 450, *a* are the incisors, *b* the canine or tusks, and *c* the molars.

"This is the order of coming out of the second or permanent dentition of the horse," observes M. Rousseau. "The first permanent molar, which is situate behind the last milk-molar, presents itself before any of the milk-teeth have fallen, and makes its appearance upon the maxillary arch from the 11th to the 13th month after birth; it will be, by numerical number, the 4th persistent molar, when all the milk-molars have fallen. The 5th permanent molar, which is situate behind the preceding tooth, breaks the edge of the socket from the 14th to the 20th month. During this time the decaying teeth die from their roots, and wear down their crowns to such a degree that the hollow which characterizes the surface of the incisors at certain periods cannot be observed, so that the veterinarians call them lost-mark. The central incisor or pincer is ordinarily of the 9th or 11th month; the lesser incisor from the 11th to 13th month; and the lateral incisor or corner-tooth, from the 14th to the 20th month. Once these teeth cease to have mark, they bear upon their surface a smooth trace. brown and indelible, which diminishes the more that the teeth approach their fall. The first permanent molar replaces the first and second milk-molars from 2 years to 2½ years. The central incisor appears upon the edge of the socket after the coming out of the 5th permanent molar, from 2½ to 3 years. The 2d permanent molar replaces the 3d milk-molar a little after the same term, or 1 or 2 months of difference. The 3d permanent molar replaces the 4th decaying molar at 3 years; at this time also appears the 6th and last molar. The lesser incisor from 3½ to 4 years. The canine or tusks appear from 4 to 4½ years. At last the second dentition is ordinarily terminated by the lateral incisor or corner-tooth. It must

not be thought, however, that the coming out, as I have endeavored to indicate as the most ordinary, is without variation; this would be to give to Nature too regular a march. All teeth in general are the more developed that they belong to a large and robust subject."

Fig. 451 gives a similar representation of the dental system of the *adult*

Fig. 451.



VERTICAL SECTION OF THE HEAD OF THE ADULT OX, SHOWING THE TEETH AND THE NERVOUS SYSTEM IN CONNECTION WITH THEM.

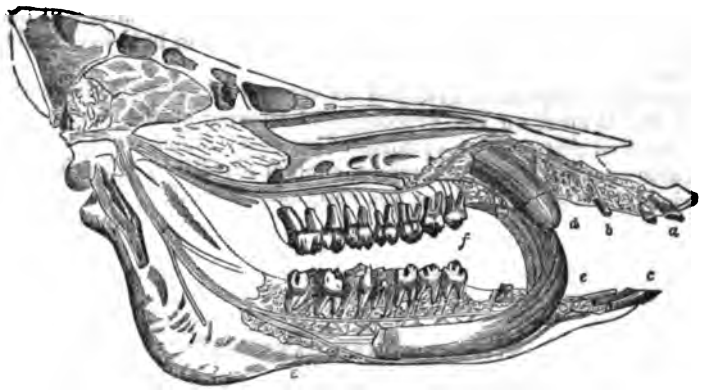
ox, and of the nervous system connected with it, that the preceding figure gives of those of the horse. The milk-teeth of the ox are, 8 incisors on the lower jaw, and none on the upper, and 12 molars, 3 on each jaw. In the adult ox are 8 incisors on the lower jaw, and none on the upper; and there are 24 molars, 6 on each jaw. In the figure, *a* are the incisors, and *b* the molars, and the same configuration exists in the sheep." "In the second dentition, these teeth show themselves upon the edge of the socket in the following order," says M. Rousseau: "The 4th permanent molar comes out from the 4th to the 6th month after birth, and commences the second dentition. The 1st or central replacing incisor from the 15th to the 22d month. The 5th or penult molar, from the 18th to the 22d month. The second replacing molar, as also the 2d incisor of this order, appear from the 28th to the 32d month. The 3d replacing molar, as also the 3d incisor, come out very near at the same time, that is, from the 38th to the 48th month. The 6th, or last molar, from the 44th to the 52d month. At length the 4th permanent incisor tooth terminates the 2d dentition, which is ordinarily completed when the animal has not yet attained its 5th year."

Fig. 452 gives a section of the head of a *wild boar*, in which the dental and nervous systems are distinctly delineated; *a* are the superior incisors; *b* the superior lateral incisor; *c* the inferior incisors; *d* the upper canine or defence tusk; *e* the inferior canine or defence tusk, the origin and form of which may be easily traced; and *f* are the molars. I have selected the head of the wild boar for illustration, because the character of all the teeth, and particularly that of the tusks, is more strongly developed than in the domesticated boar. The tusks of the sow are comparatively short and weak. The milk-teeth of the ordinary pig are 32 in number, namely, 12 incisors, 4 canines or tusks, and 16 molars half of which numbers are

(ook)

on each side of the head. The second dentition is only completed as soon as as all the milk-teeth have fallen; and these are not only replaced, but 3 other molars on each jaw rise up, one after the other, until the whole dental arch

Fig. 410.



THE VERTICAL SECTION OF THE HEAD OF THE WILD BOAR, SHOWING THE TEETH AND THE NERVOUS SYSTEM IN CONNECTION WITH THEM.

is completed, when the entire complement is 44 teeth, of which 22 are on the upper, and 22 on the lower jaws, and they are divided thus: 12 incisors, 4 tusks, and 28 molars. These teeth are composed of 2 substances, the one bony, the other enameled. "The tusks are each inclosed in a socket, filled with a substance analogous to the marrow of the long bones; it is most remarkable and most abundant in the inferior tusks. These teeth are only provided with enamel upon the external face of the permanent tusks."*

In regard to the indications of age by means of the teeth, in the horse the marks on the crowns of the front teeth on the lower jaw are almost always obliterated, or at least cannot be depended on after 9 years of age. After that period, the only means of judging is by the quantity of matter ground off the top of the teeth, and by the distance between the teeth; the older the horse gets, the wider the space between them becomes. In regard to the grinding down of the teeth, however, you should know that pasturage on sharp land, and support on hard meat, such as unbruised corn and beans, will wear down teeth much faster than pasturage on soft land and prepared food. The same remark applies to cows which have been pastured on sharp or soft land, and been fed on straw and turnips, or on boiled food, and it is only applicable to them; for as to steers, their age cannot be mistaken, from the growth and condition of the body. The teeth of cows also stand wider as they advance in years.

A horse's mouth is easily opened for the purpose of examination, by introducing a finger by the side of the mouth into the space between the incisor and molar teeth, where, in short, the bit of the bridle lies, upon the tongue, when the horse will play with his mouth, to get quit of the finger, and show as much of the lower teeth as to satisfy your curiosity. Some sulky horses require to have their lips held asunder; and vicious ones will even strike out with the fore-feet when their mouth is meddled with. I had a cart-mare, the moment her mouth was attempted to be held for examination, she would wheel round quickly, and kick with the hind-feet at the person attempting it. A cow's mouth cannot be examined without

* Rousseau's Anatomie Comparée du Système Dentaire, p. 205-230—a very complete and elegant work.

first taking hold of her nose, elevating her mouth, and drawing down her under-lip. Some cows will not allow themselves to be taken by the nose, and the thing can only be done in such a case by stratagem. Some, again, have such a power in the nose by curling up the nostrils when held, that its squeeze against the holder's fingers renders them soon powerless; but a steady pinch of the thumb-nail against the septum of the nose will make any cow give way, provided the person has strength to hold her firmly at the first burst.

I am strongly tempted to give you an account of the physiological remarks of Mr. Walker on the breeding and crossing of the domesticated animals, but find that even an epitome of his observations would occupy a considerable space. I must, therefore, content myself by referring to his very curious, instructive, and not less entertaining work.

---

41. CARTS AND CARTING.*

In the ordinary progress of the harvest, having gathered the corn together by the horse-rake, the next step is to carry it to the barn or the stack-yard. This leads us to the question of carts and wagons. The asserted saving in animal power, by the employment of one-horse carts in exchange for the ordinary harvest-wagon, has now, for some years, been the subject of occasional discussion among the farmers of England; the common result of which has been to convince pretty generally the English farmer, that on most soils and in many situations, for the general purposes of Agriculture, there is a very material saving to be accomplished in horse labor, by their employment in preference to wagons. "I early felt convinced," said Mr. Mechi, in the course of some observations he made in 1847, at a monthly meeting of the London Farmers' Club, "that it was much easier to carry a load upon an implement which weighed 7 cwts., running upon one pair of wheels, than upon one which weighed 22 to 24 cwts. running on two pairs of wheels; my powers of calculation were sufficient to convince me at once that we had been committing a perfect barbarism in the matter of wagons." And he alluded with advantage to a valuable paper by Mr. Hannam, on the use of one-horse carts, which some years since appeared in an early volume of the Journal of the Royal English Agricultural Society. In this very excellent paper, Mr. Hannam truly states that the farmers of the counties of Cumberland and Westmoreland have universally, and from time immemorial, used the one-horse cart; they have no other carriage for any kind of agricultural produce, and never is the addition of another horse on any occasion seen. The practice, apparently originating in economy, has long since spread into the neighboring Scotch county of Dumfries, and we have the authority of Mr. Wilkie, the well-

[* For a chapter of 50 pages on the philosophy and the application of Wheel Carriages, which Mr. Stephens says he had himself at one time deemed uncalled-for, we venture to substitute this one on Carts and Carting, by Cuthbert W. Johnson, F. R. S., as being more modern and better adapted to common use. We find it in "Modern Agricultural Improvements, intended also as a Supplement to the Farmer's Series of the Library of Useful Knowledge."

By adopting this course we not only present a paper of more general utility on a subject of very general interest, but it enables us to draw the whole work to a conclusion in this volume and thus present in two volumes, at a cost of $5, what would cost $25 if imported.

In reference to this subject of farm transportation, we have no doubt that great waste is committed in the United States in two ways: first, by want of a sufficient number of these and other implements, and next, by the use of heavy, unwieldy wagons in the place of carts, in which the horse may be said to *carry* a portion of the weight on his back, which in the wagon he must draw, altogether. But we will not presume to go farther, lest we might seem to be anticipating or otherwise taking the subject out of abler hands. *Ed. Farm. Lib.*]

known implement-maker of Addington, near Glasgow, for saying that it is all but universal at the present moment throughout the West of Scotland." As relates to the economy of the cart, it is evident that a considerable saving in the expense for animal labor on a farm may be often accomplished by substituting one-horse carts for wagons. "I had no other object in entering into this practice," adds Mr. Hannam, "than lessening my expenses by reducing the number of my horses, and in this I have succeeded beyond my expectations. My farm (at Burcott, in Oxfordshire) of 370 acres, consisting chiefly of gravelly and ferruginous sandy loams, was some years ago under very able management, with a strength of 12 horses and 6 oxen; and just previous to taking it into my own cultivation, 16 horses had been employed by a very spirited cultivator. I have gradually, by the joint operation of two-horse plows and single-horse carts, reduced my number to 8 horses. My system, notwithstanding, is such as somewhat increases my aggregate amount of horse labor beyond that of the surrounding district; certainly doing a great deal more carting work, although in a few points of tillage it is transferred to the manual labor. For instance, I grow annually about 35 acres of mangel and 20 of potatoes, which necessarily cause much carriage, and, together with the other ridged crops, also a good deal of horse-hoeing." The general saving of animal power has been thus stated in a tabular form by Mr. Hannam, and I am always glad when I can avail myself of such condensed statements, since it is general results which are commonly the most practically valuable. Mr. Hannam calculates that the team labor per cent. expended, with four horses, on a farm of 100 acres, is commonly thus apportioned:

In plowing In horse-hoeing In dragging In Suffolk drill, &c	about 50 per cent.
In harrowing In rolling	about 12 per cent.
In carting	about 38 per cent.

And that the saving capable of being effected is—

By two, and occasionally one-horse plows, and double-ridging plows By forking couch grass By pair-horse cat's claw drag	27 per cent.
By one-horse six-feet heavy rollers, being 33 per cent. in the implement, and 10 or 12 per cent. on the general labor where heavy rolling is performed	1 per cent.
By single-horse-carts	19 per cent.
Being equal to a total saving of	47 per cent.

"Let me now answer the question," continues Mr. Hannam, "which will be asked. In what manner is the saving by single carts of about one-fifth of the usual proportion of horses effected? By considering that to move a bulk from one spot to another, in the way that field operations are carried on by a continuous chain of loading at one end and discharging at the other, seldom less than three carts are employed, and that in the usual practice of the Southern Counties one horse occupies the stand-cart or wagon, and three horses each of the other two that are in motion; the work thus going forward with seven horses. If two horses in a cart are used, five will be the number engaged; and if four, the number will be nine. Now, I am prepared to show, not by any series of experiments, but by the routine of my farm for the last ten years, that the same amount of work, when at a moderate distance, may be performed by three horses in separate carts; and that it is only at the greatest distance in which three three-horse carts are able to keep up the chain, that four may be required. And these will keep the same number of (and from low-filling, somewhat fewer) loaders engaged, and consequently accomplish the moving of an equal bulk. As this may seem a little paradoxical, I will enter into the reasons which combine to effect it. 1st. A horse thus harnessed draws more in proportion with equal ease; 2d. The misapplication of his strength in the constant draught of a heavy carriage is prevented; 3d. He moves more briskly and freely, and turns, &c., with less loss of time, and when any check occurs, the loss is saved that takes place by the hindrance of a large number; and lastly, there is a certain convenience and ready manageableness which can be better felt than calculated or described.

"Practice and general opinion are agreed in assigning a greater power of draught to a horse working singly than to any number harnessed together; but the amount of difference I have never proved by actual experiment. Mr. Culley, in his Report of the three English Border counties, gives an instance in which the advantage is as three to four; and another, in which, with a horse of 16 hands, 24 cwts. was the load, on the hilly* road from Hexham to Newcastle. I am in the regular practice of sending out to any distance, on a turnpike however hilly, 5 qrs. of wheat, which, with the cart, 6 cwts., seldom amounts to less than 30 cwts. It is also considered, universally, that the nearer a horse is to his load the easier will be the draught, but to what extent I have never proved.

"The misapplication of power caused by a heavy carriage is often enormous, there being sometimes, especially by wagons in harvest, double the weight of timber moved, in going backward and forward, to that of produce brought home; for instance, a common harvest, except at a great distance from the homestead, seldom exceeds one ton, and one ton more or less is the weight of a wagon: at any rate, 1 to 1 is the common proportion of the carriage to the harvest load. It is admitted that there is no perceptible difference between the size of my neighbors' loads and my own; the weight of my harvest-cart I have stated is about 6½ cwts.; therefore my proportion is 1 to 3; and under less favorable circumstances than mine, it need never, with a similar carriage, be less than 1 to 2; and this goes a very considerable way to explain why I am able to perform the same work with half the strength, and without straining the powers of my horses. In the dung-carts the case is not quite so strong in my favor, as there is not so large a disproportion in their weight.

"It is certain that a horse can exert his powers with greater ease and effect by himself than when incommoded by the diverse pulling of companions, and also that a sluggish animal must draw his own share. In turning, one horse is much more handy than a string; and no comparison can be made between the turning of a two and four-wheel carriage. I have never practiced trotting.

"The question," concludes Mr. Hannam, "is not, as is frequently supposed, whether one horse single can draw more in proportion than any number harnessed together, which I believe is generally admitted; it is not altogether which will move the greatest weight; but the question is, which will transport in the most ready and economical manner the materials required to be passed between the field and the homestead, or between one field and another. For in the carrying operations of a farm, with the exception of drawing corn to market, a certain bulk has to be transferred from one point to another, not by one effort, but by a continuous succession of them. Practically speaking, the loading and unloading have to be kept in constant activity by a chain of carriages passing between them. What, then, is the best and most economical intermediate conveyance is not an easy matter for consideration. The best implement and best moving power have to be ascertained; and, among known methods, the selection ranges widely between the barrow or pack-saddle and the eight-horse wagon. Our present consideration, however, is whether one-horse carts are more ready and economical for the purpose than the methods now generally in use."

The *outlay of capital* is certainly in favor of the substitution of carts for wagons. Mr. Bowly, of Siddington, has given the following comparative calculation of the outlay required by the two systems, on 50 acres of arable land:

1 wagon	£25	2 4-inch wheel one-horse carts	£24
1 dung-cart	15	2 horses	40
3 horses	60	Total	£64
Extra harness	2	Balance in favor of carts	41
Proportionate cost of light cart to 50 acres	3		£105
Total	£105		

* I had occasion to send my skeleton cart with 15 cwts. of hay up the steepest hill (Cuddesden) in this part of the country, and directed a very intelligent laborer to go with it and report: his statement was, that besides observing at a steep descent that the breeching was tightened more than the back-chain, on stopping on the sharpest ascent he found the breast-band tolerably slack, and that the horse drew the load up this steep point (1 in 7) without difficulty; and he thought he might have managed a ton. "The horse, however, had a *knack of thwarting the road*," a method of easing the ascent horses are very ready at in the North; in a wagon they cannot do it. His opinion also was that four horses, with two tons on a wagon, would have very tight work at this part of the hill.

"In conclusion," says Mr. Bowly, "I may remark that the principle of one-horse carts is quickness of motion; therefore they must be loaded according to the land to be passed over, so as not to reduce the pace of traveling; and I can assure those who are timid about them that they are much less liable to accidents of every kind than wagons, and that however prejudiced the workman may be against their first introduction, when he becomes acquainted with the system he will prefer it.

"The descriptions of carts I make use of are, five common Scotch carts and one skeleton cart; those of the former, with narrow wheels, cost me 10 guineas each; and with the 4-inch wheels (which I recommend) £12, with harvest-frame, &c., complete. The skeleton with narrow wheels cost me £10; it will carry more hay or straw than the others, its loads being in proportion of four carts to three wagons; it is more convenient for conveying poles, hurdles, &c.; and one on a farm may be useful, but it will not answer in dung-carting, and its advantages in harvesting are not sufficient to remunerate for the additional outlay of a double set."

The one-horse carts, then, we perceive, have been successfully tried, and preferred to wagons in the Northern Counties and in Oxfordshire. We have equally satisfactory evidence of their employment on the stiff clays of Gloucestershire and the Weald of Kent, and the deep soils of Huntingdonshire. "My land," observes Mr. T. Baker, of Hardwicke Court, near Gloucester, "is a stiff clay; my carts are on six-inch wheels, and made to hold half the quantity that my neighbors carry in theirs. My land is hilly; my carts generally go with one horse; but up hill, when loaded, another is put on before, which comes down the hill with the next returning cart. Thus, on level ground, with two carts and two, or perhaps three horses, I take out the same quantity of dung that my neighbors carry in their large carts with never less than three horses, and often with four. All my carts have reins; a boy walks and drives them when loaded, but when returning empty he gets into the cart and trots back at the rate of about five miles an hour, which of course saves about half the time in returning. Here, again, I have a manifest advantage in using lighter and more active horses.

"Some time ago I made the following trial. Two heaps of stone, of 32 tons each, were landed from a barge: they were to be taken to the same place, about a mile and a quarter off. A farmer began the first with two large carts and three horses; one cart was being loaded while the other was moving; and the horses were taken off and put on at every load. Finding that he could not do it in the day, he gave over at the end of about six hours, and set to again the next morning; this rest, of course, giving him an advantage, as you will see; but, anxious for their own credit, both he and his man made the very best use of their time. Their work was completed at eleven loads, (which of course is nearly three tons to each load, or one ton to each horse,) in nine hours and fifty minutes. I began the other heap with three small one-horse carts, and completed it in one day, at twenty-one loads, (being nearly a ton and a half to each horse,) in six hours and one minute; which was a saving of about three hours and a quarter on nine hours and fifty minutes, or rather more than one-third. In this I had three decided advantages—first, the saving of time by trotting back; secondly, the rest that each of my horses got in his turn while his cart was being loaded; and thirdly, the ease with which my carts were loaded in consequence of being lower."

"Having," remarks Mr. Jesse French, of Rolvenden, "pursued this plan of carrying corn and hay for two years, and one of my neighbors having followed my example last year, I draw the following conclusion from the observations I have made: that in carrying *bound* corn, the one-horse cart system has several advantages over that of wagons; and in carrying *loose* corn or hay, though the loader and he who throws it off may complain, and strong prejudices, the effect of habit, may possess the minds of all the hands employed, there is, upon the whole, no advantage. Three carts will generally be sufficient where the distance does not exceed half a mile, for one cart to be always loading; and for every additional half mile, one additional cart will be about sufficient; but this will depend in a great measure upon the road." It is true, as he very justly adds, that "there certainly are various things which a farmer may have to carry, for which one-horse carts are not adapted, as timber and hop-poles, which in

Kent and Sussex are often carried a long distance. In the same district many farmers bring their hay from the marshes, a distance of from three to eight miles. For this purpose small carts are not so convenient; and for carrying hay, and particularly where it has to be carried a considerable distance, a small cart may be enlarged by this expedient. The draught-staples being generally about a foot from the ends of the shafts, by attaching rings to their extreme ends for the horse to draw by, the wheels will be thrown a foot farther behind the horse; consequently the fore-ladder may be fixed a foot forwarder on the shafts. This will allow for the tail-ladder to lean farther back, so as the load may balance. By thus lengthening the load, and keeping it a good width, as much hay may be loaded as a horse will be well able to draw."

"And it will be seen," remarks Mr. E. Loomes, of Whittlesea, near Peterborough, "from the following Table, (which I have laid down from a careful observation of the capabilities of one-horse carts and wagons,) that one horse in a cart is capable of conveying much more than half what can be carried on a wagon with two horses":

One-horse Carts.		*Two-horse Wagons.*	
Wheat-sheaves	172	Wheat-sheaves	207
Corn-cake, &c.	cwts. 25	Corn, cake, &c.	cwts. 45
Bones	bush. 60	Bones	bush. 100

In dung-carting, under ordinary circumstances, *one*-horse carts appear to have, in ordinary circumstances, a decided advantage. Mr. Love has given the following comparative Table of the economy of both *one* and *two*-horse carts, in the different distances supposed to be traveled; and each boy driving is counted as the fourth of a man tipping; a man's wages is reckoned as 2s. per day, and the expense of each horse 3s. per day of nine hours:

	One-horse carts.	Two-horse carts.	One-horse carts.	Two-horse carts	One-horse carts.	Two-horse carts.
Distance in furlongs	3	3	3	3	7	7
Time of traveling a revolution	15	15	15	15	35	35
Number of horses	3	3	5	5	9	9
Number of carts	3	2	5	3	9	5
Men filling the carts	2	2	4	4	4	4
Time of filling	10	15	5	7½	5	7½
Men tipping and driving	1½	1	1½	1½	2½	1½
Time of tipping	3	7½	5	7½	5	7½
Total time to each revolution	30	37½	25	30	45	50
Number of loads drawn	54	29	108	54	108	54
Number of yards drawn	54	43½	108	81	108	81
	s. d.	s. d.	s. d.	s. d.	s. d.	s. d.
Expense of horses	9 0	9 0	15 0	15 0	27 0	27 0
Expense of men	6 6	6 0	11 6	10 6	13 6	11 6
Total day's expenses	15 6	15 0	26 6	25 6	40 6	38 6
Expense of carting thirty yards	8 7½	10 2½	7 4½	9 5	11 3	14 3
Saving by one-horse carts per acre	1 7½		2 0½		3 0	

Mr. John Dryden has described a plan for an improvement in single-horse carts, by which the evils of a fixed balance of the load in a cart are avoided; and it is probable that the use of the Welsh drag in hilly countries would materially facilitate the general employment of one-horse carts.

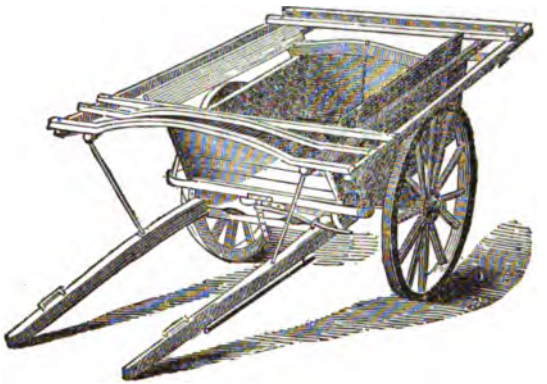
"That the state of the road has a very material influence upon the animal power required to draw a given weight over it every person is well aware, but few persons regard the difference between the labor of drawing a carriage over a road in good condition and the same road when out of order. This has been, however, experimentally determined, and we commend to every farmer and every overseer the careful and steady consideration of the results thus obtained. In these trials it was found that a light carriage with four wheels, weighing with its load 1,000 lbs., required a force of traction as follows":

On a turnpike-road, when hard and dry	30½ lbs.
On the same road when dirty	39 "
On a hard, compact loam	53 "
On an ordinary by-road	106 "
On a turnpike-road newly graveled	143 "
On a loose, sandy road	204 "

The care with which all drivers avoid the newly graveled portions of a road is

well known, yet few of even the best whips, I think, are aware of the enormous difference of pressure upon the collar shown by the previous Table to exist, when the load is passing over a hard and dry turnpike-road, and the same road when newly graveled, composed of loose, sandy materials. The Farmers' Club, then, we cannot but feel, arrived at a tolerably correct conclusion when they thus gave the preference to one-horse carts for the general purposes of the farm. The farmer, however, who resolves to make trial of these advantages, must be firm and resolute, for, like every other alteration, it will hardly fail otherwise of being met by a strong opposition from his servants. To this end a hint or two of Mr. Hannam's will be useful; he observes, "I market my corn, according to the Northern practice, in the dung-cart; it is not so convenient to unload sacks from as a wagon, but the load it carries, viz., 5 qrs. [40 bushels at 60 lbs. per bushel, 2,400 lbs.] of wheat, 6 qrs. of barley, and other grain in proportion, and in back carriage half a wagon-load of ashes compensates for small inconveniences. The only objection that I have heard the carters make to the system in thus carrying out the corn is that they find themselves singular, and making but a bad figure by the side of a wagon and team of horses. They should therefore be indulged with a reserve of the best carts, kept well painted, and washed after being used for manures, and with harness a little ornamented."

Of the many excellent carts prepared by various makers, we will only allude to two, those of Mr. Crosskill, of Beverley, and of Messrs. Stratton, of Bristol.



THE ONE-HORSE CART OF CROSSKILL OF BEVERLEY.

"Mr. Crosskill's," said the Judges of the Shrewsbury meeting, "is a thoroughly well made and cheap one-horse cart, having a particularly simple and safe tipping contrivance. The especial reason for awarding to it a premium of £2 was the introduction of a self-acting tail-board, which opens and shuts as the body is tipped, or brought home, so that no time is lost by having to unship and ship a tail-board, whether the contents of the cart have to be discharged at once or at intervals. At the Newcastle meeting it obtained the prize of £5.

Of the cart of Messrs. Stratton, and of their other excellent implements of a similar kind, the Judges of the Bristol meeting thus reported: "The show-yard was rich in an assortment of carts and wagons. To Mr. Richard Stratton, of Bristol, a premium of £10 was assigned for the extraordinary variety and good workmanship of his immense collection; more particularly for the ingenuity displayed in the construction of a cross-lock wagon, which facilitates its turning in a very small space, and permits the use of four large wheels of equal diameter. A tipping-wagon also possessed much mechanical merit, but it is to be recommended as better adapted to commercial than to agricultural use. Mr. Stratton produced an excellent specimen of the low-chested cart, obtained by cranking down the axles, now in such general use by mercantile men and shippers. This disposition, modified to suit farming purposes, well merits the attention of agriculturists, as it would greatly ease the toil of the laborer. Of Mr. Hannam's (of Burcot) unequaled one-horse harvest-cart, more need not be said than that

it cannot be exhibited too often, and that it ought to be found on every farm. To Mr. Robert Law, of Shettleston, near Glasgow, a prize of £3 was awarded for his Scotch one-horse tipping-cart with a spring-catch to retain it on the

THE CART OF MESSRS. STRATTON & CO., OF BRISTOL.

shafts. This simple little contrivance is much preferable to pins and cotters, which are apt to shake out, or to be neglected in the fastening, by which the load is not unfrequently let fall." At the Bristol meeting, two prizes were awarded to Mr. Stratton for his carts and wagons, and three at Southampton.

PREFACE.

HAVING finished, in the last number of THE FARMERS' LIBRARY Stephens's "BOOK OF THE FARM," we dedicate with pleasure the few remaining pages of this volume of The Library to the following Tract on "MANURES, AMELIORATORS AND STIMULANTS," and on the Action of Salt as a Manure, translated expressly for this work.

The authors are all men of distinguished character as scientific investigators, and have fortunately given their attention, in this case, to subjects of great moment to Agriculture.

The Essay by Dumas will be seen to relate chiefly to the preparation of certain Manures, of which cities supply the materials, and most particularly to *nightsoil.*

Perhaps nothing could be referred to that would more forcibly illustrate the carelessness of agriculturists in matters that very nearly concern them, than the neglect, in this country, of this, the most wasted of all fertilizers, and the most concentrated and powerful, except the excrement of birds and fowls, which contains more nitrogen. Such are the fertilizing effects of this manure, says an English author of many Prize Essays, that it has been assumed that the excrements of a man, when properly applied, can be made to produce sufficient corn and roots for his own support. Though this may be an exaggeration, a thousand experiments have proved it to be exceedingly nourishing to vegetation, and, it is said, most particularly to *potatoes!* And yet, what immense quantities of it are carried off and lost, especially from our large towns! What a resource would the privies of the public buildings at Washington afford, if arrangements for preparing their contents were provided according to the directions in this Treatise!

It has been said that nightsoil communicates an unpleasant flavor to plants; but this objection may be easily obviated by mixing it properly with ashes, or lime, before being applied. In China, where Agriculture is carried to the highest point of productiveness—from the denseness of the population, and the labor being principally manual—nightsoil is the only manure in use, both for the gardens and the fields.

The nightsoil of Paris is exported to Flanders and the low countries, where, after being converted into liquid manure, it is extensively used—being considered particularly convenient and valuable as a top-dressing for grass-lands.

We know of but few chances that offer so promisingly of great profit to the manufacturer and to neighboring cultivators, as establishments for

the preparation of poudrette, in many large cities where none such have been provided. It would seem to be superfluous to dwell on the care with which every provident farmer will husband a resource so efficient and valuable. One might as well, it ought to be supposed, exhort a sensible man not to take silver out of his pocket and throw it away!

In appending to the observations of Dumas the remarks of eminent writers and practical agriculturists, on the use of Salt, we had in view to fill with a kindred topic the little space which remained to us and at the same time to show that a *Farm* is in truth but a *Manufactory*, and that when so considered it ought to go far in dissipating that prejudice and mistaken apprehension of antagonism, which pervade the agricultural community, toward their best friends and customers, to wit: those who *(nearest to their own farms)* are the *manufacturers of their raw materials and the consumers of their produce.*

MANURES,

AMELIORATORS AND STIMULANTS—MODES OF MANUFACTURE, &c.

BY JEAN BAPTISTE DUMAS.

Translated from the French for The Library, by CAMPBELL MORFIT, Practical and Analytic Chemist.

THE term Manure, in its widest sense, extends to all substances, solid, liquid or gaseous, which are applicable to the nutrition of plants or to the promotion of their growth. Thus generally considered, manures are very diverse. In fact, every substance containing one or more elements of plants, wholly or partially susceptible of assimilation, in the act of vegetation, may be ranked as a manure. Sooner or later, the plants in contact with such substances will assimilate some of its elements—that is, either hydrogen, oxygen, carbon or nitrogen, or the water of combination, or even different calcareous, earthy or metallic salts which enter into the composition of nearly all plants.

An ameliorator (*amendment*), on the other hand, is a substance designed for the improvement of the physical constitution of the soil; that is, to render it permeable if too compact, and to impart body and consistence when too light and sandy: indeed, to partially change or to modify its nature, if its constitution is either deficient in nutritive power or prejudicial to vegetation. A combination of these valued qualifications of both a manure and an ameliorator is met with in a variety of matters.

Finally, the title of stimulant applies to those substances, solid or liquid, which give an impulse to vegetation, either by imparting a more active energy to the manure, or by stimulating the organs of the plant and thus promoting the assimilation of the elements which constitute it. Sometimes, the stimulants are of a nature totally or partially assimilative by the plant, but their more special object is to augment the activity of manure, particularly those whose which are nitrogenous. In a soil completely deprived of the latter, stimulants are ineffective, and they impoverish the soil if care is not taken to recruit its strength by fresh additions of azotized matters. Gypsum, lime, and common salt, in proper proportions, are powerful stimulants.

Although the term Manure properly refers to every substance capable of furnishing one or more of the elements of a plant, yet custom limits the application of the name to those which furnish the nitrogen, alkaline and earthy phosphates, and other salts requisite for vegetation.

The carbon, hydrogen and oxygen exist abundantly in Nature, and a supreme intelligence dispenses them, in suitable proportions, in the forms of air and water. That which is most wanting and expensive to the agriculturist, as being the most fruitful source of abundant crops, is nitrogenous matter. Since the recogni-

tion of this great truth, and since modern Chemistry has demonstrated the important agency of nitrogen, real manufactories of manures spring up and prosper, and the offal, detritus and filth which were formerly unavailable, and were even the causes of the insalubrity of cities, are now rendered subservient to Agriculture.

We divide the nitrogenous manures into two classes: the first comprises those which are employed in their natural state, and the second embraces such as should undergo preliminary preparation.

Every nitrogenous substance, liquid or solid, whether from the animal, vegetable or mineral kingdom, when employed in its original state and without previous preparation, constitutes a natural manure.

Among the animal manures are blood, muscular flesh, and the offal of the carcass. All the substances, in their rough state, should be used immediately, otherwise their rapid putrefaction will develop an infectious odor, and consequently render their use impossible in the environs of large cities where they are most abundant. We will see, however, in studying the prepared or manufactured manures, in what manner they can be indefinitely preserved and reduced to a bulk convenient for transportation to a distance, and thus made more uniform and constant in their action.

The herbaceous plants, turned under the soil in a green state, form a natural manure much used, especially in warm countries—for while furnishing nitrogen, they maintain a humidity very favorable to vegetation.

Without recommending this practice, we will merely remark that in the south of France and in Italy, certain plants, (such as the lupines, beans, and even maize) are specially cultivated for this purpose. For moist and cold soils they should be applied in a dry state; and of great advantage in this respect is the employment of rye-stalks and damaged hay. Leaves of trees are also applicable, for analysis has proved them to contain more nitrogen than other portions of the tree; and, moreover, they are not costly, being furnished in abundance and gratuitously by neighboring forests.

The seeds and fruits of plants and trees, are likewise often employed as manure. In Italy, the lupin seeds are successfully used to manure the orange and olive trees; but care is always taken to previously destroy their germinative impulse by torrefaction in a furnace: as the lupin seeds contain 4 per cent. of nitrogen, their activity is readily comprehensible—as is, for like reasons, the case with clover which is applicable under similar circumstances. So also, the residual matter of malt, of pressed fruits, oleaginous seeds, or of olives, will produce corresponding and frequently even more energetic effects, since, notwithstanding their loss in weight by expression, they still retain nearly the whole of their nitrogenous and albuminous matter, which constitutes their value and richness as a manure. In fact, the *marc* of flax-seed, colza, *Arachis hypogea*, *Madia sativa*, &c., contain the enormous quantity of 5 to 8 per cent. of nitrogen, nearly equaling the proportion in dry animal matter.

Finally, among the natural manures of the vegetable kingdom must be classed aquatic plants, growing either in fresh or salt water. The plants which are gathered green from the marshes may be used in that state for the fertilization of the soil, as it suffices to merely turn them into the ground by plowing.

Sometimes, however, they are previously subjected to incipient fermentation under water, but the resultant peat cannot be used without certain precautions, for its acid reaction renders it hurtful to vegetation. To remedy this, and to

render it suitable for agricultural purposes, the free acid must be saturated with lime—or as well by promoting putrefaction, which destroys these acids, or rather saturates them, by the formation of ammonia.

In some localities they are merely burned, and the ashes spread upon the surface of the fields; but it must be remarked that this process destroys their most fertilizing portion, viz., the ammonia or nitrogenous matters; still, however, the residuum, by reason of its constituent salts, forms a stimulant of much energy.

The marine plants, such as the fucus, sea-wreck, hair-weed, &c., where they can be procured abundantly and cheaply, make a very advantageous manure, as they contain, in addition to some nitrogen, a certain portion of salt which stimulates their fertilizing power. In Normandy and Brittany they have been used from time immemorial. Sometimes they are applied to the soil in their natural state, and again sometimes in the form of litter. But another practice is to make a compost of them, either by stratification with alternate layers of earth, so as to produce a mould, or by admixture with other mucks. In this last process there is evidently a partial loss of their properties, for the fermentation produced in the mass always eliminates nitrogen, which consequently escapes. As the marine plants decompose with sufficient rapidity in the earth, this previous disintegration, in most instances, is unnecessary.

In France, the use of the varech and fucus creates so extensive a cultivation on the sea-board that a royal ordinance has restricted their time of harvest to a limited period—between the full moon of March and that of April, during which they have expanded their reproducing granules, and are not covered by the spawn of fish.

The mineral kingdom also furnishes some substances suitable to agricultural purposes. They, too, may be considered as natural manures, and though generally constituted of a certain portion of nitrogen, are, by reason of other properties, powerful stimulants and ameliorators. For example, the black or red pyritous ashes from Picardy, much used in the Northern Departments, may be considered as an energetic stimulant manure.

These ashes, which also are the raw material from which copperas and alum are manufactured, exist in numerous other localities as a black powder, frequently containing shells, vegetable debris, and bituminous wood, more or less decomposed. When heated slightly in a crucible, it inflames and undergoes a slow combustion, which, after two weeks' continuance, partially changes its nature and color, which latter, from the per-oxidation of the iron, becomes red.

According to Girardin and Bidard, they are to be found at the surface of the soil, in the neighborhood of *Forges-les-Eaux*.

These pyritous earths, after having been leached, are generally mixed with one-fourth of their weight of calcined turf, and applied as a stimulant. They are exactly similar to those from Picardy. According to the analyses of Girardin and Bidard, their composition is as follows:

100 parts of lixiviated ashes contain 24 parts of water.....			
100 .. .. dry .. .. matters soluble in water	4·53	Organic matter or soluble humus	2·74
		Sulphate of protoxide and peroxides of iron	1·79
100 .. .. insoluble in water	95·47	Fine sand	38·92
		Insoluble humus	49·83
		Sulphuret of iron	
		Peroxide of iron	6·72
Total.....	100·00		100·00

The nitrogen of these ashes equals the considerable amount of 2·72 per cent. The proportion found by Boussingault and Payen in the Picardy ashes, did not exceed 0·65 per cent.—hence, probably it is the humus which they contain that gives them the property of a manure, while the stimulative influence is doubtless due to the presence of salts, especially those of iron. The warmth generated during the slow combustion of the sulphuret may also, and probably does, have some influence promotive and accelerative of vegetation.

The mixed manures which are employed without previous preparation consist of the offal of streets and excrements of animals.

Fecal matters and urine, either pure or diluted with water, are frequently applied in their natural states, merely by distribution on the surface of the soil. This mode enables all parts of such manure to be used, but it is not without inconvenience, for its great bulk renders the expense of transport heavy, and consequently limits its use to the immediate vicinity of its production. As the cities and towns produce more than is requisite for their vicinities, there is a considerable loss when it is not used in its natural state.

There are these objections, however, to fresh fecal matter: they communicate their disagreeable odor to the plants, and emit a pestilential effluvia in the act of being carried to and spread upon the field. A proper treatment previous to their application to the soil, obviates all these disadvantages.

Human excrements constitute one of the best manures. They are employed in a fresh state under the form and name of *gadoue*, or in a dry state as *poudrette*.

n China, Tuscany, Holland, Belgium, and many other countries, they are used in a fresh state, being diluted with water and then dispensed throughout the surface of the soil. In China they are kneaded with clay, and the dried mixture is then pulverized or crushed. In Flanders, where they use them for the culture of flax-seed, colza, poppy and tobacco, the farmers have reservoirs expressly for the reception of fecal matters. In these vats they remain for several months, or until transformed by fermentation into a viscid liquid matter. In this state they constitute the *Flemish manure*. To improve it, the pulverized marc of pressed seeds is frequently added, for the nitrogenous matter therein contained becoming rapidly decomposed, contributes materially to the efficacy of the manure. The addition has other advantages also in decreasing the fluidity of the excrements, and by becoming thoroughly impregnated with it, in facilitating its application and prolonging its beneficial effect. However, this effect is never beyond a year's duration. 26½ gallons of *Flemish manure* equal about 550 lbs. of horse-dung. This mode, prevalent in Belgium and Flanders, where Agriculture is brought to a full development, and where great care is observed in the preservation and application of all matters promotive of the fertility of the soil, is the one most to be recommended.

The excrements being inclosed and free from exposure, are less subject to sudden changes of temperature and to fermentation, and consequently can be retained unaltered and unimpaired in quality for a long time.

When the liquid manure is to be used, it is drawn portionwise from the reservoir, and then diluted with five or six times its weight of water, in order to modify its energy and prevent injury to the plant. Thus prepared, it is spread upon the fields when they are being sowed, and upon the meadows after having been recently mowed. Sometimes it is dropped, undiluted, by ladles-full at the foot of each plant, when its nature permits the application without too much manual

labor; but in such instances care must be taken not to touch the stalks, lest they might be injured.

In the environs of Lille, a cask of thirty-five and a half gallons of Flemish manure, costs twenty-four cents, that is, six cents purchase money, six cents for transportation, and twelve for labor in spreading it.

The excrements of birds or fowls form a manure much richer in nitrogen, and consequently much more active than the Flemish manure. They contain, in fact, 8 and even 9 per cent. of nitrogen. They undoubtedly are the richest of mixed manures, and, moreover, are among the warmest and most alterable. In the Northern Departments of France, where they are much appreciated, one of them—that most used—is pigeon's dung, $20 value of which will fertilize or manure 9,500 square yards of ground. This rich manure is especially used in the culture of flax, tobacco, &c. It is only necessary to examine the analyses of guano, to see and be convinced of the richness of the excrements of birds and their utility in promoting vegetation. They contain, in fact, independent of accidental portions of feathers and other debris, uric acid, ammonia, coagulated albumen and phosphate of lime.

In Flanders and elsewhere, where pigeon-fanciers are numerous, they collect the dung and engage it to farmers at stipulated rates. At the usual price of $20, for the product of 6 or 700 pigeons it will cost $25 to $40 to manure about three acres.

The excrements of other birds are less valuable than those of the pigeon.—Usually, these latter are employed in their natural state, and without any admixture, being in this form specially fitted to assist the growth of the cereals in humid and compact soils. They are, however, of nearly equal service in the culture of clover; but for this purpose they should be mixed with ashes. In Flanders, 4,500 lbs. per three acres is the proportion for a good yield.

As has already been remarked, these manures owe their efficacy, in part, to the urine with which they are impregnated; and furthermore, it is well known that this liquid, by the decomposition of urea, one of its principal constituents, can furnish a notable quantity of carbonate of ammonia, the utility of which to vegetation has been well proved. Independent of the urine absorbed by the litter, a portion which by a little management might be retained, runs off, and is lost.

In Switzerland, it is the custom to collect the urines in cisterns and therein reserve them for some time before spreading them. In Belgium, they are imbibed by straw and then mixed with ordinary manure, and sometimes even with loam, clay, sand or plaster. That manure known in commerce under the name of "*Urate*," is a mixture in equal proportions of urine and plaster. It is dried and powdered, and kept free from moisture.

Whether it is more useful to employ fresh or slightly putrid urines as a manure, is a question which answers the prevalent custom in favor of the latter; but the practice in this, as in many other instances, may lead to error for, for it is not based upon correct principles.

It is known, in fact, that carbonate of ammonia generated during the fermentation of urine is a very volatile salt, and that thus the more active and useful principle is liable to be dissipated when the urine is too long kept. To form an idea of the advantages which may be thus lost, remember that every 2¼ lbs.—of ammonia which evaporates is equivalent to a loss of 150 lbs. of grain, and that 2¼ lbs. of urine will produce 2¼ lbs. of wheat.

In all these cases, in order to fix the ammonia, the urine must be mixed with

plaster, sulphate of iron, or mould. Sulphate of ammonia, a more fixed, but not less efficacious salt than the carbonate, is thus formed.

The advice of some agriculturists to use the fresh urine, properly diluted with water, we rather hesitate to recommend.

There are many other substances besides bird's dung, which can without previous preparation be advantageously used in Agriculture. The excrements from sheep-folds, &c., are of this number, and this mode of manuring is simple and economical, for there is a saving of both the waste and expense of transportation.

Dung or muck itself, as obtained in most places, may be considered as a mixed unprepared manure, since all its preparation consists in receiving the excrements upon straw and stacking it as fast as it becomes impregnated with fecal matter.

The name of dung specially applies to the straw litter impregnated with the urine and fæces of domestic animals. When a mixture of this kind is exposed to air, and moistened occasionally with water, a very active fermentation ensues: carbonic acid and ammonia, among other gaseous products, are disengaged, and the straw itself becomes rotted and disintegrated. It is in this state that the dung is used to manure the land. As to the juices, which serve for irrigation, they hold in solution all the soluble matters of the manures, and owe their deep-brown color to the presence of ulmate of ammonia. Being advantageously serviceable, they should be carefully collected and preserved.

One circumstance worthy of note is, that the dung during fermentation can lead to the formation of ammonia from the nitrogen of the air and hydrogen of the water. The efficacy and value of manures, then, depend not only upon the nature and relative proportions of the excrements and straw, their bases, but also upon the processes of their manufacture and modes of preservation and employment.

The dungs obtained from the excrements of herbivorous animals are not equally efficacious. Hog dung is much less valuable as a manure than that of the cow and ox, which latter, in their turn, are surpassed in richness by those of the horse and sheep.

Below are Girardin's comparative analyses of the excrements of the cow, horse, and sheep:

	Cow.	*Horse.*	*Sheep.*
Water	79·72	78·36	66·34
Organic matters soluble in water	5·340	4·34	4·10
" " " in alcohol	2·00	2·60	2·60
Woody fibre	8·70	12·16	16·26
Saline matters, viz., phosphates of lime and magnesia, carbonate of lime, chloride of sodium, silicate of potassa, silica	4·23	2·34	8·15
Total	100·00	100·00	100·00

Sheep manure is considered the most preferable of all other species. Being hard and of a shape which prevents a ready admixture with the litter, it is slower to be impregnated with the stable liquor, and consequently is less liable to rapid fermentation. To favor the decomposition of the straw, therefore, it is necessary to arrange it in layers, and to wet it frequently before using it.

It has been calculated that the excrements of a sheep produced in one night, suffice to manure 1¼ square yards of surface, or, according to Boussingault, even one and a third.

In comparing, for different species of animals, the weight of their fæces with that of their food, we find, after Black's experiments, the following relations:

From the ox	0·42	From the horse	0·42
From the sheep	0·40		

Experience has, moreover, shown that an ordinary beef of 900 pounds produces, annually, from fifty to sixty metrical quintals of manure. The same quantity is obtained from a horse and a half, and from ten to fifteen sheep.

The nature of the litter used necessarily exercises a marked influence upon the qualities of the manure. In fact, the different kinds of straw vary, those of the leguminous from those of the cereals, not only in the proportions of their saline contents, but also in their richness in nitrogen.

Sprengel makes the following classification of the straws, ranking each according to its practical value. Annexed, also, is a Table of their relative proportions of organic matters and saline substances:

	Organic Substances.	Solid Substances.		Organic Substances.	Solid Substances.
1. Colza straw,	96·127	3 675	7. Pea straw,	95 029	4 971
2. Vetch ..	94 899	5·101	8. Barley, ..	94·759	5·244
3. Buckwheat, ..	96·679	3·121	9. Wheat, ..	96·482	3·518
4. Beans, ..	96·797	3·203	10. Rye, ..	97·207	2·793
5. Lentil, ..	96 101	3·899	11. Corn, ..	96·015	3·985
6. Millet, ..	95·145	4 855	12. Oats, ..	94·266	5·734

The following analyses of Boussingault and Payen show the proportion of azote in several straws.

	Nitrogen per cent.	Equivalent.	Dung per 2½ acres.		Nitrogen per cent.	Equivalent.	Dung per 2½ acres.
Pea straw,	1·79	2·234	6·702	Oat straw	0·28	142·85	42·855
Lentil ..	1·01	39·60	11·880	Wheat (new) ..	0·24	166 66	49·998
Millet ..	0·78	51·28	15·384	Barley ..	0·23	173·90	52·170
Wheat, (old) ..	0·49	81·60	24·990	Rye ..	0·17	235·29	70·587

The straw of the leguminous plants is, therefore, richer in nitrogen than that of the cereals, and, moreover, contains larger proportions of potassa salts, and by putrefaction gives more ulmic acid and disengages more ammonia.

The latter are preferable in the manufacture of manures. Cereal straws, poor in nitrogen and alkaline salts, contain a large portion of silica and phosphate of lime. Oat straw is richer in potassa than other cereal straws, and the soil containing this alkali produces good oats. Magnesian earths are particularly applicable to the culture of buckwheat, the straw of which contains a remarkable quantity of magnesia.

The mode of preserving the manure, during the interval between its removal from the stable and application to the soil, has a decided influence upon its fertilizing power. Its action depends upon a carefully managed fermentation, so as to generate ammoniacal salts and other stimulant principles, and at the same time prevent a partial volatilization of the ammonia by a too active evaporation. To this end, therefore, it is requisite to stack the manure in broad heaps, so that a too great hight of the pile may not cause a too high elevation of temperature in the interior of the mass.

To prevent the escape of a part of the ammonia, the manure must be frequently wetted with the juice which runs from the stables, which should be collected and saved for the purpose. It can be pumped up from the reservoir, and thus applied uniformly and regularly.

It is also necessary to protect the manure from the unequal washings by rains.

Some farmers prevent a too active fermentation of manure by stratefying it with earth. It may also be mixed with peat or turf, as experience has shown that a uniform compost of this kind makes an excellent manure.

Manures can be immediately used, fresh from the stable, and without being previously fermented. Under this form they are called *long* or *straw manure*.

Those which have been for some time stacked have the name of *short* or *fat manure*. Both the weight and volume of manures are decreased by fermentation. It has been ascertained that 100 volumes of fresh manure are reduced

In	81 days	to 73·3	of its original bulk, with a loss of	26·7
..	254 ..	64·3	.. ..	35·7
..	284 ..	62·5	.. ..	37·5
..	395 ..	47·2	.. ..	34·8

Schattenman, the skillful director of the factories at Bouxwiller, has proposed a simple and economical mode of effecting the fermentation of manures. It consists in adding to saturated waters, or spreading upon the dung, either sulphate of iron or gypsum, the sulphuric acid of which, by forming a fixed salt with ammonia, prevents the volatilization of the latter. With due precaution, a rich manure of great power may after this manner be prepared in two or three months.

As has already been remarked, the different manures vary in properties and fertilizing power. The remarkable difference between the weight of an equal volume of cow and horse dungs, for example, is shown as follows:

A cubic foot of fat manure of the ox weighs				57	1-5 lbs.
..	fresh	..	.. ..	47	1-4 ..
..	fat	..	horse ..	37	1-2 ..
..	fresh	..	.. ..	29	1-2 ..

The better dung, and that which may be considered as normal, is from horned beasts, and approximates in composition to the following analysis:

Soluble Substances	Water	75	Insoluble Substances.	Resinous and fatty matter	20
	Albumen			Starch	
	Mucus			Salts of lime and magnesia.	
	Urea			Vegetable fibre	
	Bile				
	Mucilage or gum				
	Extractive and sweet matters				
	Salts potasse, soda, ammonia.	5			80
		100			

Boussingault gives the composition of a farm manure aged six months, and which he calls normal, as follows:

Water		79·30
Organic substances	14·03	20·70
Salts and earths	6·67	
Total		100·00

Under the name of street dung is comprised the incongruous mixture of mire and filth which is collected in cities by sweeping the streets. Its composition is complex, and before being used it should undergo fermentation. During this process large quantities of sulphuretted hydrogen gas are disengaged. Lime, which is sometimes added to accelerate decomposition, is apt to cause a partial loss of ammonia.

The mass should be left undisturbed for some time, so that the decomposition may be thorough. If applied while fresh, it will ferment in the soil; and thus, by a too energetic action, will blast the roots of the plants.

The name of compost is given to a mixture more or less similar to street dung. It is formed of alternate strata of manures of different compositions. In this way, a pile of organic debris, the detritus of plants, residual animal matters, and waste juices of dwellings and manufactories, may be manufactured into a profitable manure; but it too often happens that, in large cities, where these matters are most abundant, the profit they would yield the farmer is lost by the neglect in collecting and preserving them.

Jauffret, a Provincial farmer, has proposed the manufacture of manure by a

rapid and active fermentation of fern, broom-reeds, and organic residues. To this end, the materials must be finely divided,—heaped up and moistened with lye holding in solution some mineral substances, and putrefied organic matters. The place of manufacture should be convenient to a pool, the water in which can be made foul by additions of fecal matter, urine and sewer filth. Ashes, plaster and nitre, are necessary and advantageous additions.

By wetting the vegetable debris with this lye, a very active fermentation is produced: the confined air of the mass facilitates the reaction, and the temperature of the interior rises as high as 167° Fahrenheit.

But this manure is too expensive, for while 4,500 lbs. will cost $4 80, that amount of stable manure can be bought for $2 to $3. Nevertheless, by following the method of Jauffret, a sufficiently economical manure can be made says Lucy, with the following ingredients. The cost of the compost and its application per 11,960 square yards, will be as follows:

800 bundles of colza twigs	$4 75	22 hogsheads of salt and crude saltpetre	1 14
500 " " fern	2 47	52½ gallons of ashes	2 21
Small straw, damaged	3 42	22½ " of charcoal dust	1 14
220 lbs. of plaster	3 42	Labor	3 04
105 gallons of fecal matter	1 14	Total	$22 60

While leaving to agricultural experience the resolution of the problem in a practical and economical point of view, we, on the other hand, cannot too strongly reccommend this system of fabrication, which evidently reposes upon an excellent basis.

When the importance of nitrogenous manures in the nutrition of plants becomes fully known and recognized, all matters containing more or less of this element will be turned to account, and everywhere will be erected real manufactories for their proper preparation. Indeed, even now the preparation of manures commences to form a true chemical art—the object of which is to furnish to the land, under the best possible form, the supplement to that nourishment which the farmer cannot supply to soil otherwise well cultivated, and from which it is desired to draw the most advantageous results.

All parts of animals, being rich in nitrogen, form an excellent manure which can be used on the spot in a fresh and unprepared state; but to transport them to a distance, or to preserve them, or to render their effect more constant and uniform, it is requisite to subject them to a certain treatment that will, at the same time, render them less communicative of a bad taste to plants. The slaughter-houses, where sick horses are killed for their fat, possess advantages for the preparation of manures from offal otherwise wasted.

To preserve the blood, indefinitely, it must be coagulated at a temperature of 212° Fahrenheit, either by a direct application of heat to a caldron containing it, or, more preferably, by the intervention of steam. In the latter case, the blood can be placed in a wooden vat. The coagulated portion is removed by a large skimmer, then pressed until it ceases to yield any more liquid; afterward it is dried either in the open air or in a heated room. Thus dried and pulverized, it can be packed into casks for transportation and agricultural purposes; and being much reduced in bulk forms a very rich manure, containing the large amount of 13 to 14 per cent. of nitrogen.

In the horse butcheries, after having boiled the carcasses in wooden vats or steam tanks, they detach the flesh from the bones and dry it, first in the sun and finally in a dry room, until it becomes friable and pulverulent. When coarsely ground in a mill, this dried flesh makes an excellent manure which decom

poses much slower than fresh meat, and at the same time is of more durable fertilizing power. Unfortunately, however, the use of this material in the manufacture of prussiate of potassa and nourishment of animals makes it too expensive except for the most productive vegetables; thus, for instance, it is exported to the Colonies for the culture of the Cane—for its richness in nitrogen renders it more economical for transportation than other kinds of manure.

Bones properly prepared constitute an excellent manure which is much used in England. In France, where they are not so plenty, and command a high price for the manufacture of bone-black, they also are used to a limited extent.—Before being applied to the soil they must be freed of their grease by a long boiling in water. The fat thus obtained pays the expense of its separation and a small profit additional. The bone, after being boiled and dried, must be ground to a coarse powder between channeled iron rollers propelled by steam or horse-power. They are first passed through rolls with wide and coarse channels, and finished between a pair with finer grooves and more closely set.

This manure (bone-dust) is so well appreciated in England that it commands $3 to $3 50 per 185 lbs.; and 1,850 to 7,400 lbs. are used per 2½ acres. Its slow decomposition is a peculiar merit of this manure, as its effects are perceptible for many consecutive years. While manures much richer in nitrogen during their rapid decomposition generate fertilizing gaseous matter much faster than it can be assimilated, the bone-dust furnishes them gradually and produces in the end more profitable results.

When the gelatine and glue have been extracted, or when the bones have for a length of time been exposed to the irregularities of the atmosphere, their fertilizing power becomes impaired, and is less than that of new bones proportionably as the organic matter has decreased.

There are mills in various parts of the world for grinding boiled bones and the refuse of the comb and button factories; and the powder thus obtained, when dried, consists, per 220 lbs., of

Combustible animal matter	43·86
Phosphate and carbonate of lime	56·14—100·00

This analysis approximates very nearly to the normal constitution of bone.

The animal matter of bones, doubtless, plays an important part in their application to Agriculture; but it would be false not to recognize the importance, and even absolute necessity, of the phosphate of lime in the bones. The exportation of meat or grain from a farm is equivalent to the exportation of earthy phosphates, because the bony structure of animals is formed of it, and grain contains it in large quantities. In order to revive lands, therefore, these phosphates must be restored to it, for light soils naturally have but very little. Consequently, the most simple method is to impregnate the soil with the urine or fecal matters of man, which the consumption of the grain has produced, or with the bones of the animals whose flesh has been exported or otherwise consumed.

The natural phosphate of lime would also make an excellent ameliorator, and its application will doubtless be well worth the expense.

Among the economical means of restoring to the soil all the essential ingredients that have been abstracted from it by vegetation, Chemistry enumerates ammonia and the earthy phosphates, as of chief importance. Boussingault, who has also tried the ammonia-magnesian phosphate, recommends its use, as especially advantageous in the culture of a variety of maize known as *Mais quarantain.*

The most common and well-known manufactured manure is doubtless the *Poudrette*, which is prepared from the contents of privies, and contains the earthy phosphates in connection with fecundant animal matters. An extensive factory, established at the very gates of Paris, gives great value to fecal matters by reducing them to a suitable condition for transportation to a distance. Thus a large amount of material, which in other large cities is useless, becomes transformed, by some skill, into a source of profitable revenue.

But it must be remarked, that the mode of preparing the poudrette pursued at Montfaucon is very imperfect, as it not only incommodes the vicinity, but occasions a loss of a great part of the gases most useful to vegetation. As the method is still in prevalent use, we deem it necessary to give a more correct process.—It is briefly as follows:

The operation is conducted in six or seven perfectly tight large reservoirs, placed in an elevated position and above the neighboring dwellings. These cisterns are arranged with coupling connections so that they may be united together or disconnected at will. One of them, much more elevated than the rest, is also of a proportionally greater capacity. This is the recipient for all the collected fæces of the City of Paris, which is emptied in from casks specially appropriated for its first reception. The reservoir is of irregular shape, being of 330 feet long, 150 to 175 wide, and 30 deep; and it is in this vessel that the liquid is separated, merely by decantation from the solid portion. It is drawn off through a conduit, and, passing through a *wicker* sieve, falls into one of the vessels beneath. There should be five or six of these receiving vessels, and each of 50 to 80 square metres capacity; but having to contain less solid matter, they are not necessarily so deep as the upper cistern. As has been remarked, these vats communicate with each other, so that there may be a systematic deposition of the matters suspended in the liquid running from the upper cistern. The thin juices then pass consecutively through all the vats, and are again filtered through a fine *wicker* which catches the solid particles, and allows the free egress of the liquid into a conduit which connects with a sewer emptying into the Seine.

From this it will be readily seen that the lower cisterns are a long time being filled with solid matter; a year or more frequently elapses before one is full When it is so, after several days' repose it is freed of its liquid with a pump syphon, or by drawing off. Each vat is emptied in its turn, and again set for the reception of thin juices which are constantly flowing from the large upper cistern. This latter, when sufficiently full of solid matter, must, after the excess of liquid has been drawn off, be worked in the same manner as the lower vessels.

The vats of Montfaucon are so badly arranged as to render it necessary, while working the upper vat, to continue adding the nightsoil. Care, however, is taken to immediately separate the more liquid portion and run it into the lower vessel. The process will be more readily and uniformly conducted if there are two reception reservoirs, so that while one is being worked the other can be filled.

The mode of operating and of managing the vats is very simple. When the matters have been sufficiently drained, open the gangways leading to the bottom of the reservoirs, and then gradually lift out all the matter. The dung-carts empty their contents upon a contiguous field, where it is dried in manner as follows. The fecal matter is first spread uniformly over the whole extent of the lot, and, after some hours, must be harrowed so as to present new surfaces for evaporation, and thus hasten its desiccation. The harrowing is repeated

several times, and until the drying is complete; then the matter must be thrown into piles, and after a proper repose, again spread out into thin layers and crushed to powder The gravel and other coarse impurities with which it may be contaminated are separated by a riddle or sieve. Thus prepared, the poudrette is ready for use or exportation. In the mean time it is stacked in piles of two or three cubic metres* bulk.

At Montfaucon they receive daily nearly 600 cubic metres of solid and liquid matters, from which are prepared about 100 cubic metres of poudrette.

Of late years, a new art, based upon Jacquemart's experiments, has enabled the useful transformation of the liquid portions previously wasted. A part of the thin juices is thus made into sulphate of ammonia and other ammoniacal salts. There is a factory constructed near this locality, but it consumes at most only 90 to 100 cubic metres of urine; the remainder being thrown into the Seine. A greater perfection of this art will doubtless enable the utilization of all the ammonia and other salts which are contained in the refuse urine.

There is no doubt that, after having withdrawn the ammonia by lime, as is done, the muddy residue will make an excellent manure for the irrigation of artificial meadows, as it contains all the requisite phosphates, much alkaline salt, and even organic matters.

The poudrette prepared as we have directed sells at 80 cents per 26½ gallons. Of late years the manufacture has been carried on at the Forest of Bondy, M. Mary having constructed a conduit of great diameter for the conveyance thereto of the liquid previously separated from the poudrette vats. The transportation and disinfecting of the solid matters, thus reduced to a fifth, offers comparatively much greater facilities. The arrangement of the vats at Bondy is superior to that at Montfaucon, in having two complete systems; but the difference in levels being less, much more manual labor is demanded. Another conduit conveys the excess of thin juices into a town sewer emptying into the Seine. Thus, as at Montfaucon, the urines will be lost, though they contain nitrogen enough to make them three times as valuable to Agriculture as the poudrette. Future skill will doubtless take advantage of this source of wealth, which is now thrown into the river. They might already use two methods for the purpose. One is indicated by the elevation of the vats at Bondy above the plain of St. Denis, where the thin liquors could be well employed for irrigating and greatly fertilizing the surrounding plains. If it is necessary to dilute the urine with water in order to modify its energy, the proximity of the canal whose level is above that of the cisterns, renders this operation comparatively easy. The quantity of urine thus disposable is, however, much greater than is needed for a field even five times as large as that of St. Denis.

The other method of rendering the urines useful is to convert them into sulphate of ammonia. Since Chemistry has shown the feasibility of using this salt for the fertilization of the earth, a number of experiments have been performed on a large scale in many parts of Europe. In England its use has produced most profitable effects, and in France, where the subject has been investigated, equally favorable results were obtained. We will cite one essay of many, viz., that on a large scale by Kuhlmann (of Lille) and Schattenmann.

Its large amount of nitrogen (21 per cent.) renders the sulphate of ammonia one of the richest of azotized manures; and hence there will be great economy in transforming the urines of Bondy, Montfaucon and elsewhere into sulphate

* A metre is equal to 39·37100 English inches.

of ammonia by sulphuric acid. We will prove by figures that under present circumstances, and notwithstanding the interposition of sulphuric acid and the expenses of preparation, that the sulphate of ammonia can be furnished at a cheaper rate than most manures, with which it can successfully compete even at its present prices.

For example, let us compare the sulphate of ammonia with the poudrette of Montfaucon. The pure salt now sells at $11 40 per 220 lbs, and it contains 21 per cent. of nitrogen. The poudrette sells for about 85 cents per 220 lbs., and contains, according to Payen and Boussingault, but 1·6 per cent. of nitrogen. Supposing, then, that the value of a manure is exactly proportional to the quantity of nitrogen which it contains, it follows that 220 lbs. of sulphate of ammonia will produce the same effect as 2,900 lbs. of poudrette, which amounts to the same as saying that $11 40 of the first is equal to $11 40 of the latter. It is true that the action of the poudrette is not limited to its nitrogen, for it contains salts which are excellent ameliorators of moist soils. Moreover, its organic matters have the effect of modifying the properties of water or of the air absorbed by the roots. But as the expense of transporting the sulphate is ten times less, and as the substances which furnish the elements other than nitrogen may be had at a price much lower than that of poudrette, we may hope economical and profitable results from the use of the sulphate of ammonia combined with dung, turf and bone-dust. The price of the sulphate aforementioned is that of the commercial article. If it were extensively used for agricultural purposes, the price would be brought down to $7 60, and lower.

Without dwelling upon the manufacture of sulphate of ammonia, we will only remark that the urines received at Montfaucon would suffice to produce 4,400,000 lbs. of that salt, representing in nitrogen 57,200,000 lbs. of poudrette, or even 220,000,000 lbs. of ordinary manure. It can be inferred from these figures, of what great import to Agriculture is the thorough solution of the question of the availability of the sulphate of ammonia as a fertilizing agent, and how invaluable would be the result, if long experience shall verify the success that some have already attained in its use.

In what manner should the sulphate of ammonia be applied to the soil? This is a question yet unsolved. Some advise its use in solution of one or two thousandths at least, but under this form it is not applicable in all localities; moreover it requires the expense of additional labor.

It is probable that as good results, with less expense, will follow by sowing it either in a free state or mixed with earth or chalk, provided the time of its application is favorable, so that the too active effect of the manure may not injure vegetation. However, the experiments under this form have, so far, proved less favorable and effective.

The great value of refuse bone-black (from sugar refineries) as a manure, and its advantageous effects, are fully known and appreciated. Unfortunately, however, commerce furnishes a too limited quantity for agricultural purposes, and consequently it has been proposed to form a substitute of similar properties by commingling disinfected fecal matters with a cheap charcoal.

This new manure, called *animalized black*, is made with carbonized vegetable mould and nightsoil, and thus a substance is produced which, in fact, possesses most of the properties of the animal-black from the refineries. Moreover, this compost, by its absorbent power, retains the ammoniacal compounds as they are

generated, and yields them gradually and in uniform proportions to the growing plant. It is this slow and regular production of ammonia which gives also to the bone-black a fertilizing value so much greater than that indicated by the Table of equivalents.

This effect of retarding decomposition is especially advantageous in the aforementioned instance, for almost the sole inconvenience in the use of fecal matters as manure, in the usual manner, consists in their too sudden and rapid action.

For this manufacture, a mould, as rich as possible in organic debris, should be selected, so that by charring it may furnish a sufficient quantity of coal. It should also be pulverulent, easily divisible, and not liable to become *clotted* during charring, as will happen when it is too argillaceous.

It must be confessed, however, that even under the most favorable circumstances, the charred mould is far from comparable in absorbent properties to animal charcoal, and perhaps in this respect the processes employed might admit of modification. Still, these plans yield a charred mould sufficiently cheap for an extensive and profitable application. This plan seems to be the best substitute for the manufacture of poudrette. Indeed, by the use of charred mould, we obtain manure, rich in nitrogen, which retains and renders useful all the animal parts of fecal matters, and, moreover, presents itself in a form convenient for application.

This manure, which is sufficiently rich to be exported, can be made rapidly, that is, in a month during summer, and in two months when the temperature is low. Moreover, in its manufacture there is no disengagement of disagreeable odors, as is the case with poudrette, which in its preparation requires a much longer time, and loses a portion of its ammoniacal components.

As regards the value of the products of these two systems of fabrication, there is but little difference, though the animalized black is generally the richer; in fact, we might impart to it 3 per cent. of nitrogen, an amount rarely contained in commercial poudrette. It is true that Payen and Boussingault found in the poudrette of Belloni 4·4 per cent. of nitrogen, but that of Montfaucon contains at most but 2·67 per cent. The medium dry poudrettes have but 2 and some only 1·6 per cent. of nitrogen.

It is true that by this mode of preparation and reduction of bulk, the poudrette contains the salts and the phosphates of a large quantity of fecal matter, concentrated in a small bulk, with equal richness in nitrogen, and value greater than that of animalized black, which also contains phosphates, but in a much less proportion.

Nevertheless, I do not consider this a great disadvantage in the black, for by a comparison of the analyses, it is seen that the ratio of nitrogen to phosphorus is almost the same in fecal matters and in a great number of plants; whence it follows that the quantity of animalized black sufficient to furnish the nitrogen requisite for a crop would also yield the amount of phosphorus which the crop should contain. It is true also that the animalized black is not, in this respect, a complete manure, for as its richness in nitrogen is greater than that of other constituents useful to vegetation, it requires, like some other manures, to be assisted by a complemental manure.

To facilitate such calculations, it would be useful to make Tables of equivalents for the principal mineral substances which enter into the composition of plants, similar to that which has been made for the most useful element, nitrogen.

The definite quality of a manure should depend upon the rank that it would have in each of these Tables.

Barronet & Co. make the animalized black by a process consisting of two steps: first, the extraction of the fecal matters of privies, and then their transformation into manure. Before the removal of the fecal matters from the wells, they are disinfected, and for this purpose two equally good substances are employed: the first is the residue from the manufacture of the proto-sulphate of iron, and may generally be purchased at a low rate. Where there is a choice of residues, those should be preferred which are the least acid and most rich in peroxide of iron, and even sometimes in zinc. The mode of action of these salts is readily comprehensible.

Another substance used for this purpose is a solution of the preceding matter united with an equal quantity of solution of common soap, which is thrown into the trench. A metallic oleate is thus formed, and being of easier decomposition by sulphuretted hydrogen and sulphydrate of ammonia than are the sulphates, the soap and greasy matters are useful in this operation, for protecting the surface of liquids with an oleaginous layer which opposes the diffusion of sulphuretted hydrogen and sulphydrate of ammonia.

The fecal matters are drawn from the privies by dredging buckets attached to an apparatus called a *Machine Frédéric*. It occupies but little space, and can be conveniently used in any of the houses, as it only requires an opening into the cess-pool of about 1¼ by 1 foot for its entrance. For the convenience of perfectly emptying, the privy wells should be concave at the bottom; it hence follows that the consistency of these matters is not very great. Without these precautions it is necessary to finish their removal in the usual manner. The matter drawn up in the dredges is immediately, and without an instant's exposure, turned into casks, for the whole apparatus being inclosed with sheet metal, the disengaged gas will be driven into the air through a small apartment containing chloride of lime. By this arrangement, even when operating during the day, there is scarcely any perceptible unpleasant odor, though the material may not have been disinfected previous to its removal from the privies.

These fecal matters transported to the factory, are there converted into manure and mixed with charred soil; for the disinfection produced by the sulphate of iron will not be permanent. They are consequently turned into vats and therein treated by the shovelfull with nearly their volume of charred soil. After thorough incorporation of the whole, by stirring, the matter is left to deposit, and after having collected about the center of the vat, where the bottom is most elevated, the liquid which remains is run off through gates. The bottom of the vat has a slope of about two-hundredths of a metre.

This compost is spread out, under cover, upon an impermeable soil, and left to dry in the air. To hasten the desiccation, new surfaces should be presented by occasional stirring. When the drying is complete, add to the first mixture, a second time, its volume of fecal matters, and operate as at first. Repeat this process until the soil forms nearly a fourth of the resultant product; this happens about the third mixing, generally, when the operation has been properly conducted, and especially when the fecal matters employed contain a large proportion of solid products.

This plan of working, during which there is but little disagreeable odor emitted, requires about one month in summer and two in winter. The season

most favorable to the manufacture is spring, and it is then that the greatest possible number of emptyings should be made.

The charred soil was formerly prepared in pots, but Barronet has substituted an economical furnace.

The soil as it comes from the furnace falls into a sheet-iron extinguisher, wherein it cools, free from exposure to air. It is used as soon as cold in order to obtain the full effect of its absorbent qualities, and should be powdered and sieved as fine as possible. It is better if a little argillaceous, because the coal which it contains is then more divided and absorbent. But if the proportion of clay is too great, the mould becomes clotted.

The addition of a small quantity of carbonate of lime increases its durability and makes it flow more readily. There must be but very little, for if much lime is formed during heating, ammonia will be disengaged at the moment of mixing the soil and fecal matters. It is well also to slightly moisten the soil before carbonization, for the aqueous vapor generated by the heat carries off the air existing in the interstices of the soil of the upper apartment. In this way the carbonization is effected almost entirely apart from air, while, if the soil is too dry, it nearly always happens that instead of carbonizing, it burns, although it has only been at a dull red heat.

175 to 200 cubic feet of soil can be carbonized during 24 hours, in a furnace of 20 feet hight, and under these circumstances the whole expense of 35½ cubic feet of charred soil will be about 95 cents.

An establishment for a medium sized city, say of 20,000 inhabitants, will cost $3,800 to $4,750, that is, for utensils, furnaces and every other requisite. Such a factory will yield per annum 600 cubic metres of salable manure, which at 95 cents per 3½ cubic feet, the usual price for manure of 3 per cent. nitrogen, equals $5,700.

At the rate of 76 to 95 cents, the animalized black has the advantage over the dung; for while the 11,960 square yards of land require of the former but 70 to 80 cubic feet at the gross expense of $19 to $23 75, it needs 22,000 lbs. of manure, which cost $34 20, and are of more difficult transportation.

If the animalized black is not yet as perfect a manure as could be desired, it is nevertheless one of the best means of wholly using the products of the privies, and offers great advantages with respect to health and Agriculture.

It would be both politic and desirable for the different Municipalities to compel the proprietors to construct their privy-wells perfectly water-tight, and of cement within, so as to avoid infiltration and to protect them from rains. When this measure shall have been generally employed, the vegetable richness of the soil will be completely regenerated, for the immense quantity of manure which it might receive would soon revive its fecundity. Agriculture and hygeine are then equally interested in the success of this new manufacture.

The value of a manure can only be determined by agricultural experience; but the chemist can furnish useful data for the proper management of the experiments. In fact, it is by chemical analysis that we ascertain the precise nature and properties of materials, either organic or mineral, which a given harvest removes from the soil that produces it, and if this determines the absence of earthy phosphates, alkaline salts, potassa and sulphur, these must be restored again before the land can recover its fertility. Chemical researches have also proved that which is now an established fact, the active efficiency of ammonia in manures, and that of nitrogenous matters generally.

Manures should always contain ammonia or nitrogenous matters capable of yielding it; but as to the collected vegetable or animal offal which contain the requisite nitrogenous matter, as well also in their ashes, the salts necessary for vegetation, a question arises whether it is useful or dangerous to subject them to a prolonged fermentation? Is muck better than the litter which produces it?

I have no hesitation, and I believe no farmer would have any, in declaring that dung is much more efficacious than the materials which furnish it would be in their natural state. There are two causes contributing to this special efficacy. The first is the formation of ammonia generated during the fermentation of the muck and resulting from the reciprocal action of the hydrogen of the water and the oxygen of the air. Consequently, the muck may be richer in nitrogen than its components, if the fermentation has been properly managed. The second circumstance influencing the special activity of the muck is the presence of brown acids, which evidently have a great affinity for the oxygen of the air contained in the water, converting it into carbonic acid. If the water of the muck contains ammoniacal salts formed by such acids, the action of the oxygen of the air will create the presence of the carbonate of ammonia in the solution.

Now every one knows that it would be very different for a plant to absorb, by its roots, *aërated* water containing carbonate of ammonia in solution, or water deprived of air containing carbonic acid and carbonate of ammonia.

Such seems to me to be the part of the muck which gradually supplies the water with very combustible materials, capable of attracting oxygen from the air, and of transforming it into carbonic acid: and which contains, moreover, ammonia, together with alkaline and earthy salts. If neither meat nor grain is exported, then it becomes the medium through which the ingredients of the soil, abstracted during vegetation, are restored to it. Bone-dust, urines and the like, however, are the most prolific sources of the earthy and alkaline salts and phosphates, and are the best manures for reviving land, exhausted by the removal of grain and live-stock.

But the ulmate of ammonia, as a source of carbonate, which has latterly been too much neglected, is also a manure worthy the particular attention of farmers. Its constant presence in muck is a matter for consideration, and indicates plainly the utility of those previous fermentations of the components of muck, to which Jauffret has directed the attention of agriculturists.

Jacquemart, quoted above, has communicated to me the following remarks upon ammoniacal salts as manure:

"In 1832 and 1833, I tried various plans of extracting ammoniacal salts from substances which would furnish liberal proportions, with the view of ascertaining whether salts, rich in nitrogen, if cheap and abundant, whould not be of beneficial and profitable application to Agriculture."

"I found that 150 lbs. of poudrette are equivalent in nitrogen to 10 lbs. of crystalized sulphate of ammonia, and 53 per cent of the nitrogen exists as ready-formed carbonate of ammonia, and 47 per cent. is comprised in organic matters."

"This result, and the promptness of the action of poudrette upon vegetation, lead to the idea that the carbonate of ammonia might be very favorable to its development, and that to this salt should be attributed the energetic influence of the poudrette and Flemish manure. In fact, when this manure is employed, all the urea of the urines is transformed into carbonate of ammonia, and this salt is in greater proportion than all others."

"Circumstances did not permit me to continue these researches, and I only pro-

gressed far enough to prove that the sub-carbonate of ammonia has a very beneficial influence upon vegetation. My essays upon the applicability of ammoniacal salts to Agriculture, were limited to April, 1843. They had for their object,

1st. To determine the value of sub-carbonate of ammonia as a manure or stimulant, in comparison with the poudrette as the standard.

2d. The use of these matters in small bulk and in convenient form.

The poudrette was applied in the proportion of 25 bushels per acre. As has been said, 150 lbs. represent, in nitrogen, 10 lbs of crystalized sulphate of ammonia; 3,000 lbs., therefore, are equivalent to 200 lbs. of sulphate."

"The quantities of ammoniacal salts were proportioned so as to contain as much nitrogen as the poudrette, and were, per 2½ acres.

180 gallons sub-carbonate in solution, formed of 1 equivalent of acid.
.. .. 2 .. of ammonia representing 200 lbs of sulphate.
.. .. Carbonate in solution, formed of 2 equiva. of acid and 2 equiva. of ammonia ....200 lbs.
200 lbs. of sulphate in solution .. .. 200 lbs.

"In order to the ready and easy transportation and distribution of the solutions of ammoniacal carbonate, they should be heated with charcoal, or other porous matters, in quantity sufficient to form a thoroughly impregnated mass. It will be seen in the essays of October, 1843, that the solution of the carbonate can be employed in a reduced volume of one-half, merely doubling the quantity of salt then the bulk of the manure is reduced to that of poudrette."

"The sulphate of ammonia was used in two states:

1st. As solution in six times its weight of water, imbibed by dry calcareous matter in powder.

2d. In the form of powder, and sown similarly as fine seed. To prevent the formation of carbonate of ammonia, the calcareous matter must not be wetted with the solution of sulphate. In fact, a mixture of chalk or marl, and sulphate of ammonia, when placed in a flask, emits an ammoniacal vapor, strong enough to blue a reddened litmus paper. As this reäction, however, is very slow, good effects may be expected from the use of a mixture in which the carbonate of ammonia disengages gradually enough for its assimilation, by the plant, in a nascent state. The first crop derived no benefit, scarcely, but upon the second its good effects were decidedly evident. Unfortunately, I was unable to repeat the experiments in the third year.

"Finally, to approximate as nearly as possible the composition of poudrette, the ammonia of which is partially carbonated and partially free, I made a mixed solution of sulphate and carbonate of ammonia in the proportion of 88 lbs. of the first, and 132 pounds of the latter per 2½ acres. This solution was caused to be imbibed by peat dust, and all the matters employed in this essay were sown on the same day, April 29, 1843, simultaneously with the oats, and plowed in with the grain."

"The land was newly cleared, limed and marled ground from which two crops had been taken. Each essay occupied 274 yards of surface, and was separated from the other by intervals of ten feet. The limits were enclosed by cords, the harvest gathered with great care, and the products weighed."

RESULTS OBTAINED WITH THE FOLLOWING SUBSTANCES.	Weight required per 11,960 square yards	Ditto per 11,960 square yards	Volume of gas absorbed by pure sulphuric acid, compared with that of the gas	Nitrogen in 100 parts of gas
			Per ct	Per ct.
No. 1. Carbonate of ammonia and carbon (charcoal)	4,300	3,200	96·3	75
.. 2. Sub-carbonate	4,640	3,120	94	69
.. 3. Carbonate and peat	4,120	3,160	95	77
.. 4. Sub-carbonate and peat	4,520	3,120	94	69
.. 5. Carbonate, sulphate and peat	3,960	2,750	38	69

"From these experiments it follows:

1st. That the carbonate and sub-carbonate, combined with charcoal or peat, give 94 per cent. of the product of poudrette, containing an equal quantity of nitrogen corresponding to 202 lbs. of crystalized sulphate of ammonia per hectare:

2d. That the degree of saturation of ammonia by carbonic acid has no influence:

3d. That the sulphate by itself, and as a salt, furnishes no results:

4th. That the mixture of carbonate and sulphate of ammonia gives 84 per cent. of poudrette. This number is deduced almost exactly, *à priori*, from the salts composing the mixture.

5th. That the calcareous matter imbued with sulphate of ammonia gives 79 per cent., that is to say, 8 per cent. more than nothing. This result, so different from what might have been hoped for, ought probably to be attributed to the mild composition of the sulphate, and to the short time (about four months) that the plant was in the ground. The following experiments seem to show the propriety of farther testing the matter.

These trials were made in October, 1843, upon a crop of wheat, and on the same spot as the before-mentioned experiments.

Having already ascertained that the carbonate and sub-carbonate of ammonia give similar results, the latter only was used in these experiments; but in order to reduce the volume of the mixture, the solution was made of double strength.

The standard of comparison was, poudrette employed in the proportion of about 79 cubic feet, nearly 3 cubic yards, per 11,960 square yards, and representing, in nitrogen, 227 lbs. of crystalized sulphate of ammonia.

The ammoniacal salts were used in the proportion of 238 lbs. of sulphate of ammonia; that is to say, they contain 5 per cent. of nitrogen more than the poudrette.

"These essays were made in the same spots as the preceding, and the same numbers correspond with the same places: time (October) and other circumstances were likewise corresponding.

RESULTS OBTAINED WITH THE FOLLOWING SUBSTANCES.	Threshed corn per 11,960 square yards.	Wheat per 11,960 square yards.	Value in commercial units by produce.	Proportion of grain to straw (straw being=100).

.. 8. Sulphate and calcareous matter	3,112	1,787	90	57
.. 9. Sulphate in salt	2,675	1,412	71	53
.. 10. Nothing	2,700	1,400	70	52

"It follows from these trials as from the preceding:

1st. That the sub-carbonate of ammonia gives 94 per cent. of the product of the poudrette, as proved by trials Nos. 1, 2, 3, and 6. The 5 per cent. excess of nitrogen that was used produced no effect; probably, because it only served, from the length of the experiment (nine months) to compensate for the difference of fixity between the principles of the two substances.

2d. That No. 3 indicates that the concentrated carbonate (14½ cubic feet per 11,960 square yards) acts in the same manner as that which is weaker.

3d. That No. 4 apparently proves that a mixture of poudrette and peat in equal proportions, imbued with sub-carbonate, has the same value as poudrette. No. 7 does not confirm this, but it allows the inference that there was some error in the last experiments, for in those of April, Nos. 4 and 7 presented no anomaly.

4th. It is shown by No. 8 that calcareous matter moistened by sulphate of ammonia yields 90 per cent. of the poudrette, while in the spring it only gave 79 per cent. This difference is doubtless attributable to the difference in time between 9 and 4½ months. It is difficult to say whether the calcareous matter moistened with sulphate and sown in the spring united its action with that sown in autumn; for it was buried by the plowing which followed the crop of oats.

"It would have been interesting to have made an examination of the products of a third crop, but circumstances did not permit.

5th. The sulphate in salt, as in the preceding case, gave no result.

6th. Finally, if we compare No. 4, in which turf imbued with sub-carbonate, was sown in the spring, and no other manure used in autumn, with No. 10, which received no manure, in either season we find the product is nearly the same; hence either the conclusion that the effect of the sub-carbonate of ammonia was not perceptible after the first crop, or that this substance, being on the surface, was plowed in too deeply.

"To conclude, therefore, it seems demonstrated by the experiments of the spring and fall, that the carbonates of ammonia have evidently a very happy influence upon the growth of cereals; that the sulphate of ammonia, in a state of salt, is without influence upon these plants, at least under the aforementioned circumstances. Perhaps better results might be obtained by sowing it in spring upon the cereals, when they cover the soil; that the sulphate of ammonia in solution and absorbed by calcareous matter, produces very favorable effects, especially when the growth of the plant is of some duration. Its action should be studied during many consecutive crops.

"These facts, as is readily observed, are of great importance to Agriculture; for they prove the advantageous applicability of ammoniacal salts. In fact, it results from the experiments that a quantity of sub-carbonate of ammonia equiva-

lent to 198 lbs. of sulphate of ammonia, gave per 11,960 square yards an excess of product as follows:

Oats—680 kilogrammes of grain, say 15·8 hectolitres, of 43 kils. at 6 francs	95
400 .. of straw, say 80 bundles, at 10f. per 100, net	8
Total	103 francs

"That a quantity of the sub-carbonate of ammonia equal to 108 kilogrammes of sulphate of ammonia, gives in excess of products per hectare, as follows:

Wheat—435 kils. of wheat, say 6 hects. of 73 kils. at 18 francs	108
430 kils. of straw, say 86 bundles at 10f. per 100, net	8·60
Total	116·60

Or, in English:

Oats—1,496 lbs. of grain	$19 00
880 lbs. straw, say 80 bundles, at $2 per 100	1 60
Total	$20 60
Wheat—957 lbs. grain	$21 60
946 lbs. straw, say 36 bundles at $2 per 100	1 72
Total	$23 32

"In the provision market of Paris, where straw is generally of very high price, the revenue would be increased $1 52 to $1 90 per 100 of straw, thus giving as its gross overplus $26 60 to $27 74 per 11,960 square yards.

"From these sums must be deducted the expense of the sub-carbonate of ammonia. But the ammoniacal salts are now so low in price, the sub-carbonate being abundantly extracted from the refuse liquor of gas-works, that its net benefits, the straw being valued as above, may be guarantied at $9 50 to $15 20 for the crop of oats, and $10 45 to $16 15 for the crop of wheat.

"In 1843 I studied the action of ammoniacal salts upon meadows, and of solutions of carbonate and sulphate, with which I cultivated definite portions of a lawn. I also sowed the sulphate in powder, so that two equal surfaces watered with solution, or dusted with powder, should receive the same quantity of ammonia. After thirty-six hours, the wetted surfaces acquired a deep-green tint, and exhibited a striking contrast with the rest of the sward. This effect must be attributed to the salts, for the parts wetted with pure water did not exhibit any change. After the first rain the experiment with the sulphate in powder resulted as favorably as the other.

"This last result made me renounce the use of saline solutions, which to the farmer presents many difficulties. I propose the employment only of sulphate in powder to be sown like the seeds.

"I will remark that when the lawn was reaped and the grass had commenced to re-sprout, it was impossible to observe any difference between the dusted and watered plots, for the action of the salts had been limited to one crop.

"In the latter part of March, 1844, I sowed the meadows with sulphate of ammonia in powder, at the rate of 90 to 100 kilogrammes per hectare, each experiment occupying about one-third of a hectare. After the first rain the parts thus treated were distinguishable from the remainder of the field by their deep-green color; and subsequently the grass grew luxuriantly, but circumstances did not permit me to accurately estimate the results.

"In 1845, these experiments were repeated, and the plots fenced in. When planting, I also measured off, adjoining these plots, others of equal dimensions, that is, a third of a hectare each, and at the harvest compared the products of

the sulph-ammoniated parts with those which were cultivated without this treatment:

1st *Experiment.*—100 kilog.* of sulphate per hectaret	Grass.....3,746 kila.	*Excess of product with the sulphate.*
Good medium soil	..Hay .....2,907 kila.	.....839 kilogrammes, or 29 per cent.
2d *Experiment.*—100 kilog. of sulphate per hectare	Hay .....4,956 kila.	
Very good soil	.....Hay ..... 3,892 kila.	...1,064 kilogrammes, or 30 per cent.
3d *Experiment.*—100 kilog. of sulphate per hectare	Hay.....3,970 kila.	
Strong soil	.....Hay.....3,450 kila.	.....520 kilogrammes, or 15 per cent.

"We will remark that the sulphate apparently has an action much greater proportional to the quality of the soil, and its deficiency in strength and argillaceous matter—provided, however, it is not too light. It remains to be determined whether, with a less quantity than 220 lbs. per 11,960 square yards, we would not obtain as good results—whether a stronger proportion would not produce even better effects—in fine, whether the influence of the salt extends beyond a year, especially in argillaceous soils. If the latter is not the case it is probable that the whole influence of the salt is exhausted by the first crop. These queries, however, must be resolved by some future harvest."

The results of the above experiments, such as they are, are nevertheless not without interest to Agriculture.

According to experiment No. 2, sulphate of ammonia costing $10 26 per 220 lbs., the receipt equals the expense when the price of hay is $5 89 per 100 bundles; and there is a gain of $3 42 to $5 70 per 11,960 square yards, when it brings $7 60 to $8 36 per 100 bundles. Again, according to experiment No. 2, where there is an equality between the outlay and return, the hay should be worth $6 65 to $7 60 or $8 36—an advantage of $1 43 to $2 47 per 11,960 sq. yds.

Experiment No. 3 always gave a loss.

But whether a soil annually treated with ammoniacal salts will yield liberal crops for consecutive years, or whether, on the contrary, its fertility is limited to one season only, and requires renewal yearly by fresh additions, are questions for future determination.

* 2 lbs. 3 oz. 4·428 drachms avoirdupois. † 2 acres, 1 r. 35 p.—11,960·4604 square yards.

NUTRITION OF PLANTS.

BY JEAN BAPTISTE DUMAS.

Translated from the French for The Library, by CAMPBELL MORFIT and BARNET PHILLIPS.

PLANTS nourish themselves upon animal excretions, that is to say, upon water, carbonic acid, and ammonia: all of which they receive through the medium of the atmosphere. In a general sense, therefore, the study of the nutrition of plants, is, in fact, the examination of their relations to the atmosphere.

A plant, during a growth of some time, presents an evident accumulation of matter in all its tissues; it also acquires carbon, hydrogen, oxygen and nitrogen, together with earthy and mineral matters; but of this more hereafter.

By limiting the examination to the principal phenomena, (discarding all the accidental circumstances which may intervene,) we can readily, by some simple but conclusive experiments, be convinced of the truth of the preceding results. These leave no doubt, either as to the fixation of carbon, hydrogen, and nitrogen by the plants, or the mode in which it is effected during vegetation.

Boussingault proposes to demonstrate this by means of a large bell-glass, with three tubulures. Adapted to the first is a washing apparatus filled with water, for the removal of the dust suspended in the atmospheric air. In the principal tubulure is a funnel, opening and closing at pleasure, through which to introduce distilled water for the irrigation of the seeds and plants placed under the bell-glass. These are contained in a capsule or saucer filled with calcined sand.—The bell-glass rests upon, and is hermetically cemented to, an earthen pan, so as to prevent the admission of air. The third tubulure communicates with a large flask, by means of two U tubes and a washing apparatus, which retain the water and carbonic acid.

The flask being filled with water, and the apparatus tightly closed, the displacement of the air from the bell-glass is determined by opening the cock in the lower part of the washing-flask. This operation can be repeated as often as desired. By these precautions, it is seen that the plant or seeds under the bell-glass receive definitely, as their whole nourishment, only water, air and carbonic acid.

Now if peas be sown in this calcined sand, taking care to water them and frequently renew their atmosphere, they germinate, develop their leaves, and what is remarkable, flower and fructify. Nothing is easier than to estimate the amount of matter lost or gained by the seed in developing itself; a simple comparative analysis of the seed and of the crop suffices. Boussingault has determined by analysis the nature of the elements and their proportions in both the seeds and the crop. The following are his results:

The peas contained:

	Before Vegetation.		After Vegetation.
Carbon	51·5	parts.	237·6 parts.
Hydrogen	5·9	..	28·1 ..
Nitrogen	4·6	..	10·1 ..
Oxygen	44·0	..	168·0 ..
Total	106·0		443·8

Showing the fixation, during the process of vegetation, of

186·1 parts of Carbon — 139·5 parts of Water
5·5 .. .. Nitrogen — 6·7 .. .. Hydrogen.

These results prove in the most evident manner that peas, as well as many other plants, can pass through all their phases of vegetation even when nourished only with water and air. The crop thus obtained is, however, very meager and incomparably less than that yielded by manured soil.

The phenomenon which we are about to study is complex: in fact, a seed, a plant, in certain periods of their growth, present modifications both in their vital functions and in their relations to the atmosphere. To the amount of fixed principles, already considerable, must be added another large portion, which is dissipated after having been momentarily fixed. But if the result, apparently simple, which I am about to give, is the final result of a complex theory, it does not the less fully confirm the fixation of carbon, nitrogen and hydrogen in the plants, besides that of a certain quantity of hydrogen and oxygen, which is fixed as water, or in the proportions which constitute water.

It is not sufficient to have clearly proved that the fixation of the elements constituting plants can be effected by the sole intermediation of the air; we should investigate farther in order to clearly determine the principal sources of these elements.

When we reflect upon the enormous quantity of carbon in continual fixation by vegetation, the question naturally arises whether it really does not originate wholly, or at least in part, from the decomposition of the carbonic acid in the air. We know that the atmosphere contains, usually, 4-10,000ths of its volume, or as well, 6-10,000ths of its weight of carbonic acid; an evident proof that this quantity is sufficient.

A very simple calculation will determine this matter. Let us suppose, in fact, that the atmosphere is compressed by a force which would give it the density of water; the column of air at this density, has a hight of about ten metres: in this column of ten metres carbonic acid enters to the extent of four millimetres, and by reducing the carbonic acid to carbon, it will be finally seen that the quantity of carbonic acid in the atmosphere, is sufficient to form a stratum of carbon covering the surface of the whole earth to the thickness of nearly one-third of a millimetre.

The amount of carbonic acid in the air is increased by the torrents emitted from volcanoes, and the supply is constantly kept up by the large quantities emitted during combustion in our fireplaces, by the respiration of animals, and also their decomposition, and by the nocturnal respiration of plants. The quantity is being constantly diminished by the diurnal respiration of plants. We may then ask whether this actual state of the atmosphere has always existed, or if in remote periods, it did not present an entirely different composition.

Ad. Brogniart, relying upon the precise information of Geology, has calculated the composition of air before the formation of the coal fields. France, as a fair average of the coal lands of Europe, and perhaps of the whole world, was taken as the standard. It contains 1·200 of coal land, forming a stratum of

twenty metres thickness, and is poorer in this respect than England and Belgium, but much richer than a large majority of the other countries of the earth.

Estimating by France, we then find that a *pro rata* apportionment will give to the whole surface of our globe a stratum of coal of a decimetre thickness; by changing the weights into carbonic acid, (for it is incontestable that coal has its origin from vegetable debris whose carbonic acid must necessarily have been drawn from the atmosphere,) we then have the inference that the air before the formation of the coal-fields must have contained at the very least from 4 to 5 per cent., a medium, and by a little exaggeration, perhaps as much as 8 to 10 per cent. of carbonic acid. Air charged with a like quantity of carbonic acid is injurious to, if not destructive of the warm-blooded animals; and, indeed, we learn from geological fossils that in that epoch there were no animals of that nature. Saussure's experiments have shown that vegetation thrives much better in an atmosphere containing some hundredths of carbonic acid, and we know also that the vegetation of remote periods was much more active than at present, as is well evident in the singular development of fossil debris.

But supposing there were no animals, or at most but a few of them, whence comes this carbonic acid of the air, unless from numberless volcanoes now extinct?

What is the action of the carbonic acid, and what are the conditions requisite for the regular accomplishment of the phenomenon now under study? We will answer by the aid of some historical details. Bonnet first observed that green leaves, when placed in aërated water and exposed to the sun's light, disengage a gas which Priestly proved to be oxygen; and Jennevier in his turn showed that this oxygen proceeds from the carbonic acid held in solution by the water, and associates this fact with the nutrition of plants. To effect the decomposition of the carbonic acid, the green part of the plants must be exposed to the solar light. A plant which is not struck by the light does not decompose carbonic acid; on the contrary, in the presence of aërated water or air, it generates it, as is unequivocally determined by the following two experiments:

Take a bell-glass containing an atmosphere of carbonic acid, in which plants are also inclosed, and place it under an opaque vessel, and keep it thus secluded from the light for several days. After this time, an examination of the transvased gas shows that it is still unaltered carbonic acid. Again, take a second bell-glass similar to the first, and inclose therein, as before, the green parts of plants; but this time expose it to the sun's light weakened by a gauze screen or sheet of transparent paper. This precaution is necessary, for though a plant thrives perfectly in the open air even under the direct action of the solar rays, it is requisite, when operating under bell-glasses, to provide against the concentration of light by the lenticles which their surfaces present, else the parts of the plant opposite to the foci become torrefied and the plant perishes. With proper precautions oxygen is obtained nearly pure. Hence the necessity of light in this phenomenon. Without it there would be no action—no durable vegetation upon the surface of the earth.

Let us now examine under what forms the carbonic acid reaches the plant. We can determine a current of air in a bulbed apparatus, with three tubulures, by means of a *flacon à ecoulement*. A bulbed apparatus, adapted to the first tubulure, serves to wash the air which enters. To the third tubulure is adjusted an U tube containing pumice-stone saturated with sulphuric acid, for the retention of the water. There must be also a second bulbed apparatus, containing a

concentrated solution of potassa, for the absorption of carbonic acid. Following this is an U tube again, filled with pumice-stone saturated with sulphuric acid, to retain the little water which may pass over from the potassa solution. The two apparati are accurately weighed before the experiment, and in order to prevent the reëntrance of moist air there should be a third U tube filled, as before, with vitriolized pumice-stone.

All the air which passes through this apparatus during exposure to the sun's light is entirely deprived of carbonic acid, without any increase of weight accruing to the apparatus during the experiment. Thus we have evident proof that plants draw carbonic acid directly from the atmosphere. We do not admit, however, that this is the sole source, for it can be conveyed into the plant through its roots, which imbibe it from the soil. The moisture of the soil which is imbibed by the roots is also charged with carbonic acid. Moreover, the slow combustion of the dung deposited around plants is also a continual source of carbonic acid. The arrangement of the apparatus, before noted exemplifies on a small scale, this phenomenon, as also the *rôle* of the carbonic acid. The roots of the plant, inclosed in the balloon, being dipped into a vessel filled with water charged with carbonic acid, absorption conveys this water to all parts of the plant, and the carbonic acid, as soon as it reaches the leaves or green parts, is decomposed by contact with the light. When the apparatus is to be arranged for this experiment, the first bulbed tube must be filled with a concentrated solution of caustic potassa, in order to arrest the carbonic acid proceeding from the air itself.

To sum up, plants have two sources of oxygen: 1st, the atmosphere, from which they abstract it directly; and, 2dly, the soil, from which they receive it through their roots. They receive it also from dew, but it is the carbonic acid of the air reaching them in an indirect way.

Light is necessary to the decomposition of carbonic acid, as will be proved by a few words. If green twigs or branches are presented to the object-glass of a camera, the light reflected by the green portions of the plant acts very feebly upon an iodinized silver plate, as if all the chemical rays of the light absorbed during the process of life in the plants, when reflected back by their green parts, no longer exercise any chemical action.

Green leaves act nearly in the same manner as those black bodies which are most capable of entirely absorbing the light. This is a matter worthy of deep study, for at the moment the light strikes the leaves, the most mysterious actions of Nature, and the most important to be revealed, are in some way accomplished, while we have no authority for supposing that these actions are produced by any of the methods now known either in Physics or Chemistry.

The decomposition of carbonic acid is effected by the influence of the sun's rays and the green matter of plants; but is this green matter endowed, in itself, with this property, or does it require the coöperation of vegetable organisms? The thorough experiments of Morren afford a conclusive decision of these questions. The green matter, when in contact with the solar rays, acts always in the same manner, whether it is or is not coupled with a vegetable organism.

Water sometimes holds in suspension a green matter formed by green animalcules. If this water is analyzed, under different meteorological circumstances, it will be found that the ratio of oxygen in the gas given off during ebullition varies from 16 to 60 per cent., or in the ratio of 1 to 4. After being some time insulated it shows an excess of oxygen, and the animalcules assume an active life.

Under the influence of the sun's rays the green matter of the plants decomposes carbonic acid, and sets the oxygen at liberty; but if light is wanting, then the inverse phenomena occur.

The fish of a pond rapidly absorb the oxygen of the air held in solution by the water, and if the green animalcules do not in turn replace this oxygen by the decomposition of carbonic acid, the fish suffer, and gradually suffocate. If, on the contrary, the sun shines, the animalcules quickly restore the oxygen to the air, and the fish become active. These alternatives occur ceaselessly, and are peculiarly remarkable for the strange rapidity with which the results become manifest.

This experiment, besides assigning a *rôle* to the green matter, gives an exact idea of the phenomena occurring in the atmosphere. In fact, in the atmosphere the equilibrium is due to the same causes, but the variations are much more limited. The motion of the air is much more rapid, its mass enormous compared with the causes which tend to modify it; while in the water of the fish-ponds, or preserves, the masses are small and the influential causes enormous.

Independently of the green animalcules which act in the same manner as green plants, Morren has shown that there are those of a red color which produce the same effects. This discovery is of the greatest importance, for heretofore this action has been, compulsorily, attributed to the green matter of plants, although the foliage of certain vegetables and trees have a purple or nearly red tint, even in their normal state. According to Morren's experiments, there are a number of coloring matters which are capable of decomposing carbonic acid.

Those plants which are not green, the fruits which lose their green color in acquiring the shades peculiar to their maturity, flowers, &c., do not decompose carbonic acid. As soon as the green matter appears in a plant exposed to light, the decomposition of carbonic acid commences. Is this green matter the instrument or the product of the decomposition? If it is the product, will it be transformed by the successive repetitions which constantly renew themselves into the various products developed by vegetation? We would be disposed to think that the green matter is an instrument, an agent; that it is doubtless but little altered, and that under its influence the other matters are produced and carried from cell to cell by endosmose, even to the vessels which convey them to the different organs of the plant.

There are, however, colorless plants which run through all phases of their existence without being colored. Fungi are of this class, and there are certain kinds which grow in the darkest mines; and hence, very naturally, their absence of color, which, in preventing their action upon light, enables them to dispense with its influence. We will remark, however, that the fungi of the mines are sunny white, while those reared in the light are always diverse-tinted. But fungi are always parasitical; they thrive upon living or dead animals or plants, and always by means of organic matters which they contain already made.

The life of a fungus is every way comparable with that of animals; their nourishment is the same, and perhaps the analogy between these two beings, apparently so very different, might be much farther traced.

Thus, for our benefit, the vegetable kingdom is particularly characterized by those plants which possess the property of decomposing carbonic acid, and thus it is that it enjoys the full extent of its purpose, and accomplishes its errand upon the earth. The reproductive organs of plants are but a transition. Fungi are too little known, in this respect, to claim our attention longer. It is

therefore only in the green parts of plants that the great apparatus exists which may exercise a certain influence upon the constitution of the air, and which deserves to be classed among the great instruments which the physics of the world should acknowledge.

Supposing that the plants had ceased the performance of their functions upon the surface of the earth, calculation proves that the amount of oxygen of the atmosphere will suffice for the respiration of the present existent animals for thousands of years. Our knowledge of the nutrition of animals teaches us that the disappearance of plants would on the contrary speedily produce their death by inanition Hence, from what has been said, the unavoidable conclusion that the carbon of plants proceeds mainly from the decomposition of carbonic acid.

A last consideration compels us to make an important restriction. In citing the beautiful experiments of Boussingaul; upon the complete development in a close vessel of peas nourished by air, water, and carbonic acid, we remarked that the harvest was very poor in comparison with that produced by manured grounds. By manuring the soil, the conditions of growth are augmented, for the dung contains nitrogeneous matters; it moreover surrounds the roots with an incessant source of carbonic acid. which being carried up with the sap of the plant, is decomposed by contact with the green matter of the leaves. The manure contains, also, the mineral salts which are indispensable to the complete development of plants, besides the soluble organic matters which, according to Saussure, in certain cases are equally necessary for the nutrition of plants.

As regards the decomposition of the water, we have to repeat all that has been said relative to the decomposition of carbonic acid by plants, for the hydrogen of plants is derived from water, and besides it fixes water in its natural state.

We have now the certain proof that many fungi disengage hydrogen naturally. Edwards and Colin have shown that the stem of the *Polygonum tinctorium*, when placed under water, disengages hydrogen. Payen has proved by the analysis of the ligneous parts of vegetables, that the amount of hydrogen is always slightly excessive of that of oxygen. Added to these, also are Boussingault's direct experiments upon the growth of peas, clover, and wheat. Thus:

WHEAT.

Grains.	After three months vegetation.				
Carbon..... 46·6	88	100·0 grains have fixed carbon			41·4
Hydrogen..... 5·8	10·0	..	..	.. nitrogen	6·0
Nitrogen..... 3·5	3·7	..	..	.. (water) HO	41·8
Oxygen.....44·1	81·0	..	..	.. (hydrogen) H	0·0
Total.....100·0	183·2				183·2

CLOVER.

Grains.	After three months vegetation.				
Carbon..... 50·8	131·3	100·0 grains have fixed carbon			80·5
Hydrogen..... 6·0	17·1	..	..	..	nitrogen 3·6
Nitrogen..... 7·2	9·8	..	..	..	water 72·8
Oxygen..... 36·0	100·7	..	..	..	hydrogen 3·0
Total..... 100·0	258·9				258·9

In the wheat there was no fixation of hydrogen, but much of carbon and water; while in the clover, carbon, hydrogen, nitrogen and water were all assimilated. If I have insisted upon the decomposition of water, as established by Boussingault, it is because that incident in the life of plants—the fixation of the carbon by the decomposition of the carbonic acid—thus becomes the grand theorem of the general physics of the globe, which forms an equivalent to that other phenomenon so well demonstrated by Lavoisier, the combustion of carbon and nitrogen which characterizes the life of animals.

Plants decompose water and assimilate its hydrogen; they reduce carbonic acid and appropriate its carbon—they decompose ammonia; they are, in fact, the reducing apparatus. Animals, on the contrary, burn the carbon and hydrogen, and may be styled oxidizing apparatus.

This property in plants of securing the carbon of carbonic acid, and setting the oxygen at liberty, has no parallel in any chemical force. Chemistry at present is incapable of imitating this phenomenon in the life of plants: Physics must some day afford an explanation. It should be tried whether a daguerreotype in regarding a plant behaves as in the presence of a black plate, if the reflected light is deprived of its chemical rays. Plants certainly absorb a portion of the intensity of the sun's rays, and as all these phenomena are colleagued; if the animal produces heat and electricity, the plants in their turn absorb heat and electricity.

It remains to be inquired how the nitrogen is introduced into plants. It reaches them by two channels: 1st. Through the air. 2d. Through manures. It has already been shown in the experiment upon the growth of peas in a close vessel, that nitrogen is abstracted from the atmosphere. Clover as well as Jerusalem artichokes cultivated under similar circumstances present a similar action. If, however, the experiment is repeated upon the plants, this phenomenon is not evident; for instance, the cereals do not abstract their nitrogen from the air, and hence plants, in this respect, are divisible into two distinct groups:

1st. Those which abstract their oxygen from the atmosphere, namely, peas, clover, and Jerusalem artichokes.

2d. Those which obtain it through manures, namely, the cereals, and the oleaginous plants.

Though we know that the nitrogen of some plants is borrowed from the atmosphere, we cannot tell the condition or state in which it is assimilated; it may be supposed that it enters directly into their organs, some one of which have the natural property of abstracting it from air. It can be conveyed thither by the water, always aërated, which is imbibed by the roots. The leaves of the plant may convert it into ammonia by means of the hydrogen of the water, which they decompose. Finally, this fixed nitrogen, according to Saussure's experiments, proceeds, certainly in part, from the traces of ammonia contained in the air. If there are any doubts in this respect, doubts removable by experiment, there can be none as to plants which receive their nitrogen through the medium of manures. Manures act by virtue of their urea, uric acid and animal matters, which, by decomposition, are transformed into ammoniacal salts. A single experiment readily proves this fact: Schattenmann (the director of the manufactory at Bouxwiller) observed that by watering a field with the solution of sulphate of ammonia, obtained by treating horse-dung with sulphate of iron, he could readily distinguish the irrigated spots from those which were not watered, by the vigor of their vegetation. Letters traced with the liquid manure were visible at a great distance during the whole term of vegetation. Hence, the evident importance of its application to Agriculture. In some countries the explanation of this theory has occasioned a profitable practice: for instance, in the Canton of Grisons the dung-liquor is treated with sulphate of iron; the ammonia which is generated decomposes the sulphate of iron, and forms sulphate of ammonia, which, in this state, is potential and not volatile. Elsewhere, the urine or dung-liquor is mixed with sulphate of lime, which is equally efficient in fixing the ammonia; but its application to the dried faces is not effectual, owing to the generation of carbonate of ammonia, which is wholly volatile: consequently, the efforts to pre-

tralize the ammoniacal odor in the stables by means of sulphate of lime, have not been successful.

The researches of Payen and Boussingault have removed all doubt both as to the effects of ammoniacal salts as a manure, and the thorough utility of animal matter, or, more generally, nitrogeneous matter, in the dunging of the soils. They have recently shown that all true manures act by virtue of their nitrogen, and are efficient proportional to what they contain of this element. and they have given the following Table, where they are ranked according to their equivalent value.—The Table shows that 100 parts of farm manure can be replaced by 3 parts of dry blood or animal residues, and by 25 parts of grape-cake:

Farm manure	100	Pigeon-dung	5
Sea weed	50	Liquid Flemish manure	200
Residue of pressed oleaginous seeds	8	Poudrette	10 to 25
Grape-cake	25	Dry blood or dry flesh, feathers, wool,	
Liquor from starch factories	600	and horn	3
Dung liquor	70	Animal black	40

We have too often alluded to the value of urine, in vegetation, to render it necessary again to enforce upon the farmer the policy of carefully collecting the dung juices of his barn yards.

We should, however, recollect that the preceding Table does not give a perfectly just idea, in this respect; for we might be led to think that in the preparation of Flemish manure or animal black, none of the products of the juices are lost. Consequently, though the poudrette presents a greater value, pound to pound, it is not a thorough proof that this should be preferred in the great economy of a country. In fact, during its preparation, a great portion of useful products escape into and infect the atmosphere. The great advantages of liquid manure, with which we cannot be too familiar, may be summed up in a few words:

1st. Man furnishes the air with carbonic acid and water, that the farmer may always have a supply equal to the requirements of his crops.

2d. Man ejects urine and excrements, which constitute liquid manure, after a previous fermentation, all the other products of his alimentation.

3d. Consequently, in the liquid manure and the atmosphere, the farmer has all the matters requisite for the culture of those plants suitable to the nutrition of man.

The excrements of animals, which constitute the nourishment of the most useful plants—such as the cereals—are as necessary to their sustenance as bread and meat is to that of Man; and hence the culpable neglect in allowing the waste of sewer juices in large cities. Among the efforts to diminish the miseries of the poor classes, none can take precedence of that to lessen the cost of manures, and as tending to this, the collection and preservation of the contents of privies should be provided for by the authorities of all the cities and towns.

One more remark in conclusion of this subject. It is well known with what facility ammonia dissolves in water, which will take up about 430 times its volume, and it is also well known that hydrochloric acid is equally soluble. But let us compare the operation of these two solutions. By heating hydrochloric acid of a certain density, it boils at 244·4° Fahrenheit, without being altered; and it is impossible to separate it from its waters by physical means. At the temperature of 122° to 140° Fahrenheit, water no longer retains a trace of ammonia; indeed, in vacuo, it loses all its gas at ordinary temperatures and even evaporates spontaneously when exposed to air in open vessels.

This is a wise provision in the natural economy, for this property enables the condensation of the ammonia by the rains, which convey it to the plants, that it may be volatilized anew, and carried to those points where it will be seized upon and rendered available. It is doubtless the final cause of the properties of the aqueous solution of ammonia.

But, as these properties are necessary in the designs of Creation, so that vegetation may not be deprived of that ammonia which it requires; so much the more is it important, as a personal consideration, for they are noxious in the latter respect. It is precisely, this volatility of the ammonia resulting from the decomposition of the animal detritus of a city, which prevents its restoration to the neighboring soil, as might otherwise so well be done; for it is the whole sum of manure which the soil requires to reproduce the sum of organic matter requisite for its nourishment. We should therefore direct our attention to the elucidation of the mode in which the rejected nitrogenous products, which we regard as lost, can be rendered available.

THE ACTION OF SALT ON VEGETATION;

AND ITS USE IN AGRICULTURE.

BY M. BECQUEREL.

In the Memoir which I presented to the Royal Society of Agriculture in July, 1847, I treated of the state of vegetation in the saliferous soils under the influence of water, and laid it down as a principle, that salt and water, when added gradually and in small portions to plants, promoted the growth and excellence of fodder crops, especially in those soils naturally dry. My experience in this respect is based upon observations and analyses made of the old royal salines of the Levant and the surrounding countries. These experiments, it must be told, however, are only the beginning of a series which I intend to undertake upon the use of salt as an amendment [ameliorator?] in Agriculture, commencing, however, with the study of its action in the different phases, of the growth of the cereal and fodder plants. To proceed systematically, we must before passing to the application, determine the principal physiological phenomena induced by the salt during the course of vegetation, so that we may avoid or follow them, accordingly as they are useful or prejudicial to its development.

Those who deny the salutary influence of salt upon vegetation, under certain circumstances, are perhaps too much biased by the idea prevalent among the ancients, that sterility is the inevitable consequence of its application. This may be true in those countries which receive but little rain, and where the sun is intensely hot; but the exception is not applicable to humid soils.

The hygroscopic state of the soil being an important element in determining the question, by abstracting it we render it extremely complicated. On the other hand, in sowing salt simultaneously with the seed, it has never been determined how it acts or whether its mode of action is the same:

1st. In germination.

2d. During the development of vegetation, from the extremity of germination to budding, that is to say, while the plant sprouts.

3d. From the sprouting to the fructification.

4th. Finally, from the fructification to the entire cessation of vegetation, or the death of the plant.

If this had been known sooner, the opinion of certain persons as to the action of salt in vegetation would certainly have been modified, but as the question is very complex, it was necessary to divide it, and study each proposition separately.

From the experiments which I made as to the action of salt upon germination, the following conclusions are to be drawn:

1st. Common salt, in certain proportions, retards and even partially destroys the germination of rye grass and white mustard seeds.

2d. It completely destroys those of wheat and vetch.

3d. It impedes, in a measure, the germination and vegetation of many plants.

Thus it is seen that though the salt may not destroy germination, it nevertheless injuriously affects the young plants during vegetation, by inducing a change in their embryo in the initiatory development of life.

Can we not interpret this injurious tendency of the salt in the very first act of vegetable life?

When a seed is subjected to the combined action of water and of heat, it swells, and the starchy matter of the cotyledon passes into gum and sugar, as food for the nutrition of the plantlet. These substances act the same part to young plants that milk does in the nutrition of young animals. Now, as salt is, in general, an antiseptic, being often used to prevent the putrefaction of animal and organic matters, it naturally follows that if its presence will prevent those transformations of the starchy matter of the seed only by which it can be rendered alimentary of the plantlet, the plantlet must necessarily perish. Though the destruction may not be complete, still the plant suffers during its vegetation from the ill effects produced by the salt during its germination.

As regards the action of salt in the second phase of vegetation, it may be admitted, *à priori*, that it should not influence the development of vegetation, from the completion of germination to the moment of blooming, in the same manner as during germination; since, in this case, the salt seems to oppose the decomposition of starchy matter, and its transformation into gum and sugar; while in the other instance, as soon as germination is completed and respiration takes place in the leaves, the salt is carried by water into the different tissues and organs, and should then act only proportional to the quantity introduced, to hasten or retard the phenomena and the different elaborations of the juices designed for the nutrition and development of the plant. The salt, therefore, should not play the same part in both cases. Numerous experiments have effectually confirmed this deduction drawn from facts previously noted.

The facts stated in my Memoir authorize the following conclusions:

1st. That salt in solution is prejudicial to germination, being alterative or destructive of the embryo according to the quantity employed. When the change is very sensible, the development of the young plant is much less perfect than without the action of salt.

2d. That germination is accomplished without the aid of salt, and that when the plant has shot above ground, the application of salt and water even in large doses, causes no alteration of the tissues, nor any disturbance of the vegetation, not even to the budding. As to what are its effects then and afterward, is yet to be determined by the result of some experiments now in progress. The plants usually acquire more vigor than those growing in the natural way, provided the proportions of salt are not excessive. The amount taken up by plants equals, sometimes, eight per cent. of their weight when dried.

3d. That the influence of salt upon germination, even in presence of water, may serve, to a certain extent, to explain the conflicting results, as to the action of salt as an amendment [ameliorator?], of experimenters who kept no record of the time of salting.

4th. That when used as an amendment in soils destined for the culture of the cereals, it should not be spread at the time of sowing, because it is hurtful to germination. The better plan would be to apply it about the month of March, when the earth is moist, and previous to the development of active vegetation. In operating at this season, be careful that the winter rains do not carry the salt too deeply into the soil, else it will lose its power of promoting vegetation in the

spring. The quantity of salt to be used depends upon the nature of the plant under cultivation, as all plants are not equally benefited by its use.

Kuhlmann's experiments have proved that salt, when mixed with nitrogenous manures, is a stimulant of vegetation. It will then be necessary to ascertain whether, as to certain plants which require a substantial nourishment, salt uncombined with these manures would not, by inducing a too vigorous growth, enervate such plants.

5th. That the large quantity of salt required by the stalk of the cereals, under the circumstances mentioned, may contribute to give them the qualities of fodder.

6th. That all these results determine nothing as to the product in grains, which will only be known when the experiments are completed in the coming year.

7th. That in moist meadows the salt should be sown at the time when vegetation develops. In dry meadows, rain must be waited for before applying the salt.

8th. That in soils with impermeable bottoms or clayey substrata, the application of salt should not be often repeated, for the portion first added suffices for a long time, and sometimes may even injure later germinations. If, on the contrary, the substrata are permeable, it is necessary to renew the salting at each culture. Before taking a definite part in this respect, we should appeal to experiment, the only sure and safe guide.

Salt remains in the soil a shorter or longer time, according as its substratum is permeable or impermeable; and as all plants do not accommodate themselves in the same degree to the salt regime—the vetch, as an example—it is necessary, in the rotation of crops, to plant therein the leguminous and other plants whose growth would be retarded by the salt.

The end proposed in my Treatise is to point out the path to be followed in experiments for the exact determination of the part acted by the salt, as an amendment, either with or without the concurrence of nitrogenous manures.

A FARM BUT A MANUFACTORY,

THE USE OF SALT.

It was not because we apprehend that Salt is likely ever to be used in our country as a manure to an extent sufficient to make its value for that purpose a question of general interest, that we have selected the following, but because of the philosophical principles which it contains as connected with Agriculture. But the reader can peruse and judge for himself, whether such dissertations are not much more useful, though they may be *dryer*, for *young men* wanting to provide for themselves a wider and more solid basis for improvement, in a better knowledge of the *principles* of their profession, than is to be expected from a relation of the mere *details* of practice followed in some case where an acre has been made to yield a heavy crop of corn, or a bullock to yield a heavy crop of tallow. Such, at least, is our view of the matter, and such our aims, without any object or desire to deceive or be deceived.

From the London Agricultural Gazette.

THE VALUE OF SALT AS A MANURE.

In your Journal of April 8th I read that Professor Dumas, who in conjunction with Mr. Milne Edwards, was engaged by the French Government to examine into the value of common salt as

a manure, has recorded in the following terms the conclusions arrived at from their inquiries on the subject in England:

"I quit England with the conviction that the problem of the employment of salt in Agriculture is chimerical We have been sent from county to county without result Here they send us into the neighborhood of the salt-mines; when we were there we were told that salt was not a prophet in its own country. I am convinced that the most desirable mode of preparing a good manure is by employing the phosphates and ammoniacal salts, rather than sea salt, however cheap the latter." In my opinion the conclusion they have come to, viz., that salt is of very little value as a manure, is perfectly correct. Opinions unsupported by facts or reasons are, however, not worth much, and as I am aware that many practical agriculturists advocate the employment of salt, I will endeavor to explain the grounds upon which I dissent from them. I am quite willing to admit that numerous experiments have been recorded, wherein a beneficial effect of salt upon the crop was sufficiently evident The question with the French chemists, however, and that to which the remarks I am about to make refer, has not reference to the special, or occasional, but to the general applicabil ty of salt as a manure, and to its importance as such in a national point of view; I shall not, therefore, quote any particular experiments of my own, but shall endeavor to show: 1. That no substance can be nationally or universally useful as a manure, which is not largely exported from the soil. 2 That salt exists to a very small extent in the exported produce of a farm; and that it can never be substituted for those constituents which are largely exported, and in which most soils are more or less deficient. Considering a farm as a manufactory, of which the imported manures represent the purchased raw material, and from which the exported products are corn and meat, it is evident that the nature of the imports which it will be necessary to provide must depend upon that of the exports. The amount of such exports must vary according to climate, soil and cultivation; but assuming the extreme case of an export of 50 bushels of corn from an acre of land one year, and 100 lbs. of live-weight of animal the next, let us endeavor to estimate the loss to the land of several of its constituents by such means, and especially that of salt. Fifty bushels of grain may be said to contain 50 to 60 lbs. of mineral matter. In perfectly ripened grain it is doubtful whether either chlorine or sodium, the two constituents of common salt, exists; but the point of perfection in this respect is seldom attained in our climate, and it is probable that it is owing to variations of this kind that the presence and amount of salt in grain ashes are found to be uncertain The average quantity in such ashes may, however, be said to be probably little more than 1 per cent if even so much as that; so that 50 bushels of grain would contain less than 1 lb. of salt. By direct experiment I find that a lean sheep of 100 lbs. live-weight, yields about 8 to 10 lbs. of bone, 12 lbs. skin, and 5 lbs. blood; the flesh, fat and entrails, &c., comprising the remainder The bone contains no appreciable amount of salt, while the total mineral matter of the other parts of the sheep amounts only to a few ounces, of which quantity a very small proportion must be estimated to be common salt. It is evident, then, that the amount of salt exported from a farm in corn and meat is exceedingly small; but if we look at the loss of phosphoric acid and of nitrogen which the farm sustains under the same system of sales or export, the case will be found to be very different.

Of the 50 or 60 lbs. of mineral matter contained in the 50 bushels of grain, about nine-tenths would be salts of phosphoric acid, and the sheep weighing 100 lbs. alive would carry off 3 to 4 lbs. of phosphate of lime in its bones, besides a few ounces of phosphoric acid salts in its other parts Again, the 50 bushels of grain may be said to contain 50 to 60 lbs. of nitrogen, and the 100 lbs live-weight of animal 4 lbs. of the same substance It is seen, then, that while the soil would be exhausted in two years of 40 to 50 lbs. of salts of phosphoric acid, and of a still larger quantity of nitrogen, the amount of salt removed in the same period, and by the same course, would scarcely reach a pound. Some writers have said that farmers do not know their own interests when they purchase the expensive foreign guano rather than the cheap salt of home resource, and employ the bones of distant countries instead of the sulphate of soda manufactured in our own towns; but no one who will carefully consider the statements given above can be at a loss to understand why salt and sulphate of soda cannot be substituted for phosphates and ammonia. It is worth consideration, also, that in many parts of England thousands of acres have been brought from a barren waste into the highest state of fertility, by the importation, in some form or other, of phosphates and ammonia, without any direct supply whatever of common salt.

The employment of salt as manure cannot, then, I think, be advocated as providing an important constituent of the ordinary exports of a farm, but only to be of limited necessity, and applicable with economy to a small extent, or in special and occasional cases. It is considered that when corn is used for corn crops the straw is brighter and the grain of finer quality; but perhaps no one will maintain that it would increase the number of bushels upon a corn-exhausted soil; and if this be the case, but a low rank can be claimed for it by the side of manures which are known to enhance the produce of the land I fully admit some beneficial influence upon the elaborative actions in the juices of plants under the agency of common salt, but it is probable that such an effect will generally be observed only in highly manured soils, where, under certain conditions of season, vegetation would be too luxuriant; and it may be doubted, indeed, whether even in these cases an equivalent supply of soluble saline matters, more essential as constituents of the fixed products of the plants, might not with advantage substitute the salt.

On the other hand, however, the ready solubility of common salt itself, as well as that of compounds which may result from its reactions on the contents of the soil, is a property which may render it of real service in cases of over-luxuriance, arising from an otherwise too prominent supply of organic constituents to the plant. There are other instances than that afforded in salt, of mineral substances being of apparently great use in the juices of plants, without seeming to constitute portions of the fixed products of the plant; and we must be careful, therefore, not to deny the importance of the presence in the soil of any substance, merely because it does not exist in the exports of the farm; but at the same time it should be borne in mind that unless a substance be either sold off the farm or diminished in quantity by drainage or actual waste, the renewal of a supply once provided can very seldom be needed.

The solubility of salt, already referred to, might be said to be a cause of its rapid exhaustion from a soil by drainage, but such loss will be frequently compensated for by the incidental import of salt for cattle, and by the small amount contained in artificial food. Again, it may be urged that a large proportion of farms export other articles beside corn and meat; but the same local circumstances which lead to such a cause generally at the same time afford sources of manure not at the command of those circumstanced as our case supposes. Indeed, where town manures are used, the amount of salt provided must always be considerable. The discrepancies in the accounts that are published of the effects of salt as a manure need not lead us to doubt the correctness but only the completeness of the statement; and if, as I have shown above, this substance is not required in any material quantity as a constituent of the exports of a farm, and if it be also true that when useful as an agent it is so only under particular circumstances of excess of some substances supplied to the plant over others, the differences in result are what we should expect. In illustration of this point I may observe that a few years ago some experiments were carried on upon agricultural plants at the gardens of the Horticultural Society, at Chiswick, under the direction of Mr Solly, and on comparing the results which he obtained by the application of various substances to a garden soil (probably already in a state of fertility far exceeding that which is usual under a high condition of field-culture) with those obtained by the same substances upon exhausted land on my farm at Rothamsted, I found that in many important instances the effect seemed to be very beneficial in the one case, and not at all so in the other. Such facts as these plainly show us that upon soils where the essential elements of plants are wanting, no benefit can be derived from the use of salt or any other substance which does not become a constituent of the produce. Where, however, in the growth of grain, all other essentials are provided, the use of salt may be advantageous by giving a healthy tone to the vital actions of the plant, and thereby improving the quality, and even to a small extent increasing the quantity of the produce also.

The effect of salt is, however, much more marked upon the green produce of a farm than upon corn crops, and the large quantity of it which is found in some plants of the former kind might well lead us to question whether it be not an essential element of such produce, as well as a useful agent in the processes of vegetation in such cases. Mangel-wurzel, for instance, contains, comparatively speaking, a large amount of salt, and the effect of its application is perhaps more evident in the case of this plant than in that of any other. When, however, we bear in mind the small amount of selective action which is exercised by the roots of plants upon the soluble contents of the soil; that in the ash of the mangel-wurzel, as well as in that of all other green produce, we have the saline matter of the juices mixed with those of the parts formed from those juices; and, farther, that this plant, more particularly when fresh gathered, and before fermentation to some degree has taken place in its fluid contents, is known to act as a purgative to animals fed upon it, we cannot fail to admit the presence of a large amount of as yet unorganized matter, and the probability also that some of it is extraneous and unnecessary to the growth of the plant; and in this latter supposition the existence of salt in the produce would show an ample resource of it in the soil, rather than prove its importance to the plant. Reasons of this kind must not, however, be taken as satisfactorily proving the non essentialness of salt as a manure to those plants wherein we usually find it, but they should be considered more as pointing out the direction and the necessity of farther experiment on the subject, and especially so when we find in the animal economy instances of a very analogous kind. Thus it is found that although the blood of animals, which may be compared to the juice of vegetables, contains a large amount of common salt, which cannot be supposed to be unessential to the healthy action of the body, yet its presence appears doubtful in any of the resulting products of the processes of the animal. The question, then, of the use and importance of salt to some few plants, and under certain particular circumstances, is still open to investigation, and should it be decided affirmatively, we should yet have to determine whether or not it was necessary in such cases to employ it in any large quantities, or even directly as a manure at all. For the reasons I have adduced, I cannot but fully concur in the general opinion expressed by Professor Dumas, more especially as applicable to the state of Agriculture in France at the present time, and I will venture to assume the following positions: 1. That salt can never be a substitute for the constituents ammonia and phosphoric acid. 2. That no soils exporting corn and meat can be restored to fertility without the application of these two substances. 3 That much of the money now expended in purchasing salt for agricultural purposes would be more profitably employed in procuring ammonia and phosphates. 4. That salt, although apparently essential in the animal economy, and perhaps in that of plants also, is exported from a farm in such small quantities that many soils will, under an ordinary system of cultivation, never require its direct application, and others will do so seldom, and to a small extent only.

Tutors, agricultural i 40: see *Ag. Schools.*
Two-furrow plow, i. 405
Twisters of straw-ropes, ii. 402.

U

Udder of the cow, ii. 98.
—— structure of, ii. 98-9.
—— Diseases of, in Summer, ii. 277.
United States, mountain ranges of, i. 65.
—— —— grazing districts of, i 65.
—— —— mixed farming in, i. 68.
—— —— iron on farms in, i 97.
—— —— climate of, i. 198-9.
—— —— Grain produce of, ii. 25, 34, 38, 41.
—— —— Laboring population of, ii. 45.
—— —— Applicability of the BOOK OF THE FARM to: see *Book of the Farm, Observations of Am. Ed.*
Upper-barn, plan, &c. i. 106.

V

Vapor, quantities of, in the air. i 187.
Vegetation as a source of electricity, i. 180.
Ventilators for the stable, i. 95.
Vermin, preserving barn-floors from, i. 88.
Veterinary Colleges, i. 43.
—— —— the London, i. 43.
—— —— the Edinburgh, i. 43.
Von Thaër, M. agricultural institution of, i. 45.

W

Waddell, Mr. construction of floors by, i. 129.
Wages of farm-servants, ii. 45.
—— of the plowman, ii. 46.
—— when living in bothies, ii. 47-8
—— of the steward and shepherd, ii. 49.
—— of the hedger, ii. 49.
—— of the cattle-man, ii. 49.
—— of the field-worker, ii 50.
Walton, Mr. on breeding the Alpaca, ii. 451.
Walker, Mr. experiments in feeding cattle, i. 517
—— on feeding pigs, ii. 12.
Warnes, Mr. mode of feeding cattle, i. 516.
Washing sheep, ii. 286-7.
Water, supply of, for the farm, i 132.
—— causes and cure of its hardness, i. 135.
—— supplying cattle with, i. 113.
—— great expansion, when freezing, i. 196.
—— agency of, in forming soils, i 219.
—— preventing its lodgment, i. 238.
—— sources of superfluous, i. 313.
—— effect on germination, ii. 178.
Water-furrowing, ii. 136.
Watering-pots for stock, ii. 275.
—— —— mode of constructing, &c. ii. 275, 358.
Water-meadows, management of in winter, i. 7
Weaning calves, ii. 266, 270.
Weather, instruments for indicating, i. 165-174
—— the Barometer, i 166.
—— Sympiesometer, i. 168.
—— Thermometer, i. 168.
—— Hygrometer, i. 171.
—— Weathercock, i. 172.
—— Anemometer, i. 173.
—— Rain-guage, i. 174.
—— indications from the Clouds, i. 175-80.
—— agency of electricity, i. 180.
—— indications of from the Aurora Borealis, i. 185.
—— other atmospheric phenomena, i. 185.
—— in Winter, general uncertainty of, i. 76.
—— in Spring, ii. 76.
—— in Summer, ii 240.
—— in Autumn, ii. 363.
Wedge or plug draining, i. 378.
Wedgewood's table-churn, ii. 383.
Weighing wool, ii. 300.
Weight of fat oxen, rules, ii. 267.
—— fallacy of these rules, ii. 269.
Wells, Dr. his theory of dew, ii. 242.
Wells, sinking of, on the farm, i. 132.
West Highland ox, ii. 445.
Wheat, spring, sowing of, ii 125.
—— classification by the ear, ii. 26.
—— by the grain, ii 27.
—— judging of quality, color, &c. ii. 28.
—— kinds for various purposes, ii. 28-9.
—— the best for seed, ii. 28.
—— detection of damaged, ii. 28-30.
—— preserving in granaries, ii. 26.
—— grinding of, ii. 29.
—— flour and bran, ii. 29.
—— chemical composition, ii. 31.
—— microscopic structure, ii. 32.
—— nutritive matter in, ii. 33.
—— manufacture of Starch from, ii. 33.
—— Straw of, ii. 41.
—— Varieties of, ii. 137.
—— Cutting, i. 17; ii. 382.
—— Prof. Johnston on the Gluten of, i. 31.
—— proper ripeness for cutting, ii. 382.
—— Cutting of, ii. 373.
—— Carrying in and Stacking, ii. 386.
—— Weight of Grain, Straw, &c. ii. 382.
—— Autumn, sowing of, ii. 416.
—— —— plowing, &c. the land, ii. 416-17.
—— —— various modes of this, ii. 417.
—— —— thorough-draining for it, ii. 418.
—— —— preparation of the seed, ii. 418.
—— —— sowing by dibbling, &c. ii. 419.
—— —— and by transplanting, ii. 419.
—— —— expense, and saving of seed, ii. 420.
—— —— the process of germination, ii. 421.
Wheeled plow, the, i. 404.
Wheeled turnip-slicer, for sheep, i. 473.
Wildfire, a disease in sheep, i. 477.
—— treatment of, i. 477

Wilkie's drill-grubber and harrow, ii. 335.
—— horse-hoe, ii. 336.
—— plow, i. 255, 262.
Wilson, Dr. on Drainage, i. 375.
Windows for stables, i. 105.
—— for byres, i. 105.
—— for the granary, i. 107.
Winds, relation of to rain, i. 190.
—— influence on weather in Summer, ii. 246.
Winsboro', Gov., and the cattle of N. Eng'd. i 207
Winter, farm operations in, i. 74.
—— importance of these, i 74.
—— uncertainty of weather in, i. 76.
—— arrangement of field-work, i. 301.
—— wheat, sowing, &c. ii 416.
Wire field-gates, ii. 265.
—— turnip-basket, i 499.
Womb of the cow, the, ii. 84.
Wood, Kyanizing, i. 141.
Wood-floor for the corn-barn, i. 87.
—— —— advantages of, i. 87.
—— —— preserving it from vermin, i. 88.
Wood-paving, advantages of, i. 130.
—— —— various kinds, i. 130.
—— —— comparative expense, i. 131.
Wood-work of the steading, i. 138.
—— —— measurement and cost, i. 138, 148, 150
Wool, washing, ii. 298.
—— clipping, ii. 298.
—— storing, weighing, &c. ii. 298.
—— qualities of, ii. 301.
—— effects of fattening on its quality, ii. 302.
—— chemical analysis of, ii. 303.
—— microscopic examination, ii. 303.
—— causes of its felting, ii. 303-4.
Wool-room, plan and description of, i. 106-7
Wool-shears, ii. 289.
Working the shepherd's dog, ii. 172.

Y

Year, agricultural, divisions of, i. 15.
Yeast for baking, ii. 31.
Yoking horses to the plow, i. 386.
—— the young draught-colt, ii. 215.
—— to the cart, ii. 216.
Youatt, Mr., observations on wool, ii. 303.

Z

Zinc, employment for roofing, i. 143.
Zones of the earth, the, i. 201.
Zoölogy, value of a study of, i. 61.
